AMERICAN ELECTRICIAN

83287

An Illustrated Monthly Journal of Practical Electrical Engineering

VOLUME X.

JANUARY—DECEMBER, 1898

AMERICAN ELECTRICIAN COMPANY
HAVEMEYER BUILDING
NEW YORK

GENERAL INDEX.

** References to Notes in " Among Our Contemporaries " are distinguished by a star preceding the page number.*

A

Accident, Singular *266
Acetylene gas generator.................... 305
Accumulator. (See Storage battery.)
Agriculture and electricity....................*376
Air, Influence of silent discharge on......*505
——blast, Remedy for troublesome T. H. arc machine. R. H. Sterling.......... 121
Alarm attachment for clocks, Electric. Wallace Belmont 293
——Hercules high and low water.......... 177
Alternating current connections. August supplement.
——current and 220-volt systems. Prof. Geo. D. Shepardson.................... 249
Alternator design, Modern.................... 381
——Self-regulating *424
——Warren-Medbery inductor............ 299
Alternators, Parallel working of..........*268
——Synchronizing *159
——Windings of compound single phase. May supplement.
Aluminum as an electrical conductor.... 112
——brass *379
——electrodes *462
——plating *374
——working *462
American Lithographic Company, Electrical plant of.................... 1
——Street Railway Association.......... 458
Ammeter, Simply constructed. C. T. Child 468, 510
——Walker integrating 306
Ammeters and voltmeters, Inexpensive, Cherry 94
Amusement, Electrical apparatus for. N. M. Hopkins....................33, 78, 117, 167
Annunciator, Heath automatic............ 177
——Simple telephone. J. L. Brown...... 344
Arc as a telephone, Electric...............*201
——Counter E. M. F., of....................*156
——E. M. F. of, with aluminum electrodes *269
——light hanger board. K. & W.......... 522
——lighting plant, Brooklyn, transformed. 239
Aramature cores. Selection of type of. Prof. A. L. Rice.................... 537
——magnetization, What is good practice in? 371
——punchings, small.................... 94
——teeth, straight vs. T-teeth............ 427
——windings and connections. Prof. Arthur L. Rice..56, 101, 149, 197, 317, 363, 419, 501
Armatures, Windings of polyphase. J. P. Stone 10, 24, 367, 456
Arresters. (See Lightning arresters.)
Ashes elevator, Telescopic.................... 227
Automobiles at Paris, Concourse of........*506
——in New York, Electric............407, 427

B

Balloons, Searchlights on captive..........*422
Battery. (See Storage, primary.)
——fluid, New *374
——Samson portable.................... 347
Batteries, Testing-set. Jas. F. Hobart.... 293
Bearings, Roller *153
Bell arrangement, Another electric. George Eastlake 127
——Electric, arrangement. Roy J. Tompkins 88
——for electric light circuits. Edwards.. 178
——Iron box, B. B.................... 42
Bells, Ringing church electrically..........*153
Belt Dressing, "Cling surface"............ 395
Belting, Cement for leather................*332
Bicycle lamp, Dynamo....................*463
Bit stock, Meister angular.................... 131
Blast furnace gases, Power from.....*375, *539
Blasting fuse, Magneto for firing. R. H. Sterling, 36; James L. Francis.....40, 87
Blindness from the electric arc. Prof. A. J. Rowland 107
Boats for Russian Government, Electric..*542
——Powering small 314
Boiler scale and fuel consumption........ 473
Boilers, Cost of feeding. James F. Hobart 476
——purger feeder, Penberthy............ 179

Books, New:

—Applied Mechanics. John Perry.......... 351
—Arithmetic of the Steam Engine. E. Sherman Gould 351
—Commercial Cuba. William J. Clarke.. 524
—Elements of Electric Lighting. Philip Atkinson 307
—Elements of Electro-Chemistry. Dr. Robert Lupke 182
—Electrical Testing for Telegraph Engineers. J. Alton Young.................... 483
—Electrodynamics. C. A. Carus-Wilson.. 483
—Essentials of Gearing. Gardner C. Anthony 307
—First Principles of Electricity and Magnetism. C. H. W. Beggs.............. 351
—Local Distribution of Power in Workshops. E. K. Scott.................... 351
—Mechanical Draft. B. F. Sturtevant & Co. 182
—Model Engines and Small Boats. Nevil Monroe Hopkins 182
—Motor Engineers' and Electrical Workers' Handbook. Wm. Lintern.......... 49
—Patented Telephony 49
—Physical Education. W. G. Anderson.... 351
—Power Catechism 307
—"Practical Engineer" Pocketbook........ 484
—Principles of Alternating Current Working. Alfred Hay 351
—Theory of Electricity and Magnetism. Arthur Gordon Webster.............. 49
—Universal Electrical Directory for 1898. J. A. Berly.................... 182
Brake Motor, Crocker-Wheeler............ 442
Brakes, Electric, as turbine governors...*202
Brass, Aluminum....................*379
Brooklyn Bridge, Electrolytic action on.. 426
——transformed arc light station.......... 239
Brushes, Aluminum dynamo................*374
Buoys, Disappearing electric................*200
Burglar alarm circuits, Telephone connection for. G. E. Ruther.................... 38
Burns, Treatment for electrical 209
Butte, Montana, Electric power transmission plant. L. D. Tandy............ 51

C

Cab service, New York's..................407, 427
Cable, Long underground telegraph........*506
Cables, Submarine *153
——in time of war, Submarine............*270
Calcium carbide from basic slag..........*374
——carbide industry 381
Canal haulage, Electrical....................*540
——towage, Electrical *505
Candlepower rating of electric lamps...... 389
——of searchlights.................... 69
Capacity 35
——and inductance 85, 211
——and inductance in parallel.............. 125
——Measuring. H. J. J. van Deth........ 87
Carbides of sodium and potassium.........*155
Carbon, Electro-chemical equivalent of..*201
——New arc light.................... 44
Carbons, American high-grade arc.......... 306
——permanent *155
Cars, Replacement of derailed. W. H. Bonner 429
Cartridges, Electro-thermic mining........*542
Car wiring. Walter Munroe.............. 430
Catechism, Electrical..40, 89, 129, 175, 224, 294, 345, 390, 438, 477, 517, 560
Cells. (See Dry cells.)
Cement for leather belting....................*332
Central station, Brooklyn arc light........ 239
——Claremont storage battery. F. B. Sage 236
——Dolgeville. E. A. Grissinger.......... 135
——at Granada, Spain *270
——Gas engine, Prof. J. J. Flather, 156, 231
——lights... ....*464
——log book, Automatic....................*330
——Small polyphase 508
——working. R. H. Sterling..........217, 281
Central stations, Regulation in. W. H. Chapman 206
——in Spain *378
Charges for electrical power................ 209
Chloride. Diaphragms for electrolysis of alkaline *371
——Electrode for electrolizing alkaline..*332
Circuit breaker, De la Roche............519, 566
——Leonard switchboard.................... 133
Circuit breakers vs. fuses. L. W. Downes, 13; W. E. Harrington, 14; Jos. Sachs, 60; D. J. Cartwright..61, 72
Claremont (N. H.) central station. F. B. Sage 236
Climber, Lineman's 394
Clock, Magic. Nevil M. Hopkins.......... 33
Coffee pot, Electrical. George Eastlake.. 390
Coherer action *506
——Simple adaptation of....................*266
Coil winding machine.................... 564
Coils, Induction. (See induction.)
Colorado Springs Electric Power Company's plant. Ralph D. Mershon.... 527
Come-along kink. H. L. Schweigger, 127; Wallace Belmont.................... 174
Commutator compound, Gale.............. 42
——Exploring potential around the. Prof. A. F. McKissick, 110; Prof. R. A. Fessenden 453
——Repairing a burn out. N. H. Crowell 31
Compensator for arc lamps, Heat..........*463
Compounding curves. M. N. Borden...... 344
Condenser action and synchronous motors 211
——and induction coil insulation.......... 163
Condensers, Commercial *203
——in alternating current working....... 172
——for induction coils....................*424
——Practical applications of................ 222
Conductors, Relative cost of................*504
Conduit, Silex insulated.................... 303
Contact resistance of similar metals......*462
Controller, Brush arc machine. Reese Hutchinson 89
——connections. September supplement.
——Keystone elevator motor.............. 47
Converters, Rotary.................... 265
Cooking, Cost of electric....................*375
——utensils, Electrolytic *542
Cost of an electrical transmission plant.. 112
——of distributing and generating unit of electricity 322
——of producing electric power at Lachine Rapids 326
Cotton mills, Electric light in.............. 424
Coupling, Insulated electric................*540
Crane, An electric *202
Crucible, Brazing, Dixon.................... 42
Current arrester, Sneak.................... 299
Cushman building storage battery plant.. 355
Cut-out, Broken trolley wire..............*425
——for alternators, Discriminating......*333
——New arc 481
Cutting by steam. Jas. F. Hobart.......... 471

D

Death by electricity....................*155
Decorations, Electrical. C. R. Persons.... 147
Delta light and power plant. S. H. Dailey 97
Diaphragms for electrolysis of alkaline chlorides *377
Diagrams of electrical apparatus, Conventional 127
Diesel motor 113, 114
Discharge, silent, Influence of, on air.....*505
Disruptive discharge, Curves of............ 371
Distribution, European methods of underground. Francis Jehl.................... 254
——from central stations by alternating current 323
——by direct current.................... 325
——Parallel and three-wire. March supplement.
——Series. March supplement.
Distributing systems, Equalizer and single phase. April supplement.
Dolgeville water power, electric light and power plant. E. A. Grissinger...... 135
Drain cock, Geipel automatic.............. 301
Drainage, Electrical....................*158
Draft, Mechanical. W. B. Snow........244, 328
Draft, Sturtevant forced, apparatus....... 396
Drill, Electric rock....................*376
——Electricians' 566
Drilling device, Harrington rail bonding 480
Dry cell, How to make a.................... 470
Dry cells, N. T. Jarvis, 88, 174; T. Wolcott, 127; P. M. Heldt, 127, 223; V. C. Wynne, 174.................... 223
Dynamo, air blasts, Arc. H. F. Watts... 292
——Bernard marine.................... 180
——Brooklyn station, largest in the world..... 481
——C & C Marine.................... 303
——connections, Arc. January supplement.
——Design of half h.p. Cecil P. Poole... 276
——Design of one h.p. Cecil P. Poole.... 548
——for experimental purposes.............. 44
——frame, should it be grounded?........ 509
——How to design a............388, 436, 475, 515
——Lundell marine lighting set............ 298
——Model.................... 227
——New Brush arc light. February supplement.
——Special multipolar.................... 179
——Sturtevant Midget.................... 564

Dynamo, Test of a multicircuit direct-current. E. J. Murphy and P. E. Van Saun 494
——**testing, Commercial. W. H. Radcliffe** 316
——**Troublesome air blast of T.-H. arc. R. H. Sterling** 121
——Universal 212
Dynamos, Designing small. Cecil P. Poole 59, 103
——**how sold** 507
——in parallel, Compound. **February** supplement.
——Keystone multipolar 305
——Marine 180, 298, 350, 397, 482
——Operation of T.-H. arc. Carl C. Giles 39
——regulation 467
——Series and shunt 274
——**Testing** 80, 118, 316, 339

E

Edison, reminiscence of pioneer days 162
Electric lighting rates in New York City. 9
——power 24
——railway practice. Eugene C. Parham 29, 122, 171
Electricity. W. D. Weaver 106
——**as it is sometimes understood.** C. R. Fontaine 335
——What is..106; C. P. Steinmetz, Prof. John Trowbridge, Prof. A. G. Webster, Prof. Alex Macfarlane, A. E. Kennelly, A. A. Campbell Swinton, C. T. Reed, Townsend Wolcott, 160; Elihu Thomson, 161; Harvey L. Tyler, 203 164
Electrical engineers, Volunteer corps of, *156, *542
——exhibition 22, 70, 112, 163, 209, 210
——journals of the world 21
——journals. Edward Caldwell, 63, 271; Jos. Horn, 161; T. D. Lockwood, 208; R. W. Pope, 335; D. L. Davis 335
——misconceptions 465
Electrodes, Aluminum *462
——for electrolizing alkaline chlorides *332
Electrolytic action on Brooklyn Bridge .. 426
——damage to ships *464
Electromagnets, Varley 92
——**Designing. James L. Francis** 389
——for mechanical control at a distance. 466
——Possibilities in 490
——Resistance of. J. T. Jennings 438
Electrometer, Simple capillary *464
Elevator motor, Keystone 47
——with non-reversible motor, Electric .. 227
Enamel, Expansible, for electric heaters .. *423
Enclosed arc lamp. (See lamp.)
Engine. (See **gas engine, steam engine.**)
Engine room and shop floors *200
Engineers, Consulting 71
Engineering education 199
Equalizing curves. M. N. Borden 344
Exhaust head, Bundy, 91; Lippincott 521
Experience, Getting 146

F

Factory power and heating plant 264
Fan motors, 1898 models 140, 164
Feed water heater, Bundy 178
Fire damp and electricity *270
Flag, Electrical waving. C. R. Persons .. 147
Floor receptacle, Flush plug 563
Fluorescent screens, New material for *200
——screens, Regenerating *464
Frequency measurements *266
Fries Mfg. & Power Co.'s transmission plant 447
Furnace, Phosphorus, by the electric *202
——Rival of electric *375
Furnaces, Electric *423
——Regenerative electric *425
Fuse board, Shawmut combined tablet and 522
——box, High voltage 483
Fuses vs. circuit breakers, L. W. Downes, 13; W. E. Harrington, 14; Jos. Sachs, 60; D. J. Cartwright 72

G

Gage, Penberthy water 521
Galvanometer. A sensitive mirror. Jas. F. Hobart 74
——Construction of a Thomson astatic. Prof. H. S. Webb 26
——Lecture room. Prof. R. W. Quick 166
——needles, Magnetizing. Jos. F. Hobart, 88; Prof. H. S. Webb 128
Gas engine central station. Prof. J. J. Flather 231
——central station, English *153
——Dayton 397
——Foos 302
——Frontier 302
——igniter, McInnerny electric 393
——Lambert 307
——New Era 303
——Weber 301
——White & Middleton 306
Gas engines for poor gases *201
——Starters for *266
Gas in railway power station, Producer .. *503
——lighting attachment, Rousseau 445
——lighting attachment for mantle burners, Electric 307
——lighting attachment for Welsbach burners 396
Gases, Blast furnace, for engine driving .. *539
General Electric Company, annual report of. May supplement.
Generators, G. E., belt-driven 48
Germination, Effects of electricity on *331
Glass conductors *374
——discs, Cutting. A. J. Picolet 38
——Electrical conductivity of *268
——Resistivity of 341
Glucinum, Electrolytic *267
Governors, Electric brakes as turbine governors *202
Grand Central Depot, Electric lighting at. 451
Ground detector and arc light voltmeter, Keystone 133
——G. E. electrostatic 94
——**Switchboard. S. E. Sanborn** 38
Ground return and railway feeders 380
Grounded dynamo frames 509

H

Hackensack central station 487
Hanger board, K. & W. arc light 522
Haulage, Electrical canal *540
Heat unit standard for rating electric generating plants 9
Heater, Street car, electric 228
——Western electric 521
Heaters, Electrical 467
——Expansible enamels for electric *423
Heating apparatus, alterating current *505
——apparatus, Efficiency of. L. T. Rice. 292
——irons, American electric 180
Helena, Mont., transmission plant 296
Horse power, Animal. R. G. Cottrell 294
——of water wheels and turbines. Prof. O. H. Landreth 67
Hulin, alkali process *202
Hunter alternating current patents, 24; R. M. Hunter 62, 108, 73
Hydrogen, Electrolytic manufacture of .. *422

I

Idyl, An electric *203
Idle current 115
Indicator card, High speed 396
——Improved Robertson-Thompson 46
Inductance and capacity 85, 211
——and capacity in parallel 125
Induction coil and condenser insulation .. 163
——coils, H. J. Gooding 292
——coils, Condensers for *424
——coils, resistance of telephone. H. P. J. Van Deth 292
——coils, Telephone. C. Holmes 344
Inspection, Electrical. **S. E. Sanborn** 108
Insulating substance, Plastic *542
Insulation, Condenser and induction coil .. 163
Insulator, Locke high voltage line 349
Insulators and insulator pins, Locke 92
——Boch high voltage 178
——Locke line 397
Mechanically **strong** 420
Integrating indicator *267
Interior wiring. Chas. E. Knox .. 75, 121, 168, 219, 287, 385, 473, 512, 551
Inventors, An opportunity for 475
Iodoform, Electrolytic manufacture of *332
Iron, Aging transformer *374
——ores, Magnetic surveying for *503

J

Jacques cell discussion. Prof. W. Ostwald, 16; C. J. Reed, 17, 110; Prof. W. A. Anthony, 64; Prof. Julius Thomsen 64
Jungfrau, Electricity on the *422
Junction box, Chase 298

L

Lafayette (Ind.) gas engine central station. Prof. J. J. Flather 231
Lamp, Alternating current arc *266
——American enclosed arc 563
——bases, New method of attaching *200
——Bogue focusing arc 522
——Dynamo bicycle *463
——Electric desk, Waring 42
——Enclosed arc. Prof. W. H. Freedman 11
——filaments, Electric carbonization of .. *332
——filaments, Incandescent. John C. Shedd 105
——filaments, Rare oxides in incandescent *331
——G. E. enclosed arc 562
——G. E. miniature arc 479
——guards, Wire 94
——hanger board, K. & W. arc 180
——holder, Magnetic 565
——Jandus inclosed arc 305
——Manhattan inclosed arc 350
——Nernst incandescent *200
——orchestra, Ward 42
——resistance for inclosed arc, Incandescent 328
——resistance, Incandescent. T. C. Shedd 362
——safety pocket 566
——Twentieth Century incandescent 351
——U. S. electric bicycle 565
Lamps, Candle power of incandescent for decorative purposes 508
——Candle power rating of electric 380
——Control of, on three-wire circuit. A. W. Lee 38
——Ebert vacuum tube *504
——Heat compensator for arc *463
——Incandescent. S. E. Doane 329
——in narrow streets, Arc *154
——Osmium and thoria in incandescent .. *334
——Standard candle power for incandescent 327
——Substitute for platinum in incandescent *200
——Temperature of incandescent *331
Lead, Electrolytic, white *159
——refining by electrolysis *269
Lessons in practical electricity .. 35, 85, 124, 172, 222, 291, 343, *388, 436, 475, 515
Light, New standard of *333
Lighthouse, Norwegian electric *378
Lighting over 2,000 sq. m., Electric *374
Lightning arrester, Combined telephone fuse and 444
——arrester, Connecticut 299
——arrester for telephone exchanges, **Keystone automatic** 300
——arrester, Garton-Daniels 443
——arresters 329
——arresters for feeble currents *504
——arresters, Types of American. H. E. Raymond 497, 536
Line, Erecting a high voltage transmission. S. H. Dailey 194, 384, 454
——Long land *374
——voltage, Regulating alternating current 274, 291
Lines, Snow on overhead *374
Liquid rheostats. Prof. H. S. Webb 55
Liquids, Influence of electricity on clouded *464
Lithographic electric printing plant 1
Locks, Electrical combination 455
Locomotive, German electric *203

M

Magic clock. Nevil M. Hopkins 33, 78
Magnet wire, Thickness of insulation of .. 509
Magnets, Permanent 28, 334
——Steel for permanent *158
Magnetic field intensity, Measurements of *154
——surveying for iron ores *503
Magnetization? What is good practice in armature 371
Magneto, E. M. F. of a telephone *156
——for firing blasting fuses. R. H. Sterling, 36; James L. Francis 40, 87
Mail delivery in high buildings, Electric .. *155
——wagon, Storage battery *155
Marine lighting set, Bernard, 180; Lundell, 298; Riker, 350; Keystone, 397; C. & C. 482, 563
——engines, Electric regulator for *332
Maxwell, Memorial to *542
Mechanical draft. W. B. Snow 244
Mechanicville transmission plant 399
Merchant marine wiring. E. W. Countess 77
Meter, Alternating current watt-hour *377
——Blondlot current *423
——G. E. storage battery 229
——One way of connecting up a. R. H. Sterling 87
——**Queen illuminated dial switchboard** .. 520
——Simple electrolytic *331
——testing. R. H. Sterling 281
Meters, Care and testing of alternating current recording. R. H. Sterling 216
Metering, Two-rate. Lyman C. Reed 532
Metropolitan Electric Supply Company, London, American apparatus for 405
Milling machine, Garvin 523
Mining cartridges, Electro-thermic *542
Monazite mines *542
Motor, Action A. K. B. 389
——Bernard inclosed 523
——Commercial ironclad 306
——Crocker-Wheeler brake 442
——Design of half h.p. Cecil P. Poole. 276
——Design of one h.p. Cecil P. Poole 548
——for amateurs, Knapp 481
——Future street railway 426
——induction. A. E. Wiener .. 193, 317, 372, 420
——Keystone elevator 47
——Keystone multipolar 305
——Largest induction *506
——Lundell 229
——Lundell spherical bipolar 296
——Porter battery 229
——rheostats and speed regulators. P. M. Heldt 365
——Testing commercial. W. H. Radcliffe 316
——Triumph direct-connected ceiling 565
——Universal 212
Motors, Alternate current 443
——Condenser action and synchronous ... 210
——Designing small. Cecil P. Poole .. 59, 103
——for traction, Polyphase *157
——New types of polyphase *205
——Regulating line voltage by means of. 291
——Resistances for starting and reversing shunt *155
——Transforming direct and alternating current. J. C. Brown 557
Municipal ownership 312

N

National Electric Light Convention 272, 321
Naval marine electric lighting. E. W. Countiss 217, 282
Nerve currents *376
"Newark," Electrical equipment of the U. S. cruiser. E. W. Countess 491
Nickel plating on wood *376
Northwestern Electrical Convention 65, 327

O

Ohmmeter, Direct-reading 520
Oil economy. Samuel Sweet 389
——filter and purifier, Famous 298
"Oregon." Electric plant of battleship. A. J. Dickie 533
Outlet box, Chase 298
Oxygen, Electrolytic manufacture of *422
Ozone 79
——Method of manufacturing *425

P

Padlock, The obedient. N. M. Hopkins.. 167
Painting, Electric.............................*375
Paradox, An electrical. C. B. Blake, 517; O. H. Hutchings, T. W. Varley, Horace Shrader, V. C. Wynne, 558; Carl Hering, 559; C. D. Blake............... 560
Paris Exposition of 1900...............*200, *506
Patents, Hunter alternating current, 24; R. M. Hunter....................62, 108, 73
Permeameter, An industrial................*504
Phase transformers..............................*424
Philippines, Electricity in the...............*423
Phosphorus by the electric furnace........*202
Photographs by electrolysis, Color........*461
Photometer, Queen electric light............ 348
Pistons, Steam engine. Jas. F. Hobart, 515, 554
Plants, Action of electricity on............*540
Platinum, Electro-deposition of............*423
Polyphase armatures, windings of. J. P. Stone..........................10, 24, 367, 456
——connections. August supplement.
——practice at Hackensack central station 487
——stations, small 508
Potential around the commutator, Exploring the. Prof. A. F. McKissick.. 110
Powder magazines and electric conductors...*201
Power, Cost of electric.......................... 329
——factor.. 72
——from blast furnace gases.............*375
——plant of American Lithographic Company.. 1
Powering small craft.............................. 314
Primary battery, Centennial of.............*154
——battery, Copper sulphate standard..*539
——battery without acids.....................*540
——cell, Gordon.................................... 45
Printing presses electrically operated...... 1
Pump, Electric triplex............................ 43
——Westinghouse portable electric....... 479
Pumping, Hydraulic. M. L. Trowbridge.. 39
Push, "Dandy" floor.............................. 43
Pyrometers, Improvements in recording..*422
——Recording. H. L. Munnock........... 542

American Electrician.

Vol. X. New York, January, 1898. No. 1.

THE ELECTRICAL PLANT OF THE AMERICAN LITHOGRAPHIC COMPANY.

THE American Lithographic Company was formed in 1892, as a consolidation of ten of the largest lithographic companies in the East, turning out a large portion of the total product in this country. These concerns were doing business in nine different establishments in New York City, Philadelphia and Buffalo, with as many separate printing establishments, each operated by its own power plant. As the object of the consolidation of these companies was the reduction to be secured in manufacturing cost by the concentration of the business in one large establishment and shop, this latter was one of the first considerations, although on account of the magnitude of the project and of the diversified interests involved, it was not until the early part of 1896 that the actual construction of the new building was commenced.

With nine different shops turning out product, besides the large cost of management, each separate shop had its own steam plant, or purchased steam power from the owners of the building, and in addition paid for its gas or electric light. A number of the shops were equipped with expensive systems of belt and shafting transmission, which, while they were well designed for the original work, had, by means of continued extensions and alterations, become complicated and inefficient systems of power transmission. The steam apparatus used in some of the

FIG. 3.—MOTOR-DRIVEN LITHOGRAPHIC PRESSES.

FIG. 4.—HIGH-SPEED ENGINE UNIT.

MOTORS AND GENERATORS.

branches was also open to criticism as being inefficient and antiquated, and the labor employed for operating these various steam plants was of a much poorer quality than could be obtained for one large plant.

From the same causes and from the large amount of counter-shafting used, the lighting of these old establishments was not of the best quality. In addition, the item of insurance on the various buildings occupied was a large one, as most of them were in no sense fire-proof, the floors being cut up by belt-ways, elevator-shafts, stair-ways, etc. There was also a large amount of time lost in the transferring of work between the various branches.

The special work done by the company consists of lithography, comprising advertisements of high class, calenders, advertising specialties, photographic reproductions, cigarette pictures, cigar labels, newspaper supplements, etc.; letter-press work, comprising job printing and periodical printing; color printing; gilding; combination of lithographic and type press-work; advertising specialties; and the periodical *Truth*.

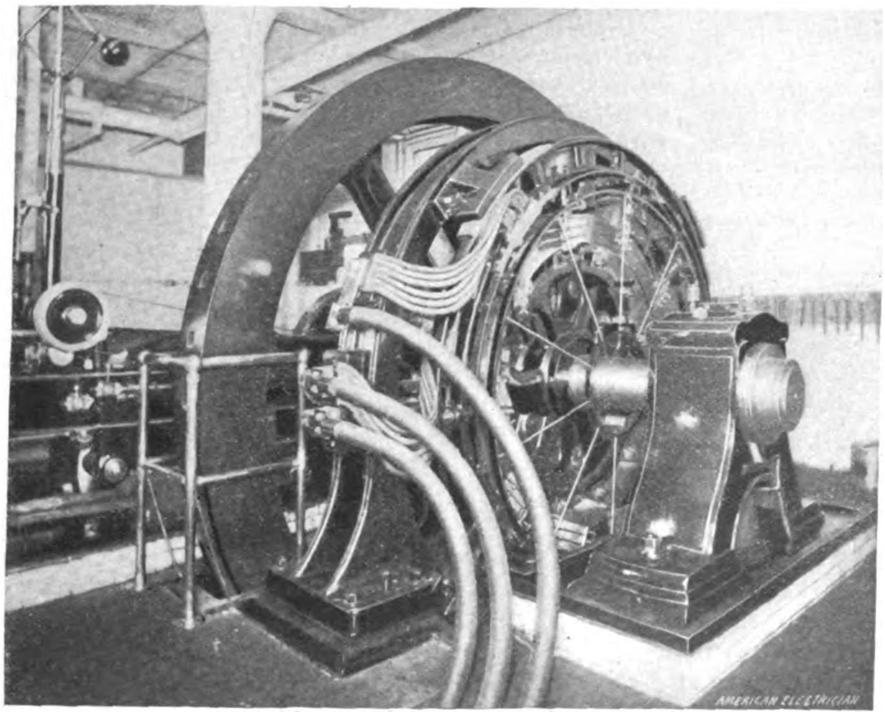

FIG. 5.—SMOOTH-BODY GENERATOR.

NEW BUILDING.

The new building of the company is located on the southwest corner of Fourth Avenue and Nineteenth Street, occupying a frontage of 131 ft. on Fourth Avenue and 200 ft. on Nineteenth Street. It comprises a basement, thirteen stories and a roof house.

The construction is entirely fire-proof throughout, consisting of steel girders and beams, iron columns and brick walls, the floors being tile arches filled in with cinder concrete with asphalt surface. The iron-work is covered with terra-cotta fire-proofing wherever exposed. The foundations extend to bed rock, a large amount of blasting having been required to obtain cellar room.

For safety and insurance against fire risk, a heavy fire wall divides each floor of the building into two parts, so that for practical purposes the building is in two sections, which will be referred to as the east wing and the west wing. Fig. 10 shows the floor plan of the building. For the same consideration of fire risk the stair-ways and elevator-shafts have been separated from the remainder of the building by fire walls, the fire walls however, being pierced at each floor by three doors. In the rear of the building is a light shaft 43 ft. × 80 ft., which, on the ground floor, forms a court-yard for the landing of freight received through a drive-way from Fourth Avenue.

The iron and steel structure of the building is of especially heavy design both to sustain the storage of heavy lithographic stones and boxes of paper on the third, fourth and fifth floors, and to prevent the vibration due to the large presses and machinery above.

The arrangement of the various floors is as follows:

Floor 13.	Artists and Provers.
" 12.	Stone Planers and Transfer Presses.
" 11.	Cutting and Embossing Machinery, Shipping Department and Storage of Stock.
" 10.	Folding and Finishing Machinery.
" 9.	Type Presses and Compositors.
" 8.	Lithographic Presses and Stock Storage.
" 7.	Lithographic Presses.
" 6.	" "
" 5.	Storage of Stock.
" 4.	Storage of Labels.
" 3.	Offices of Company and Storage of Lithographic Stones.
" 2.	Offices of Company and Art Gallery.
" 1.	Rented for Stores.
Basement.	Power Plant, Machine Shop and Store Cellars.

The first and second floors have the walls plastered, and are finished in hard woods. In the remainder of the building, the ceilings and walls are unplastered, but are pointed with cement and are whitened with cold-water paint.

ADVANTAGES OF ELECTRIC-POWER TRANSMISSION IN LITHOGRAPHIC ESTABLISHMENTS.

From tests made at one of the old printing shops of the company, the loss of power in belting and shafting throughout the building when indicated was found to amount to 60 per cent. of the full power indicated by the engine when driving all the machinery loaded. In times of slack work, this transmission loss, which is practically constant, aggregated as much as 75 per cent. of the power developed by the engine. This condition may be taken as an average of that obtaining at the other establishments. The cost of maintenance of belts and shafting was also a considerable item, with the annoyance and expense of delays from stoppage. In a lithographic establishment, the subdivision of the working machines into a number of small units necessitates the use of much counter-shafting and belting, which are especially objectionable on account of the dirt created and the obstruction of light. Good light is needed for the nice distinctions of registry and color, and dust is fatal to fine work.

Besides increased efficiency, there are many incidental advantages derived from the use of an electric-power transmission plant in a large manufacturing building. In general, the building can be laid out to greater advantage; in this case it was possible without the sacrifice of efficiency, to construct a manufacturing building in an expensive business section of the city, using the lower floors of the building for stores, offices and storage, and the upper floors for the power machinery. The flexibility of the system and the ease of control from the central engine room of any section of machinery or lights, also recommend it. The manufacturing machinery can be laid out to suit manufacturing conditions, and is not dependent on the limitations of line shafting and belts. Absolute protection from fire is guaranteed by obviating the necessity for holes in walls and floors for beltways. The electricity for lighting the building is generated from the same machines that furnish electric power, and consequently larger generators can be used, thereby securing higher efficiency. For one central power plant, a higher grade of engineers and electricians can be afforded, who will operate the machinery to better advantage. The evenness of power and speed of machinery driven by electric motor is another important feature. With conductors of proper proportions, a sudden demand for power by the working machine is instantly responded to by an additional supply of electric current from the generator. The smooth running due to this cause enables many of the machines to be operated at a higher speed than with a belt drive, thus increasing their output for the same labor cost.

Largely on account of the foregoing considerations, it was decided to install in the new building of the company an electric-power transmission plant, the electric power being generated from a central steam plant in the basement and transmitted through a system of conductors to each floor, to the electric motors driving the various machines. It was furthermore decided to equip each of the lithographic and large type presses with a separate motor direct connected to the main driving shaft of the press, and controlling it independently. This equipment with individual motors was also to be adopted for other special machines. For rows of small machines, such as cutters, embossers, die cutters, job presses, stone planers, transfer presses, etc., it was decided as more economical to operate these in groups of four or five machines belted to a short line shaft which is driven by a motor suspended from the ceiling and direct coupled to it. In this class of machinery there is no advantage to be gained by independent control. It was considered advisable not to install motors smaller than 2 HP on account of their relatively low efficiency, high first cost per HP and greater cost of repairs by reason of the larger number of units used. Electric elevators were adopted on account of their economy of operation, and ease of control.

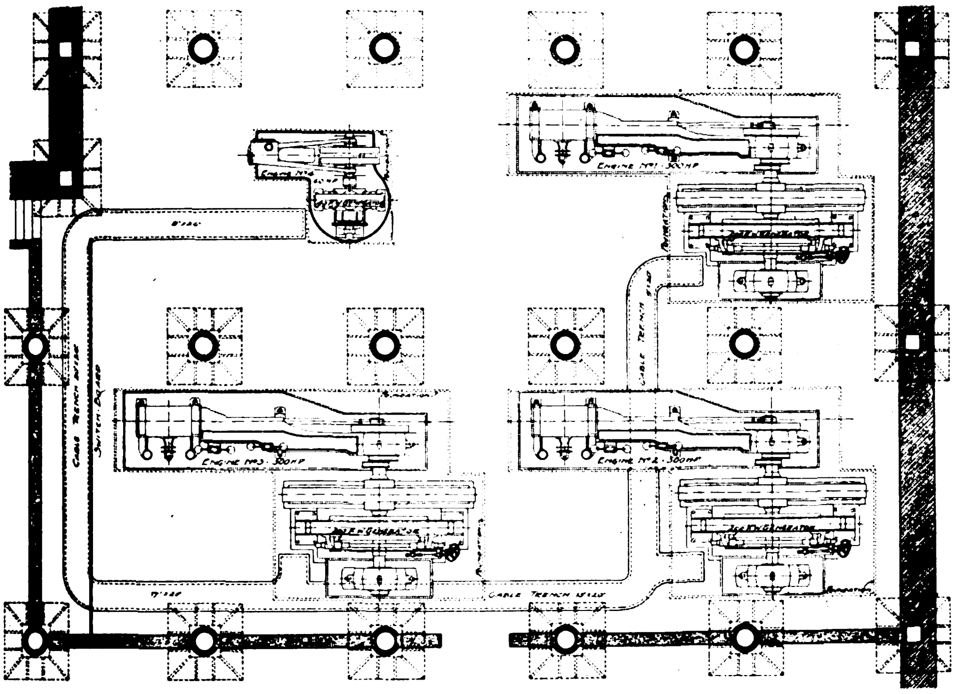

FIG. 6.—PLAN OF ENGINE ROOM.

With a few exceptions, due to excessive speed conditions, the entire equipment of motors is direct connected, either to the main driving shaft of the machine or to the ceiling shaft, thus obviating the use of belts or gears. The advantages gained by the good mechanical design of the equipment, the increased efficiency and longer life due to the slow speed, much more than outweigh the slightly increased cost.

THE GENERATING PLANT.

The engines and generators forming the electric generating plant are located in the basement of the west wing of the building, the boiler plant of five return tubular boilers being under the court yard and outside of the fire walls of the building.

Steam Engines.—The electric generating plant (Fig. 6) consists of two 20 in. × 36 in. non-condensing Watts-Campbell Corliss engines, running at 120 r. p. m., each direct connected to a 200-KW generator, and one 10 in. × 14 in. Straight Line engine running at 285 r. p. m. and direct connected to a 40-KW generator. Space is reserved in the engine room for a third 200-KW generator and direct-connected Corliss engine unit.

The Corliss engines (Fig. 2) are built extra heavy throughout to withstand the severe conditions of the service. The weight of each fly-wheel is 34,000 lbs., and running at the stated speed this has been found, in actual operation, to give a very close regulation. From tests made, it is found that the actual regulation secured is well within the limit specified, viz., 2 per cent. under a variation of load of from 40 per cent. overload to no load, this variation being obtained by tripping the main circuit-breaker. The speed at which these engines run is somewhat high for the Corliss type of engine, but on account of their special design, they fill the conditions of actual operation in a most satisfactory manner, the dash-pots and valves working most satisfactorily.

The cranks of these engines are of the balanced disk type, and the steam and exhaust valves are operated by separate eccentrics to increase the capacity of the engines for overloads. An additional safety governor has been attached to each engine. This is so constructed as to stop the engine by means of a butterfly valve in the steam admission pipe when the engine runs at more than 10 r. p. m. more than the normal speed, although the trip of this governor is subject to adjustment. As the engine room and foundations are below the level of the sewer, it was necessary to waterproof all openings in the foundation work, and accordingly heavy cast-iron, water-tight fly-wheel pits were furnished for the engines. Similarly, the field-magnet frames of the generators were enclosed in water-tight cast-iron pits.

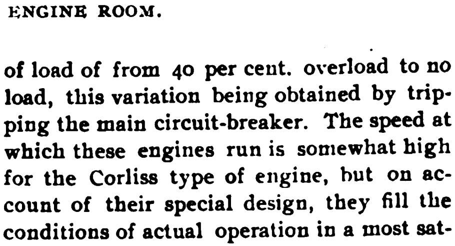

FIG. 7.—SECTION THROUGH CABLE TRENCH.

The Straight Line engine (Fig. 4) was installed to provide for the night-lighting load of the plant.

Generators.—The 200-KW generators used in this plant are of the General Electric "smooth-body" type (Fig. 5), such as are largely used throughout the country in Edison central stations, with the exception that these machines are compound wound instead of shunt wound, as is usual, and they are also provided with out-board bearings, an improvement upon the usual type of overhung armature used with this machine. The dimensions of these generators are as follows:

Number of poles, ten; speed, 120 r. p. m.; height, 99 ins.; floor space, 35 ins. × 146 ins.; diameter of shaft, 11 ins.; approximate weight of armature, 9600 lbs.; approximate weight of dynamo, 24,500 lbs. These machines are of the most mechanical construction, as they consist simply of the massive field-magnet frame and an armature which is so constructed that the windings are copper rods connected by end bars which form the surface of the commutator. The commutator, therefore, has as many segments as the armature has coils. Losses due to resistance in commutator leads and segments are eliminated, while the large number of segments reduces the volts per bar to a minimum, rendering the machines absolutely sparkless. It is possible that in the course of time if the commutator should wear down sufficiently, the armature can be turned end for end and the other side used for a commutator. The windings of straight copper bars with two joints for each convolution, render short circuits practically impossible. The brushes are of pressed-copper gauze and the brush holders are supported on studs which are held by a ring clamped between grooved brackets and bolted to the frame in such a manner that all the brushes can be shifted at once or raised simultaneously from the face of the commutator.

The small generator (Fig. 4) is of the usual General Electric "iron-clad" type with drum armature.

Foundations.—The foundations for engines and generators are shown in detail in Fig 20. The floor of the engine room rests on bed rock with the cast-iron foundation shoes, supporting the columns of the building, extending 3 ft. below the floor level into the bed rock. The foundations of the machinery are carried 3 ft. below this, or 6 ft. below the floor level, the rock having been picked out until a firm surface was encountered. The expansion bolts for anchoring the machinery were then sunk into bed rock and the excavation filled to a depth of 3 ft. with Dyckerhoff cement concrete in the proportions of 1, 2 and 3. With this as a base, the foundation was constructed of hard burned brick laid in Dyckerhoff cement mortar, the facing brick above the engine-room floor being enameled brick. An iron sole plate with elevated edge to receive oil or water drips from engine is used to cap the foundations. These foundations have proved to be of excellent design and construction, there being no perceptible vibration in the engines or in the adjoining columns of the building when the machines are in motion.

THE DISTRIBUTING PLANT.

The distributing plant will be considered in three parts: first, the connections between generators and switch-board, and the switch-board; second, the feeder system from switch-board to centers of distribution on each floor, including panel-boards; third, the branch circuits from panel-boards to outlets for lights and motors.

Generator Connections.—The connections between generators and switch-board are Habirshaw red-core, rubber-covered, insulated cables with lead armor, laid in trenches under the engine-room floor. The trenches are of the size shown on the engine-room plan (Fig. 6) and of construction as shown on detailed drawing (Fig. 7). The rock is excavated to the necessary depth and a 4-in. layer of concrete placed upon the bottom and sides, leaving a smooth inside surface. To this is applied a water-proofing of 1-in. felt and asphaltic cement, on which is laid 8 ins. of hydraulic cement concrete in the bottom, and 8 ins. of brick laid in hydraulic cement mortar on the sides. The object of these precautions is to obtain a thoroughly water-proof trench as there were encountered numerous springs of water in the location of the engine room, the floor level being below the level of the sewer.

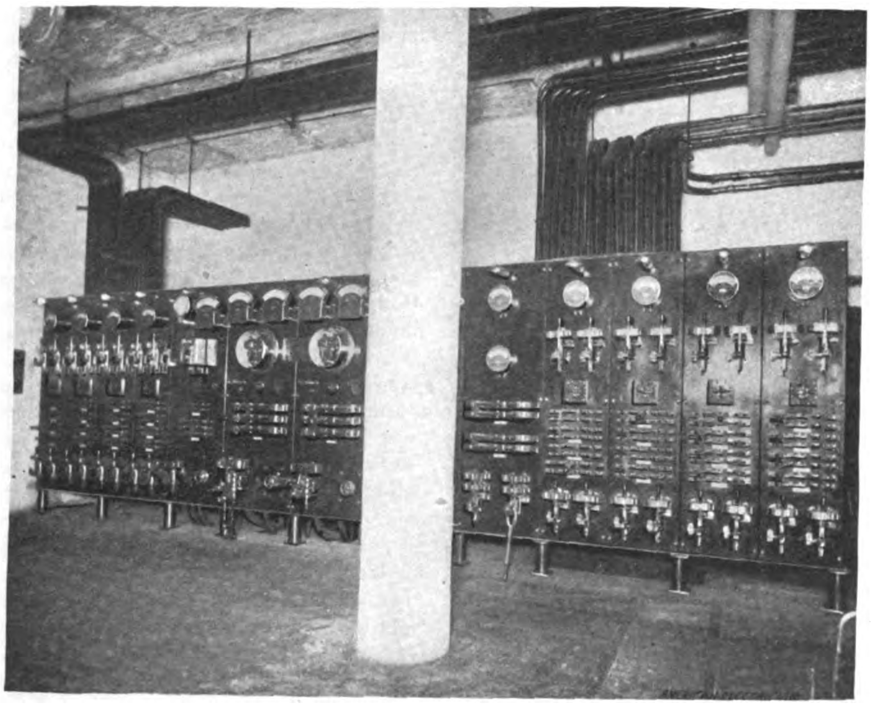

FIG. 8.—FRONT OF SWITCH-BOARD.

In the sides of the trenches as constructed, there are built cast-iron eyes for receiving the pins of the iron bridges which support the generator cables. The top of these bridges is covered with insulation to prevent injury to the lead armor of the cables. If it should be necessary to have access to the lower set of cables, the upper ones and the upper bridges can be readily removed. The trenches drain to one point where water can be removed, in case of its accidentally entering. Cast-iron plates, in sections, are used to cover the trenches, fitting into cast-iron frames, which are bedded in cement on top of the trench walls, and to which the asphalt floor of the engine room is joined.

The generator connections to the 200-KW generators are of 3,100,000 cm. section. These are so designed that under full load, the loss between generators and bus bars is not more than one-half volt. The equalizer connections are of the same size as the other cables. The generator connections to the 40-KW generators are 375,000 cm. in size. In order to secure the proper contact surface where the large generator cables join the terminals at the generators and at the switchboard, special heavy connecting clamps are used. Where the cables extend above the surface of the engine.room floor at the generators and switch-board, they are served with wrapping of hemp rope to protect the lead armor.

Switch-board.—The switch-board for this plant, as shown in Figs. 8 and 9, is 28 ft. 10 ins. long, 7 ft. 6 ins. high and is supported on pedestals 7 ins. above the floor of the engine room. The frame-work of the board is constructed of angle and T-iron shapes, firmly bolted together and securely braced from the wall in the rear. The supports from the floor are heavy ornamental brass castings. The board itself is of polished black enameled slate 2 ins. thick. The switch-board is divided into three general sections, the generator section being in the middle, the lighting section on one side and the power section on the other. Each section is divided into a number of panels, each panel being of the same size, but entirely separate and distinct from all of the others, so as readily to permit of future extension upon the same symmetrical arrangement. The generator section consists of four panels of equal sizes, one for each of the three generators now installed, and one for future use. A generator and a feeder panel are shown in section in Figs. 23 and 24.

Two independent sets of bus-bars extend the full length of the board, and, as all generator and feeder switches are double-throw, this arrangement allows two combinations of any generator and any circuit. In addition, the bus-bars are parted between the two center generator panels and provided with clamp connections, so as to afford still further subdivision of the plant if desired. At the top of the board behind the feeder panels are bolted iron spacing plates, to which the ends of the armored conduits for feeders are fastened. As shown in the photograph of the back of the board (Fig. 9), all of the flexible connections are enclosed in flexible conduit. All of the copper-bar and clamp connections are of sufficient size to secure the proper contact surface to correspond to the carrying capacity of the connections.

In addition to the usual apparatus, upon each one of the generator panels, there is mounted a Thomson recording wattmeter and a Cutter automatic circuit-breaker, besides the regular fuse connections. A careful daily record is kept of the amount of current generated by each machine. The generator panels are provided with Weston voltmeters and ammeters, together with a Bristol recording voltmeter. Carpenter enamel rheostats are used.

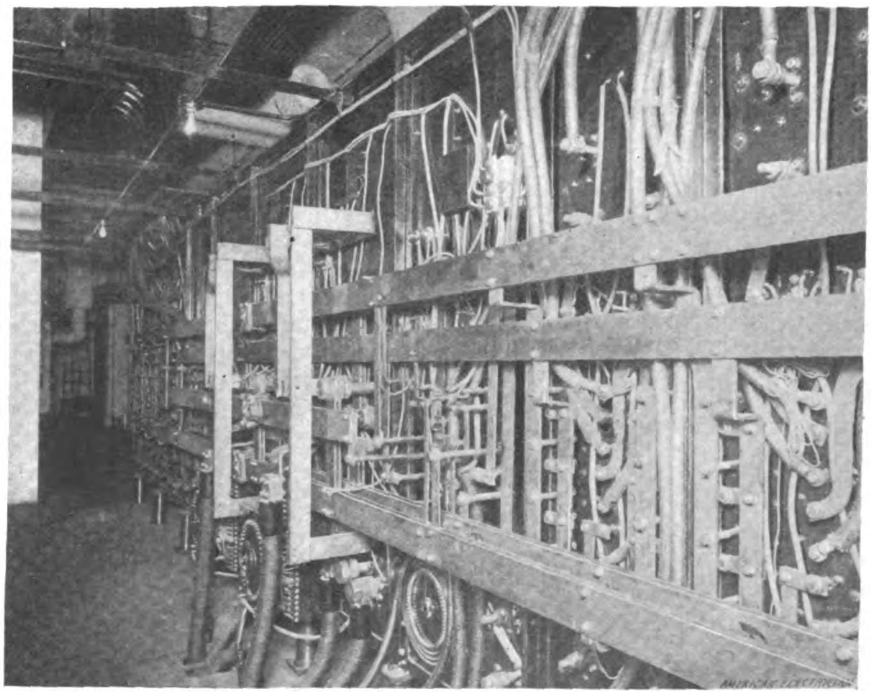

FIG. 9.—REAR OF SWITCH-BOARD.

There are 16 lighting feeder circuits and 16 power feeder circuits terminating at switches at the switch-board, together with 2 elevator feeder circuits. Each feeder panel contains the switches, circuit-breakers, etc., for controlling four feeder circuits. A Cutter automatic circuit-breaker protects each feeder circuit. In order to obviate a multiplicity of ammeters on this board, special knife-blade ammeter switches were designed for connecting in turn the leads from each of the four feeder circuits of one panel to one ammeter. The ammeters were calibrated in connection with these special switches, so as to insure accuracy.

Feeder System.—The general arrangement of the feeder system for light and power, is such that the east wing and the west wing of the building have each an entirely separate set of conductors from the switch-board; in fact, the two wiring systems are so completely distinct that they could be in two separate buildings. In the event, therefore, of one wing of the building being disabled in any manner, the remaining portion could be operated entirely independent of the crippled part. In addition the feeders for lighting and for power are entirely separate and distinct. This is shown in the illustration of the switch-board (Fig. 8), in which four separate runs of steel conduit can be seen, consisting of power feeders and lighting feeders for each wing of the building.

On each floor except the first for each wing, there is located a center of distribution for the floor, which consists of a slate panel-board, with switches for lighting and power branch circuits. All of the wiring throughout the building, from the switch-board to the outlets for lights and motors, is run in steel or iron-armored interior conduit, one conductor per tube. The cable and wire used is provided with Habirshaw red-core rubber-covered insulation. Wire larger than No. 6 B. & S. is stranded.

For each wing there was provided during the construction of the building, as shown in Fig. 10, a vertical recess in the center wall of each wing, to be used as a wire-way for the feeders to the various floors. This recess varies from 4 ins. to 8 ins. in depth, and is 5 ft. wide, the dimensions being such as to allow of about 50 per cent. reserve space after all the feeders for present use have been installed. The front of these wire-ways is provided with an iron frame-work on each floor, bolted to the beams of the building and covered with crimped galvanized iron. Fig. 21 shows the construction of the recess, framing and covering for one floor. The crimped-iron covering is fastened to the iron frame-work by screws, so that it is readily removable, should it be necessary to have access to the feeders to remove them or to make additions.

At a convenient distance from each floor in the center of the wire-way space, is placed the panel-board supplying the floor. This panel-board, which is shown in Fig. 21, is constructed of black enameled slate 1 in. thick, which is bolted to two light angle-irons, which in turn are secured to the iron frame-work supporting the wire-way covers. The panel-board is enclosed on all sides by slabs of slate, which project out to the crimped-iron covering, forming a box about 2 ft. 6 ins. wide, 4 ft. high and 4 ins. deep, in which are contained the small bus-bars, switches and fuses for controlling the power and lighting branch circuits for the floor. Supported by the iron framing are two doors which form the outside cover of the panel board. These doors have iron stiles 1 in. wide, with removable iron straps in which are screwed heavy plate-glass panes, which are bedded in rubber strips; each door being furnished with a Yale lock.

By this construction, the whole wiring system, from the switch-board to the centers of distribution, has been made entirely fire-proof and of the most permanent and mechanical construction, and at the same time all parts of it are readily accessible for repairs and additions. The lay-out for the feeder distribution is shown on the isometric sketch (Fig. 22), feeders for lighting being shown dotted, the power feeders by full lines. As shown, there is a separate power feeder for each wing of each floor upon which power machinery is used.

For lighting, there is a separate feeder in each wing for the first and second floors and above this for each two or three floors, as shown. A separate feeder is run in the elevator-shaft for lighting of elevator halls and stair-ways. There are no main centers of distribution on the first floor, this being the floor which is rented by the company for stores. There is a separate sub-feeder circuit for each store, running from the basement centers to small panel-boards placed in each store. Usually the store circuits are furnished with current from the Edison Illuminating Company's street mains by a service connection to special double-throw switches placed upon the basement panel

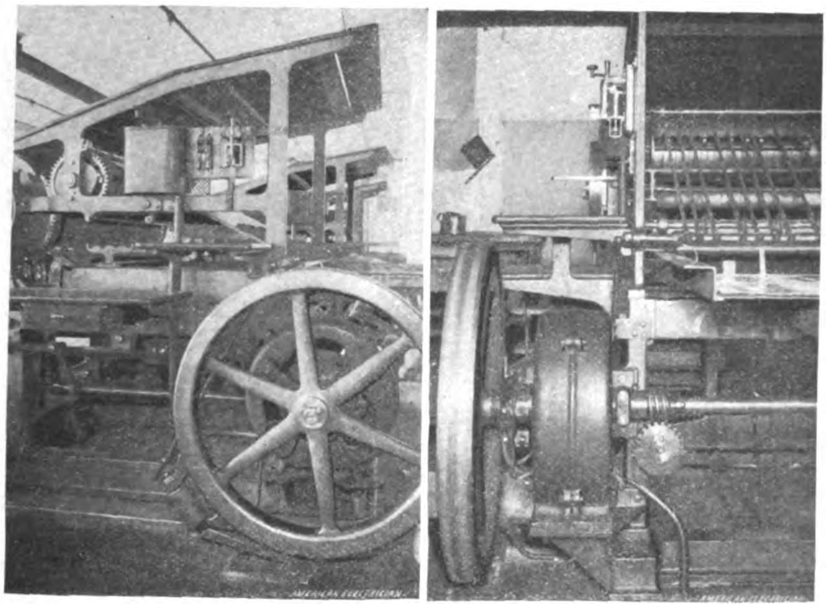
boards. By throwing these switches, the store circuits can by changed from Edison service to building service at any time, and the 3-wire system of the branch store circuits changed to the 2-wire system, used throughout the building.

The heavy runs of iron-armored interior conduit enclosing the feeders, from the switch-board to the wire-way recesses, are supported from the ceiling of the basement by special pipe hangers. For supporting the iron conduit and feeders in the vertical wire-way recesses, there are built into the brick-work, at the first, fourth and eighth floors, heavy cast-iron fire-stops which are drilled to accommodate the lines of conduit, the couplings of the conduit resting on the fire-stops. At the other floors, the fire-stops are of ¼-in. sheet-iron drilled with the necessary holes for conduit. The covering for wire-way recesses at the first and second floors, where the walls are plastered and finished, is constructed of metal lath, plastered, and made to conform with the surrounding finish.



FIGS. 11 AND 12.—SIDE AND END VIEWS OF LITHOGRAPHIC PRESS-MOTOR EQUIPMENT.

The lighting feeders, when fully loaded to the capacity of the plant now installed, are designed to have a loss of potential between the bus-bars of the switch-board and their respective centers of distribution, of not more than 3 volts; under the same conditions, the power feeders are designed for a loss of not more than 4 volts.

Branch Circuits.—As shown on the horizontal section of the wire-way recess in Fig. 21, the power and lighting feeders occupy the part of the wire-way which forms a recess in the wall, and the slate panel-board and branch circuit wiring for each floor occupy the part of the wire-way which extends out into the room. Each branch circuit on the panel-board is controlled by a double-pole knife-blade switch, the space between the panel-board and glass doors being deep enough to allow of switches being open or closed. In addition, on each panel-board there is left reserve space for the future installation of from 25 per cent. to 50 per cent. more branch circuits.

Referring again to Fig. 21 showing the wire-way construction, the connections for branch circuits from the panel-board to the steel conduit in the room are shown. Except on the first and second floors, where the ceilings and walls are plastered, the remainder of the branch wiring is run in exposed steel-armored conduit, which is suspended from the tile arches by means of small iron toggles. The floor construction of the building rendered it impossible to conceal these branch circuits. It was also considered desirable in a factory building to have all of the branch circuits readily accessible, and as all of the wiring construction is entirely protected by steel-armored conduit, the only possible objection to such construction is on the ground of appearance. At the point of entrance to the wire-way, the steel conduit on the ceiling is joined to a special multiple-corner insulating box supported by the iron frame-work of the wire-way. This special corner box is of cast-iron and made of such size as to permit of the future installation of about 50 per cent. more branch circuits, the holes for the entrance of these circuits being closed with small iron caps. In the wire-way recess, from this corner box to the panel-board, the branch circuit wiring is protected by flexible conduit.

For the power branch circuits, where the motors are placed on the floor, the branch circuits, instead of running to the ceiling of the room and dropping down to the motor, are run down through the wire-way from the panel-board to the ceiling corner box of the next room below, from which point they run on the ceiling to a position directly under the motor and then come up through the floor to the motor; the motor outlet box in this case being on the ceiling of the room below. Branch circuits to motors suspended on the ceiling run to outlet boxes on the ceiling located at the column nearest to the motor, the controlling apparatus for ceiling motors being placed on the nearest column or wall.

Outlet Boxes.—Special insulating iron outlet boxes are used for motor circuits, of sufficient size to include porcelain cut-outs of the required capacity. Runs of conduit for power branch wiring are shown in Fig. 15, which also shows the outlet boxes and the conduit to the controlling devices. The branch circuits for lights terminate in cast-iron insulating outlet boxes which, in the case of heavy fixtures and arc lamps, are supported by pipe hangers running up through the tiling and secured by washers. As it was, in many cases, impossible to arrange the lighting of the rooms until the machinery had been placed, the five-light outlet boxes on the upper floors are supplied with two branch side outlet openings for future extension of branch circuits, these, when not in use, being closed with iron caps. The one-light outlet boxes throughout the building are provided with special covers, the receptacle boxes have a socket bushed through the cover, and the pendant boxes having rubber bushings for the outlet of the flexible cord. There are about 2100 outlets for lights throughout the building and 150 outlets for motors.

Switch Control.—In addition to the switches controlling the branch lighting circuits upon the panel-boards, certain classes of lighting outlets are controlled independently. Upon the third and fourth floors, which are used for the storage of labels and lithographic stones in racks, the aisles between the racks are lighted by rows of incandescent lamps, each aisle being separately controlled by a Cutter flush switch with iron wall box fastened to the end of the rack, so that each row of lights is used only when the workman is searching for a particular label or stone. All 3- or 5-light ceiling outlets in the stores and offices are controlled by Cutter flush-switches.

THE MOTOR SYSTEM.

The motors used for driving the various classes of machinery in this building vary in size from to 2 to 35 HP. As it was the desire to make the entire equipment of the most permanent and mechanical design, slow-speed motors were adopted direct-connected to the machine or counter-shaft which they drive.

The equipment of the lithographic presses is as shown in Figs. 11, 12 and 26. The motors used for this work are of the series-wound, iron-clad type, relatively narrow so that they can be placed directly on the extension of the main driving-shaft of the press between the fly-wheel and the press frame. The mechanical design of these motors is such as to make them simple, strong and durable in every part and easily accessible for repairs, the general outline being neat, compact and symmetrical. The motors are supported upon heavy cast-iron brackets securely bolted to the frame of the press, and the upper part of the motor frame is also attached to the press by means of a heavy iron strap. In order to regulate more closely the variation of speed of these lithographic presses, extra heavy fly-wheels are used. A special electric brake, consisting of a solenoid magnet, acts upon the periphery of the fly-wheel.

The controlling apparatus for these equipments consists, as shown in the illustrations, of a main double-pole, knife-blade switch with fuses, a Cutter automatic circuit-breaker and a special cylinder controller enclosed in an iron case and operated by a short lever with pointer. Upon the lithographic press equipments, five speeds can be obtained, so that the output can be varied from 660 to 1140 impressions per hour. A motion of the controller lever automatically sets the electric brake, stopping the press as quickly as may be desired, and a movement to still another notch causes the press to reverse at a slow speed. The variation in speed is accomplished by commutating the field of the motor, which method, besides being efficient, obviates the necessity for using external resistance in the form of a rheostat.

The absolute control of the speed and movement of presses by means of the electric controller is considered by printers as one of the greatest improvements that have been made upon printing machinery in recent years, saving both time and annoyance over the old method of shifting belts, foot brakes and backing up by tugging on the fly-wheel. The wiring connections between the motor, the controller and the electric brake, are carefully insulated and neatly run in one line of iron-armored conduit, as shown in the illustrations, so that every part of these equipments is entirely protected from mechanical injury.

A view of one of the lithographic press rooms is shown in Fig. 3. In addition to the lithographic press equipments, there are a large number of other classes of machines, which are shown in the following list:

MOTOR EQUIPMENTS OF THE AMERICAN LITHOGRAPHIC COMPANY.

Motors.		HP.

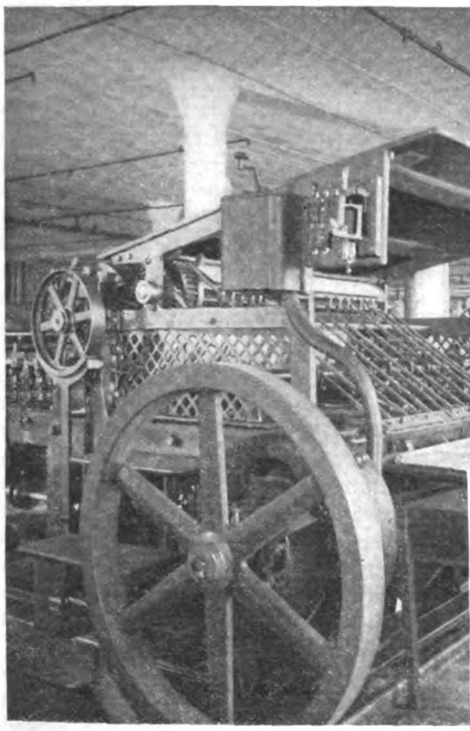

FIG. 13.—STOP-CYLINDER TYPE-PRESS MOTOR EQUIPMENTS.

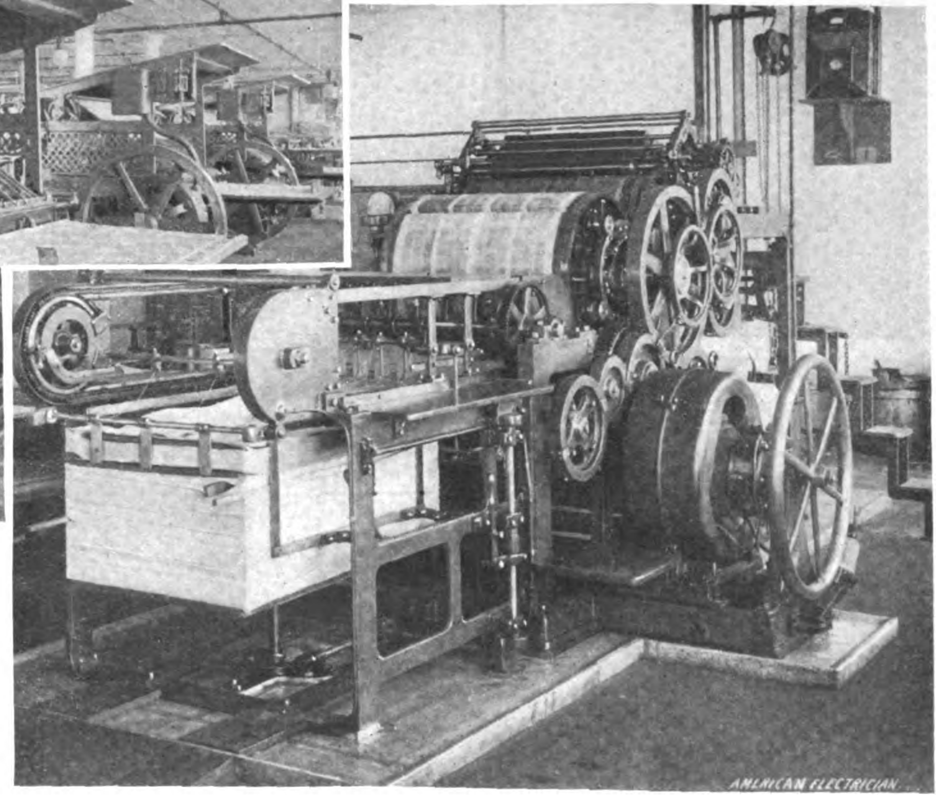

FIG. 14.—ROTARY-PERFECTING-PRESS MOTOR EQUIPMENT.

Three floors of the building are devoted to lithographic press-work and one floor to the typographic presses. The large type presses consist of two-revolution, stop-cylinder, rotary and perfecting presses of many sizes. These are driven by motors direct connected to the main driving shaft of the press and supported either by cast-iron brackets, as shown in Fig. 13, or by means of cast-iron pedestals resting upon the floor and bolted to the main press-frame (Fig. 14).

The controlling apparatus is in every case conveniently located with reference to the press feeder. The controllers are designed for obtaining the same number of variations in speed as with the lithographic presses, by means of commutated-field control, and also for obtaining reversal and electric braking. In the case of a rotary press, such as is shown in Fig. 14, the press can be stopped in addition to the movement of the controller, by means of several push buttons conveniently located at the delivery end of the press. These push buttons operate a secondary circuit, auxiliary circuit-breaker and electric brake, so that by pushing any button, the main circuit is opened and the electric brake applied.

The sizes of the type-press motor equipments vary from 2 to 10 HP with variations of speed to meet the actual operating conditions imposed by each different kind of equipment. The thirty-two small Gordon and Allen job presses are belted to short line shafts, which are driven by ceiling motors direct coupled to them.

The design and support of the ceiling motors are shown in Figs. 18 and 25. As the shafting to which they are coupled runs at moderate speed, varying from 100 to 500 r. p. m., the same type of slow-speed motor is in general employed. These motors are suspended from a frame-work of special channel and angle-iron shapes, which are secured to the steel girders and beams of the building by special beam clamps as shown, the position of the motor, vertically, being fixed by means of special distance blocks. Each motor has its own independent bearings, so that it has no dependence upon any of the shafting hangers, the motor shaft being coupled to the line shaft by means of a special adjusting Brown coupling. All of the ceiling motors are shunt wound, and with but few exceptions run at one speed without reverse. The controlling apparatus of these motors is shown in Fig. 15. It consists of a double-pole knife-blade main switch and fuse cut-out, a Cutter automatic circuit-breaker and a Cutler-Hammer automatic underload starting box. The wiring, as shown, between ceiling cut-out boxes and controlling apparatus, and between controlling apparatus and motor, is all in steel-armored interior conduit.

As shown in the accompanying list, almost all of the miscellaneous and finishing machinery used in this building are arranged in groups of several machines belted to a line shaft, which is driven by a ceiling motor direct-coupled to it. For machines of this kind, the operation of which is intermittent in character, such as cutting machines, embossing machines, stone planers, die-cutting machines, bronzing and dusting machines, stitching machines, stone grinders, roughing machines, plating, calendering and burnishing machines, it is more economical and satisfactory to operate them in groups with motors averaging 5 HP than to drive each machine by a small direct-connected or geared motor; the first cost is considerably less and the operating efficiency is higher. There is generally no need for separate and independent control of each one of these machines, as while it is in operation there is a heavy fly-wheel in continuous movement, the starting device of the machines throwing into action the clutch, which takes up the stored momentum and gives an even start, so that it is a disadvantage to stop and start the electric motor whenever the application of power is necessary.

In cases of some special finishing machinery, such as sizing, calendering and burnishing machines, it is necessary to obtain an extremely slow speed by means of spur gearing or special worm gearing between motors and main driving shafts.

Fig. 16 shows a number of ceiling motors direct-coupled to lines of shafting driving paper cutters, and Fig. 1 shows ceiling equipments operating lines of embossing machines. Fig. 17 shows a special ceiling motor coupled to a counter-shaft driving a heavy plating machine. In machines of this class and in calendering and burnishing machines, the character of the work turned out by the equipments driven by electric motors is found to be more satisfactory than with the belt drive on account of the more even application of power. With almost all of printing and finishing machinery it is found that a larger amount of product can be turned out from electrically driving machines, due to the more even application of power. The motors used for driving the machinery above described are of the Lundell slow-speed, multipolar type.

Elevator Motors.—The elevator machinery consists of two banks of four elevators, or eight in all; two of these being passenger elevators. Each freight elevator is designed for a regular load of 4000 lbs. at a speed of 150 ft. per minute. These machines, however, have been tested with a total load of over 7000 lbs. The passenger elevators are each capable of lifting 3000 lbs. at a speed of 250 ft. per minute. The elevator machines are of the drum type with Keystone motors connected to the hoisting drums by means of duplex worm and spur gearing. In addition to the safety devices ordinarily employed, each elevator motor is protected by a Cutter automatic underload and overload circuit breaker.

Safety Appliances.—The protection against overload of all generators and motors in the building has been carefully provided for by a number of safety devices, as shown. Each generator is protected by fuses and circuit-breaker; each feeder circuit on the switchboard is also protected by fuses and circuit-breaker, and each branch circuit on the panel-boards is protected by fuses. Each motor is protected at the outlet box by fuse cut-out and, in addition, on the controller-board by fuses and automatic circuit-breaker. In the case of shunt motors, the automatic underload device on the starting-box protects the motor from the accidental cutting out and throwing in again of the generator circuit.

Finish.—The engines, generators and motors upon completion, have been painted with two filler coats and one finishing coat of enamel paint, and each motor has, in addition, been plainly marked with a number, which designates the location of the motor in the building with respect to the floor and room.

THE LIGHTING SYSTEM.

The lighting of this building is obtained by the combination of arc and incandescent lamps. Arc lamps are used as much as possible for the general illumination of rooms containing machinery. The lighting for special work in connection with small machines is obtained by incandescent drop pendants. The illumination of rooms containing apparatus for hand work at tables is obtained by means of a combination of arc lamps and incandescent lamp clusters, the arc lamps giving the required intensity of illumination and the incandescent lamps softening its quality. The arc lamps used throughout the building are Bergmann enclosed lamps with opalescent inner and outer globes, so as to obtain a complete diffusion of light with absence of sharp shadows. The floors devoted to storage are lighted with incandescent lamps, as are also the office and store floors.

The rooms where the most careful and best illumination is necessary are those in which the lithographic presses are located. A brilliant illumination is obtained by a large number of enclosed-arc lamps, which are located with reference to the best possible distribution of light for the presses. As shown in Fig. 10, which gives one lithographic press floor, there are 28 arc lamps used for lighting 30 presses. By the use of arc lamps for this work, the most delicate distinctions of color can be made, and the pressmen are enabled to mix and match their colors as well at night as in the daytime.

The offices of the company are fitted with handsome fixtures, the incandescent lamps used in every case being shielded by means of ground-glass globes. The principal feature of the electrical illumination of these rooms is found in the art gallery. Here are shown a number of fine paintings, which have been used as originals for lithographic work. These pictures are lighted by rows of incandescent lamps placed in an alcove moulding at a distance of about 6 ft. from the wall, thus obtaining satisfactory illumination without interfering with the decorative proportions of the room, no fixtures being visible.

RESULTS.

This plant has been in complete operation for over six months past, and therefore the actual practical results of the electric equipment can be determined. The total capacity of engines is 660 HP, of gener-

ators 440 KW, and the rated capacity of all the motors installed is 847 HP. There are 3000 incandescent lamps and 140 arc lamps connected. During this time, the average electrical load at the switch-board has been approximately 200 HP, and the maximum load at the switch-board has been 2400 amperes at 115 volts or 370 HP. Thus the average load upon the plant is 17.6 per cent. of the total rated capacity of motors and lamps connected, while the maximum load is 32.7 per cent.

For the same period of six months, from the daily records of power produced, as recorded by the switch-board wattmeters, together with records of weighings of the amount of coal burned, it is found that each electrical HP-hour at the switchboard has been produced by 4.45 lbs. of coal. This includes the coal used for starting fires, banking fires over nights, Sundays and holidays, and also includes the running of the small high-speed unit for night work at an efficiency considerably less than the large Corliss engine units. Considering alone the operation of the large Corliss engine units in their daily ten-hour runs, during this same period they show an economy of 3.25 lbs. of coal per electrical HP-hour at the switchboard. The coal used is anthracite buckwheat.

Careful records are kept in the accounting department of the American Lithographic Company, covering all the items of the cost of manufacture. For the period during which the building has been in complete operation, comparisons have been made as to the cost of light and power in the new building with relation to the same period of former years. These figures include, for the present plant, the cost of fuel, wages of engineers, firemen and electricians, engineers' supplies, and gas bills. The figures for the same period of last year include cost of fuel, rented power, wages of engineers and firemen, engineers' supplies, and gas, and electric-light bills. Including all of these items, the cost of power and light in this new building per unit of manufactured product is 55.8 per cent. of the previous cost, or a saving of 44.2 per cent. Aside from this increased economy in the generation of power and light, there has been obtained a great improvement in the convenience of operation of the machinery and in the quality of the lighting, all of which tends to enhance the quality and increase the quantity of the manufactured product.

The officers of the American Lithographic Company are as follows: President, Joseph P. Knapp; first vice-president and purchasing agent, George W. Donaldson; second vice-president, Robt. M. Donaldson; treasurer, Louis Ettlinger; secretary, John R. Giles. Charles Eddy is superintendent of the company, and Wm. Hickey, chief engineer of the power plant.

The building, including the power plant and wiring construction, was erected for the American Lithographic Company by the the Central Real Estate Association under the direction of George P. Slade, treasurer, Alfred R. Kirkus, secretary, and Richard Berger, architect. The contractors for various portions of the electrical work were as follows: Engines; Watts-Campbell Company and Straight Line Engine Company. Generators; General Electric Company. Switchboard and wiring construction; New York Electric Equipment Company. Arc lamps and fixtures; General Incandescent Arc Light Company. Motors; Interior Conduit & Insulation Company. Elevators; McAdams & Cartwright Elevator Company.

Alfred R. Wolff was the consulting engineer for the steam-generating plant and for the steam-heating and ventilating apparatus.

For the electrical plant of the building, all the details of the engineering were performed by Ford, Bacon & Davis, Engineers, under whose supervision the equipment was installed, and by whom the foregoing plans were furnished to the *American Electrician*.

Charges for Electric Light and Power in New York City.

The New York Edison Illuminating Company has recently made some important reductions in the price of its electric service, the present rates being as follows: For incandescent lighting the price is 1 cent per 16-CP lamp-hour, including lamps. Discounts for quantity are given, ranging from 5 per cent. for $100 monthly, to 40 per cent. for $1000 or over; for long-hour use by customers using 5000 or more lamp-hours monthly, a further discount is given, ranging from 5 per cent. for 2 hours to 20 per cent. for 5 hours daily average. A minimum charge of $1.50 monthly is made. For arc lighting the price is 10 cents per 8-amp. lamp-hour, with discounts for quantity graded from 10 per cent. for 100 lamp-hours ($10) to 35 per cent. for 1000 lamp-hours ($100) or over per month; for long-hour use, to consumers of 2000 lamp-hours ($200), from 5 per cent. for an average burning of 100 lamp-hours ($10) to 15 per cent, for 200 lamp-hours ($20) monthly. The minimum charge is $3 per lamp. Consumers owning arc lamps are allowed a special discount of 10 per cent., and the minimum charge is reduced one-half, the company trimming and supplying carbons without additional charge. Power service is supplied at 10 cents per HP-hour, the discounts ranging from 20 per cent. for 100 HP-hours ($10) per month, to 50 per cent. for 1500 HP-hours ($150), 55 per cent. for 5000 HP-hours ($500), and 60 per cent. for 10,000 HP-hours ($1000). Long-hour use is taken into account in these figures. A wholesale price, on the kilowatt basis, is made to consumers using not less than 2500 KW-hours per month for lighting and power, with an average use of 2 hours or more daily, of 10 cents per KW-hour, the price including incandescent lamps, carbons and the trimming of arc lamps. Discounts are made of 1, 2 and 3 cents (10, 20 and 30 per cent.), for an average use of 4, 6 and 8 hours per day, and of ½ cent and 1 cent (5 per cent. and 10 per cent.) for use reaching 5000 KW-hours and 10,000 KW-hours, respectively, per month. When the consumer supplies incandescent lamps, carbons and the trimming of arc lamps, a further discount of 1 cent per KW-hour (10 per cent.) is made. In each case the percentage reduction applies to the gross bill. As will be seen, on the lamp-hour basis and 50-watt lamps, the minimum charge for incandescent lighting is as low as 8 cents per KW-hour, including renewals. For arc lighting, the minimum is 4 cents per 2000-CP lamp-hour, the consumer furnishing the lamp, but not trimming and carbons. The minimum rate for power service is 4 cents per HP-hour. On the kilowatt basis, the minimum is as low as 5 cents per KW-hour, or 3¾ cents per HP-hour, the consumer supplying renewals and trimming.

Alternating Currents for Electric Traction.

In a paper read at the December meeting of the Chicago Electrical Society, Mr. Cloyd Marshall expresses the opinion that with apparatus in the present state of development, the best plan for furnishing electric power to electric railways is to generate alternating currents at a place located with respect to the most favorable conditions, and to transmit them at high voltage to substations, where rotary converters will change to a direct current and supply sections of line of medium length. He considers that the recent improvements in alternating-current motors may lead to their adoption for street-railway work. Their speed may be regulated by changing the number of excited poles, since the speed is inversely proportional to the number of pairs of poles, and also by the introduction of resistance into the armature circuit. In recent experiments in Germany a single-phase motor with auxiliary starting coils gave a starting torque two and a half times normal in a short-circuited armature parallel to the exciting coils. While this starting torque is not so great as that obtained in a series motor, it could have been increased in the experiment quoted. In using the single-phase alternating current for electric power, Mr. Marshall considers that it is desirable to transmit it on one wire and use a phase-shifting or splitting device on the car for starting.

Heat-Unit Standard for Rating Electric Generating Plant.

At the annual meeting last month of the American Society of Mechanical Engineers, Prof. W. S. Aldrich read a paper supplemental to one read at the annual meeting last year, on the subject of the thermal rating of electrical plants. After discussing briefly the progress made in the past four years in the economic performance of steam-power electric plants, and showing that the very low economy of such plant is not entirely due to uneconomical engines and variable loads, he returns to the question of the heat-unit as a basis for the rating of plants. Such a system is pronounced both rational and scientific. Referring to the claim that the common rating of performance of pumping plants in foot-pounds per 1000 lbs. of steam would be amply sufficient for all purposes of rating electric plants for which the heat-unit basis is advocated, it is shown that such a basis would give results within one per cent. of what comparative ratings would be if based on the B. T. U. standard.

WINDINGS OF POLYPHASE ARMATURES.

BY J. P. STONE.

With the introduction of polyphase apparatus, a number of different windings have necessarily been developed, although all of them have the same general features. Since they are slightly different, it may be thought that they are of essentially different character. It is the object of this paper to illustrate how these windings are made, and to show that it is rather unessential what type of connections are used as far as behavior and output of machines is concerned.

The single-phase winding in its simplest form consists of a number of coils connected up so as to give alternate polarity all round the surface of the armature. Assume that an alternator has ten poles, we could thus have a winding consisting of ten coils, as illustrated in Fig. 1, each coil connected in reverse direction in regard to the preceding; or we could have a winding as illustrated in Fig. 2, consisting of five coils, which coils are connected so as to give the same polarity, but separated from each other by the pitch of the poles—that is, by the distance between two adjacent poles.

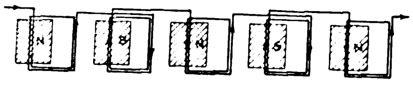

FIG. 1.—SINGLE-PHASE WINDING.

Necessarily, if all coils are connected so as to give the same polarity, the space between the coils will have the opposite polarity to that given by current passing through the coil.

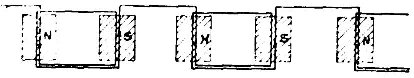

FIG. 2.—SINGLE-PHASE WINDING.

A two-phase generator could be made from a single-phase generator by adding a set of new coils placed midways between the first coils and wound in identically the same way as the first winding. Since the distance in phase between two adjacent poles is 108 degs., it is evident that the beginnings of the two independent windings will be 90 degs. apart; thus, if the two windings have the same number of turns, the generator will have two independent sources of power of same magnitude, one displaced 90 degs. from the other, that is, we have a two-phase generator with independent windings. Such a machine would then, of course, have four collector rings, two for each of the windings. By connecting two adjacent collector rings together, a two-phase relation still remains and we have a two-phase machine with interlinked winding.

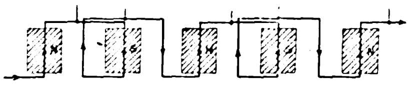

FIG. 3.—TWO-PHASE WINDING.

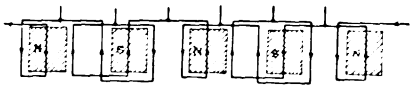

FIG. 4.—THREE-PHASE WINDING.

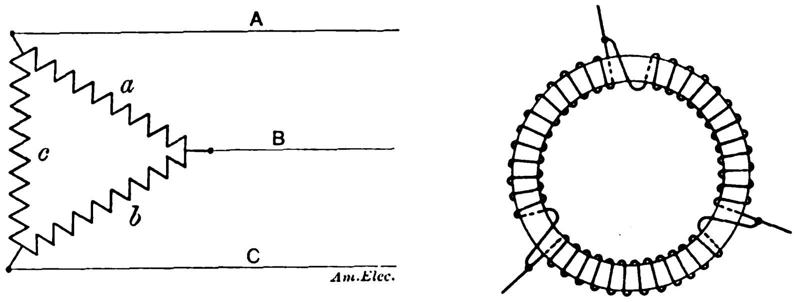
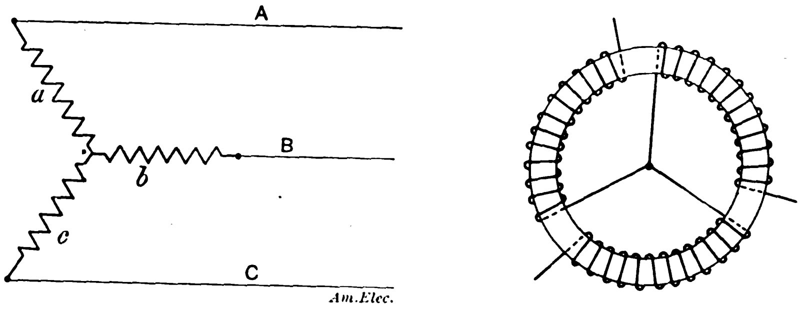
The same results can also be obtained from a distributed single-phase winding by proper connections, provided that the number of coils between each pair of poles is divisible by 2. Such a winding is illustrated in Fig. 3, and is, as can be seen, essentially a direct-current winding in which four taps are taken out to four collector rings (bipolar machine). Thus no new features in winding are introduced in making a two-phase generator.



FIGS. 5 AND 6.—THREE-PHASE DELTA WINDING.

A three-phase generator is made on essentially the same plan. It consists primarily of three independent single-phase windings, such as are described in Fig. 1 or 2, each starting 120 degs. in phase from the preceding; that is, since the distance between two pairs of poles is 360 degs., if the first winding starts midway under one pole, the second winding, wound identical with the first should start at one-third of the distance between two poles and the third at two-thirds the distance between the poles. Thus we see how a three-phase generator can be wound. If these circuits are not joined, six collector rings are necessary, two for each phase. Since, however, each winding has a point of equal potential with either of the other two, that point can be connected on all three.

That is, one end of each of their windings is brought to a common junction, from which they branch out starwise, and the remaining ends are connected to the three line wires. The three lines thus serve in turn as outgoing and return circuits, the maximum current shifting from one to the other in succession. We thus obtain a Y-connected machine which necessitates three collector rings only.



FIGS. 7 AND 8.—THREE-PHASE Y-WINDING.

Similar to what was stated regarding the two-phase winding, the three-phase winding can be obtained from the distributed single-phase winding by tapping the winding at suitable points; that is, points differing in phase by 120 degs. Such a winding is illustrated in Fig. 6, and is called the delta winding. This is also shown diagramatically in Fig. 5. Here the coils form a closed mesh, the six terminals being united two and two, the lines being connected to the windings at the three points of junction, forming a triangle. In order to make such connections, however, it is, of course, necessary that the single-phase winding should have at least 3 slots per pole and phase (for a full pitch winding) or a multiple of 3. Such a winding is illustrated in Fig. 4.

The three-phase windings can also be shown as simple Gramme windings, having only one coil per phase, as in Figs. 6 and 8, which are shown delta and Y connected, respectively. Thus it will be seen that a direct-current winding may be connected into a three-phase delta connected winding by tapping it at equidistant points, the number of leads being governed by the number of poles.

Denoting the E. M. F. induced in each winding by E, it is evident that the E. M. F. between the lines in a delta-connected armature must be E, since the lines are connected directly to the ends of the winding. In a Y-connected armature, however, one end of each of the 3 windings are connected together, and the other 3 ends are connected to the lines, as in Fig. 7; but, since the E. M. Fs. induced in each winding are not in phase with each other, the E. M. F. at the terminals is not the sum of the E. M. Fs. induced in each winding; that is, it is not $2E$, but is the geometrical sum of the E. M. Fs. in the two phases—that is $E\sqrt{3}$.

The output of a polyphase generator is that of the sum of each individual phase; that is, denoting the current in each wire in a Y-connected motor by C, and the E. M. F. induced in each phase as before, by E, the power of the three-phase generator is $3 \times CE$. Since, however, the E. M. F. between the lines is $\sqrt{3}$ times the E. M. F. per phase—that is $E \times \sqrt{3}$—we find that the power of a three-phase generator expressed by the line E. M. F. and line current must be $\sqrt{3} \times C_1 \times E_1$, where E_1 and C_1 and the E. M. Fs. and the currents, respectively, between the lines and in the lines. In a delta-wound motor, in the same manner, we find the power delivered to be expressed by the same equation.

Regarding choice of winding, in some cases, undoubtedly, one is preferred to the other. In such cases as with alternators where rectified current is used for compounding, the Y-connection adapts itself more readily, as the commutator can be connected in the common junction of the three phases.

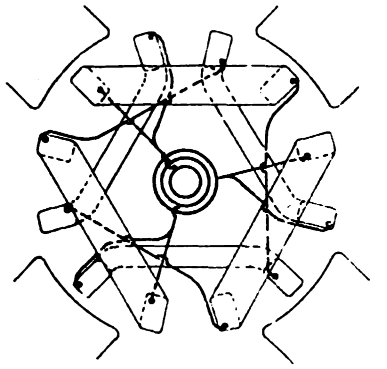


FIG. 9.—DELTA WINDING.

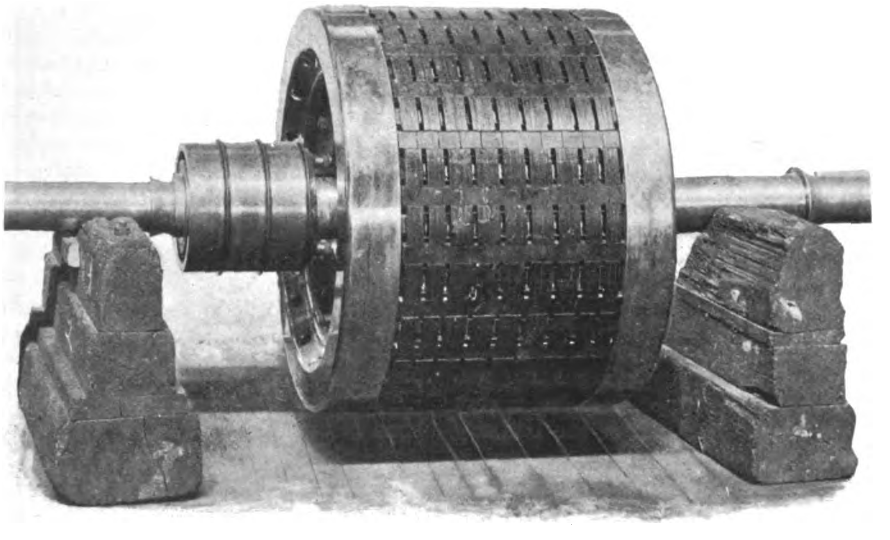

FIG. 10.—POLYPHASE ARMATURE.

The delta winding, however, is essential in generators which shall combine direct-current output or input with alternating-current output or input, such as a rotary converter, where, on account of the direct-current feature, the winding must be of the delta form; that is, must be continuous, as shown in Fig. 5, which represents a continuous winding tapped off at three points 120 degs. apart. Furthermore, by the choice of one or the other it is often possible to make a decidedly better motor, both mechanically and electrically.

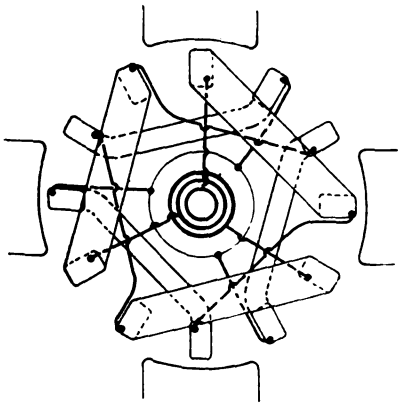

FIG. 11.—Y WINDING.

An armature designed for a given working voltage measured between the lines, would, if planned for Y-connection, have fewer turns of larger wire than if intended for delta connection. This is sometimes convenient, and is useful in keeping the voltage between coils low. The delta connection, on the other hand, has more turns of smaller wire, as the current is diminished while the E. M. F. in each coil is the full E. M. F. between the lines. This property is useful under certain conditions, as it makes the E. M. F. between any two lines somewhat less; for instance, in a machine with very large currents, the delta winding would be preferable, since in that winding the current in each wire is smaller than the line current (the line current being supplied from two phases as illustrated in Fig. 5). The contrary is the case in a machine for very high potential; it is often possible to get a simple winding by a Y-connection, since then the number of turns necessary to give the requisite voltage are less than those in a delta-connected winding.

The same winding can, of course, be connected Y or delta according to the dictates of convenience, as in Figs. 9 and 11 which show the same armature connected delta and Y respectively.

Thus it will be seen that the manner of connecting the windings of a multiphase armature is largely a matter of convenience, and thus does not influence the working of the machine.

A completed armature for a polyphase generator is shown in Fig. 10, the winding and connection of which are covered by a shield at each end to protect them from injury.

* * *

Junketing in England.

An English newspaper, according to our London contemporary, *Electricity*, is in a state of excitement because a party of fifteen municipal representatives out on a trip of examination of electric-light stations in the country, extending over three days, spent 2s 2d per head on drinks and cigars.

THE ENCLOSED-ARC LAMP.

BY WILLIAM H. FREEDMAN.

The enclosed arc of to-day has gained its position in the lighting world in the short period of three years, not only greatly increasing the total number of arcs installed but also in many instances supplanting the open arc. Its use has spread with marvelous rapidity, mainly due to the fact that it will burn without change of carbons from 75 to 100 hours, according to the make of the lamp, thereby saving considerable in carbons and trimmers' expenses. This long life of carbons, 15 to 20 times that in the open arc, has been obtained by the simple expedient of enclosing the arc within a small globe and preventing the free circulation of air around it. Upon starting the arc, the air in the enclosing globe gives up its oxygen, forming carbon monoxide and carbonic acid gas. The heat which in the open arc is radiated into the air is here confined and raises the temperature of the enclosed gases and carbon vapor. The arc proper is scarcely visible, but the entire contents of the enclosing or inner globe seem to be luminous, giving the appearance of a solid mass of light.

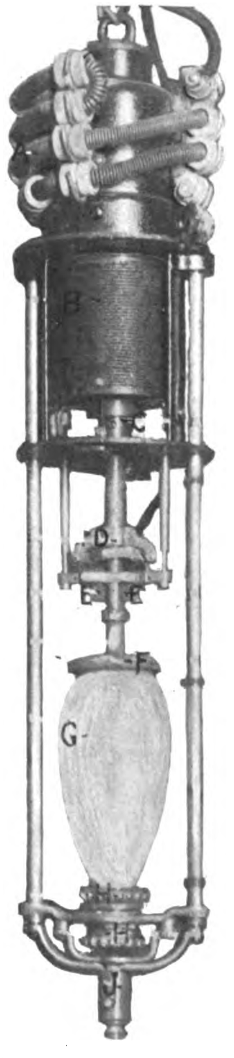

FIG. 1.—ENCLOSED-ARC LAMP.

Mechanism of the Enclosed-Arc Lamp.—All of the enclosed lamps now on the market, work on the same general principles. They are placed singly across the ordinary incandescent-lighting circuit, and are regulated to take, approximately, 80 volts across the arc, the rest of the potential being consumed in the regulating solenoid and extra resistance (shown in Fig. 1). The standard current is 5 amperes, the arc being about $\frac{5}{16}$ in. long. In indoor lighting where a strong light is not desired there are, however, quite a number of 3-ampere lamps in use.

The various parts of an enclosed-arc lamp are shown in Fig. 1. *A* is a resistance to cut down the voltage of the circuit to that required for the lamp; *B* is a solenoid which regulates the length of arc and feed of carbons; *P* is the core of the solenoid with a dash-pot arrangement added; *D E* is the friction-clutch mechanism; *F* is the gas cap (shown in detail in Fig. 4); *G* is inner globe, *HH* the lower carbon holder, and *D* the holder for the outer globe.

The current passes through the extra resistance, the solenoid and the carbons, in series. This series arrangement makes a very simple lamp, with very few parts, and working much steadier than the open-arc lamp. When no current is passing, the carbons touch; the moment the current is thrown on, the core is drawn up, and lifts the upper or positive carbon by means of a friction clutch. The negative carbon is fixed in a holder or socket, at the bottom of the lamp.

The simplest form of friction clutch consists of a straight horizontal rod fastened to the end of the plunger of the solenoid, and having at each end an arm so pivoted that the two arms cross each other like a letter D (as shown in Fig. 2). At each lower end of these arms is pivoted a friction piece, with either a rounded or V-shaped surface, which grasps the rod holding the upper carbon. Lifting the upper ends causes the lower ends to come nearer together, thus gripping the rod. The carbon and its rod are dropped when the device falls far enough to touch a stop which prevents the lower part of the clutch from coming down any further.

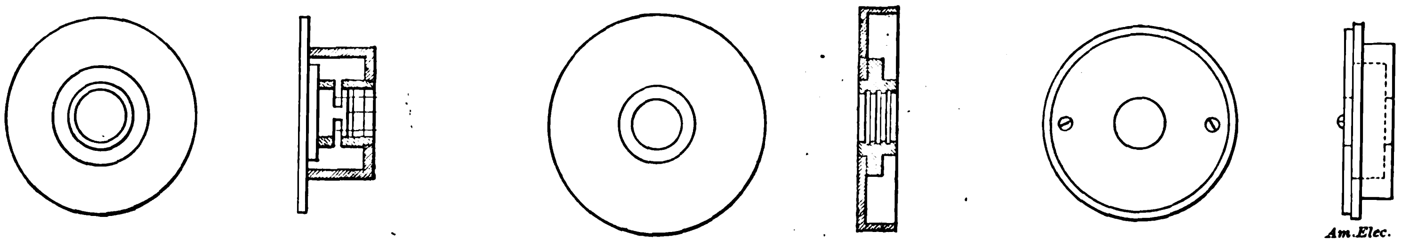

FIG. 4.—GAS CAPS—HALF ACTUAL SIZE.

A novel departure from this form of clutch consists of a cylindrical piece of brass fitting around the rod, and having its upper end grooved to hold a row of steel balls. These are held in place by a conically shaped cup. When the inner cylinder rests on the stop, the cup, which is attached to the plunger, descends far enough to release the friction on the balls by reason of its sloping sides, and the carbon rod falls. When the core is drawn up, the cup follows, the balls being caught in the apex of the cup, and the rod is drawn up.

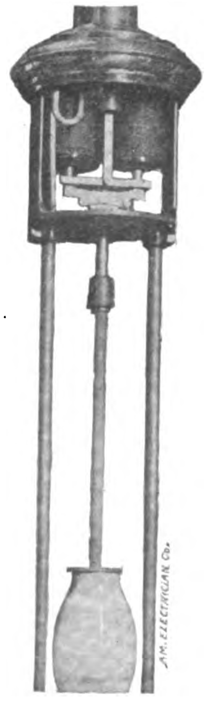

FIG. 2.—ENCLOSED-ARC LAMP.

As the carbons wear away, the armature of the solenoid gradually descends (the current remaining practically constant whatever the position of the plunger) until it reaches the stop that releases the carbon from the friction clutch; the carbon then falls and strikes the lower one, but is immediately picked up again—the light sometimes going out and sometimes remaining. This process, however, occurs at comparatively long intervals, as the core has a play of $\frac{3}{8}$ in. to $\frac{1}{2}$ in. before the stop is reached. The positive carbon wears away at the rate of .05 in., approximately, per hour, and the negative at half this rate; there will consequently be from five to eight hours between the times of the resetting of the core to its top position. The open-arc lamp, allowing a consumption of 1 in. per hour, feeds about fifteen to twenty times as often.

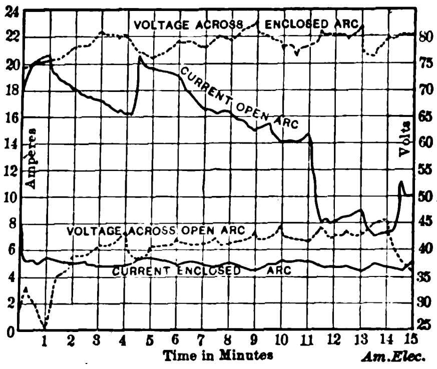

FIG. 3.—COMPARISON OF OPEN AND ENCLOSED-ARC REGULATION.

Regulation.—The simple regulating mechanism of the enclosed lamp has a very great advantage over that of the ordinary open lamp. The series mechanism used is not applicable to short-arc lamps, as a given variation makes a large proportional change, whereas this is obviated by using a long arc.

The current and voltage variation in both styles of lamp at starting, each on a constant-potential circuit of 115 volts and the open arc being one of two in series, are shown graphically by the curves of Fig. 3. The voltage is that across the arc. The normal currents were 4.75 amperes for the enclosed, and 8 amperes for the open-arc lamp.

The normal voltage across the arc, for 5 amperes, in the enclosed lamp is 80, which gives 400 watts expended at the arc; the remaining watts, due to a higher voltage of the circuit to which the arc is connected, is wasted in the extra resistance. On a 110-volt circuit, 72.7 per cent. of the energy supplied to the lamp is, therefore, spent at the carbon points. Eighty to 85 volts seems to be as high as is desirable in order to get the best regulation. Some extra resistance is necessary for regulation, as a given change in the resistance of the arc will make a less change relatively in the whole resistance when this is large.

Fig. 5 will be of interest in showing the steadiness it is possible to get in current and voltage across the arc. The readings were made every two seconds. Considering that the arc is constantly moving and that the external voltage is not absolutely steady, the regulation is very good.

Life of Carbons.—The life of the carbons of a lamp, for one trimming, depends on a large number of conditions, most of which are self-evident. 1°. It is influenced by the size and quality of carbons. 2°. It depends upon the current strength. 3°. The size of the enclosing globe affects the life. 4°. The position of the arc in the enclosing globe affects the rate of consumption of carbon. 5°. The form of the gas cap used changes the rate of ingress of air and egress of gases, thus affecting the life. Fig. 4 shows different styles of caps. They vary in form from a simple circular plate with the hole for the carbon grooved in two circles parallel with the plane of the disk, to the arrangement having a chamber fitted with slits through that wall which is next the carbon. The object of this chamber is to obstruct the circulation as much as possible, and yet have sufficient air to keep the carbon from depositing on the globe in excessive quantities. 6°. Whether the run is continuous or intermittent, changes the life, although slightly. 7°. Some lamps make use of an air-tight outer globe to keep down the supply of air, thereby slightly increasing the life.

The usual method of renewing the carbons is to use the remainder of the upper carbon for the negative in the next run. The lower carbon might even be used for two continuous runs, if the position of the arc in the lower portion of the globe is not objectionable.

The long life of the enclosed arc may be considered its chief advantage over the ordinary open arc, the saving in carbons and trimmers' expenses being very large. The old style of lamp requires two carbons for each trimming, and lasts six or eight hours. The enclosed arc requires to be trimmed about $\frac{1}{15}$ or $\frac{1}{20}$ as often. Furthermore, each re-trimming costs less. For, although the cost per 1000 for the same size carbon is greater for the enclosed arc, being $23 for 12 in. × $\frac{7}{16}$ in. rods, only one is required for retrimming, while the open arc needs two,

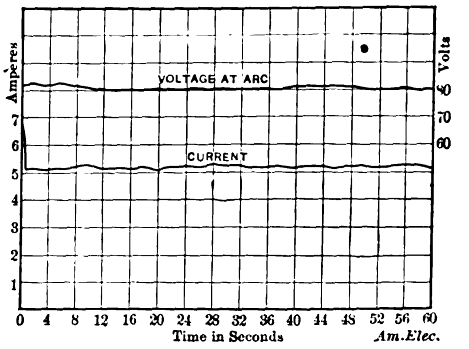

FIG. 5.—CURRENT AND VOLTAGE CURVES OF ENCLOSED ARC.

costing \$18.70 per 1000 for 12 in. × $\frac{7}{16}$ in. rods, and \$8.30 per 1000 for 6 in. × $\frac{7}{16}$ in. rods; so that 1000 retrimmings cost \$23 for the enclosed lamp, against \$27 for the open lamp, or a saving of \$4 per 1000 trimmings in favor of the enclosed-arc lamp.

Intensity aud Distribution of Light.— The distribution of light from an enclosed arc is somewhat different from that of an open arc, due to the different shape assumed by the carbons and to the different styles of globes employed.

Fig. 6 shows the difference in appearance between the two styles of arc. The enclosed arc burns flat on the top or positive carbon, the lower or negative one becoming slightly convex. The arc itself does not remain in any one spot, but wanders all around the flat ends. In the case of large carbons, this is objectionable, as it results in the casting of rather heavy shadows, but which, to a large extent, can be prevented by the use of proper globes. If the ends of the carbons are rounded slightly, the shadow is lessened, but the carbons burn flat again in a very short time.

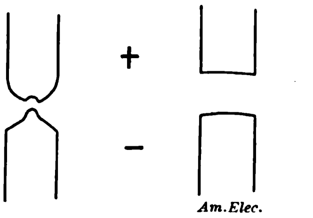

FIG. 6.—OPEN AND ENCLOSED ARCS.

The inner globes furnished by the different manufacturers vary, with respect to the glass, from a globe that will show the unlit carbons inside very plainly, to a type that while translucent, is not transparent. This latter form diffuses the light better than a thinner globe, although cutting off more light. All the opal globes, when held up to a window, show a reddish orange color, which has the effect of softening the violet light cast by the naked arc. The use of a fairly dense opal inner globe and a light outer globe, gives a soft light that is pleasing to the eye and free from shadows. When an opal globe is used, it appears like a solid source of light. It is this effect that does away with the shadows of the side rods. The shadow cast by the bottom of the lamp is also made very small, so that the effect to the eye is that of a bright, even illumination, apparently as much as the illumination from the naked arc, although the intensity has been cut down considerably by the globes. This is due to the fact that a light very intense in one spot seems to give no more illumination than a diffused light of smaller total value.

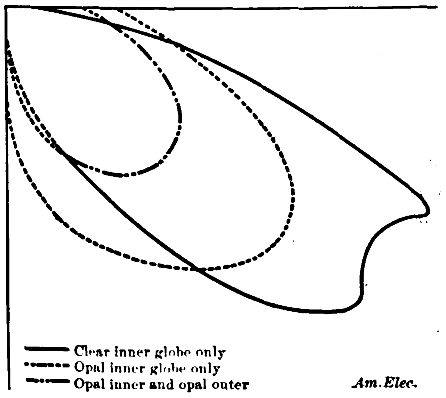

FIG. 7.—DISTRIBUTION OF LIGHT FROM ENCLOSED ARCS.

The distribution given by an open-arc lamp is not the same as that from an enclosed-arc lamp. The maximum in the latter is at an angle of 25 degs. below the horizontal instead of 40 degs. The intensity, after decreasing, reaches another high value at 40 degs., but not quite as great as at 25 degs.

The comparative distribution of light from enclosed arcs is shown graphically in Fig. 7. It will be seen that the enclosed arc gives a wide zone of illumination that is not far from the maximum. The curves of Fig. 7 as well as those of Figs. 3 and 4, are from the data of experiments conducted by Messrs. Burroughs and Rapaport, at Columbia University.

Conclusion. — Besides direct-current enclosed arcs, there are now on the market several makes of alternating enclosed arcs. These have the advantage over the open that the energy employed at the arc may be a higher percentage of the total energy supplied than in the direct. They, however, work best at one particular frequency, which might be in some cases a serious objection.

In general, the enclosed-arc lamp as compared with the open has the following advantages:

Long life, and consequent saving of carbon, trimming expenses and annoyance from frequent renewals; pleasant light, free from hissing and spluttering, and with very little flickering; absence from flying dust and sparks, and fireproof qualities resulting from the use of two globes; being run on the incandescent circuit, there is no danger from high potentials, and no need of an automatic cut-out; simplicity of mechanism, and, consequently, less need of repairs. Ability to install only one lamp and not necessarily two.

Against the above are, however, to be balanced the disadvantages of lower efficiency, and decrease of light with the time of running.

FUSES vs. CIRCUIT BREAKERS.

ACTION OF FUSES AND CIRCUIT BREAKERS.

BY L. W. DOWNES.

Having given considerable attention to the subject of fuses, I read with interest the two articles in your last issue which bear upon this subject—one by Mr. Harrington, and another by Mr. Sachs.

I beg, however, to call attention to certain statements that I believe need some modification. Mr. Harrington in his criticism of Mr. Cutler's paper, expresses surprise that he is not acquainted with the advantages of a device "that will open the circuit more and more quickly as the current causing such opening, increases," apparently assuming, or at least giving an impression, that he does not consider that this is a feature possessed by the fuse, even to a greater degree than the circuit-breaker.

Certainly no greater mistake could have been made than assuming that this is a feature alone of circuit-breakers. As a matter of fact, when we consider the cause of operation of the fuse, it will be seen that the ratio of the rate of operation, for increased current strength, is far more rapid in the fuse than in the circuit-breaker, since in the fuse the heating effect increases as the square of the current, the resistance of the fuse itself at the same time rising.

With the circuit-breaker, however, dependent as it is upon the magnetic effect, the magneto-motive force, or force tending to operate the armature, is by no means even proportional to the rise in current, except possibly at a very low magnetic density, much less its square.

I do not, of course, wish to give the impression by this, that I mean that the fuse is more rapid in its operation than the circuit-breaker, but to call attention to the oversight. He further goes on to state that the reason why circuit-breakers are preferable to fuses, even in the extreme case of elevator motors, is due to the uncertainty and unreliability of the latter.

This may be partially true for fuses of imperfect design, but for those constructed upon correct principles, this no longer holds as an argument, since they are quite as accurate as any circuit-breaker, and far more certain in their operation. Mr. Harrington then speaks of "the notoriously bad quality of fuses in permitting such enormous currents to flow in event of a short-circuit, giving an empirical formula established by himself, for the current flowing on short circuit, with fuses of various composition.

The method employed by Mr. Harrington in establishing this formula was, I believe, to use a circuit-breaker in series with the fuse, assuming that the knocking off point of such a device would indicate the maximum current flowing. It can scarcely be questioned that a formula established by such a method would be anything but correct, since the breaker is in no way adapted to the measurement of sudden rushes of current. Moreover, such a formula could not by any possibility be correct for any circuit, if at all, other than the one in which the measurements were made, since the actual current flowing on short-circuit is dependent on more than the factors of resistance and E. M. F., namely, the inductance of the circuit; at every instant during the rise of the current, since the sudden rise of current value in any circuit is opposed by a counter E. M. F., the magnitude of this factor would be dependent entirely on the conditions in the circuit. That such is the case is shown by Helmholtz' formula, to which reference is made by Mr. Harrington in the first part of his paper and which was apparently lost sight of.

It cannot be assumed from this that the fuse will permit a greater current to flow on short circuit than a circuit-breaker of equal capacity, for the short time interval in the fuse under such circumstances is about equalled by the friction and inertia of the latter; moreover, if such was the case, the breaker should operate first, whereas, as a matter of fact, it will be found, that with a properly designed fuse connected in series with a breaker which is set at a point not greatly in excess of the normal load of the fuse, it will, on short circuit, apparently operate later than the fuse, since there is no sign of flash or spark at the carbon blades; and further, if breakers will not permit of these abnormal rushes of current, why is it that it is not an unusual occurrence for those of excellent design to be totally destroyed by a short circuit, for this certainly could not take place without excessive current being involved?

In fact, Mr. Harrington, I think, loses sight of the point that is now generally admitted by engineers, namely, that for properly designed fuses there is a wide field of usefulness to which circuit-breakers are not applicable, and certainly this field is not as petty as he would intimate. On the other hand, there is an equally wide field of usefulness for the circuit-breaker, and one for which it will unquestionably be used.

Mr. Sachs in his support of fuses, advocates a method of rating that is somewhat at fault, since he says "Would not the proper method be to rate it at its maximum continuous carrying capacity, and at the percentage of overload blowing current?" In the first place, rating at the maximum continuous carrying capacity would be quite as vague as the present method of most manufacturers, unless a fixed standard for the surrounding temperature be taken, since the rise in temperature in any body due to the flow of current through it, is from and above the temperature of the surrounding air, and a fuse calibrated in this way at 60 degs. would not by any means carry the same current at 80, 90, or 100 degs.; no mention of this, however, is made by Mr. Sachs.

Obviously, a definite temperature for calibration must be taken, especially for fuses of the enclosed type, in which the temperature of the mass of adjacent material affects the blowing time for any given overload value. Moreover, I fail to see the advantage of including the time factor for any percentage of overload, since unless the whole curve of time factors for different overloads were given, the chances are, that a knowledge of what it was at any arbitrary point, would be of little or no assistance to the user. Further, Mr. Sachs, referring to a fuse recently described by me in an article on the subject, says that while the "device mentioned accomplishes excellent results, the fuse actually blows in an air chamber inside the enclosing jacket and therefore retains some of the objections of the air fuse," apparently failing to realize that an enclosed fuse constructed as described is quite worthless as a protective device, except in cases of short circuit, without the chamber, for the reason that its maximum carrying capacity changes with the length of time the fuse is in circuit, gradually becoming less as the mass of surrounding material becomes heated, with a proportional change in its blowing time, for any given overload factor.

As this change is a very large percentage of its actual carrying capacity at maximum temperature, a fuse which hot would be a protection, cold, is no protection at all. By the use of the air chamber this defect is nearly eliminated, the difference in blowing time for any given overload between a cold fuse and one that has been in circuit for sometime, being but a very small percentage.

The calibration of such fuses to their maximum carrying capacity at a given temperature is, however, a very tedious process, requiring the most careful attention for many hours, as with large sizes it requires from eight to ten hours for the mass to reach its maximum temperature.

Mr. Sachs then describes a fuse of his own design, stating that they can be built to blow on 10 per cent. or even less above its continuous running point. The intention of the author of the paper at this point is somewhat obscure, as without any mention of time value, he practically says, that a fuse which will carry a certain definite current and no more, will melt at 10 per cent., or even less excess of this maximum current value. What there is remarkable about this, it is difficult to comprehend, since it must of necessity be true of any fuse, whether enclosed or not. In the assumption that it is impossible to construct air-suspended fuses, with a short time interval, is another error, as it is possible to secure almost any desired time factor by a suitable adjustment of the various parts.

The one-second operating point spoken of by Mr. Sachs, which I presume is for a 10 per cent. overload, is, I believe, for too high a a degree of sensitiveness for ordinary commercial work, as it would result in the so frequent blowing of fuses as to be a great source of anoyance. The underwriters after careful consideration of data on this subject, state that the operation of a fuse at 30 per cent. excess of current in two minutes gives ample protection to either wiring or apparatus, and my own experience in this direction would indicate that, with the exception of lamps, this rating is well within the safety limits, while for motor installation, I believe a higher value preferable.

CIRCUIT-BREAKERS.

BY WALTER E. HARRINGTON, B. S.

The two articles in the December issue upon circuit interrupting methods are very interesting to me, owing to the emphatic and positive assertions made by both writers, upon premises which experienced engineers know to be wrong. Of course, when such arguments are adduced and statements made contrary to facts, the controversy then departs from one of engineering interest.

Mr. Cutler states that the article by Joseph Sachs "is sound engineering from beginning to end;" that "I agree with every word of it, and would not ask for a better support in the position I have taken." Now notice the peculiarly inconsistent position in which Mr. Cutler has unwittingly placed himself. I will quote from Mr. Sachs' article, last issue of American Electrician, "How can it possibly be good engineering to adopt an expensive and comparatively complicated device to do exactly that which can be accurately accomplished by one far simpler and cheaper?" "The use of one effect of the current to guard against results due to another cannot be basically correct."

In face of the above, Mr. Cutler unfolds before us a device combining the heating and magnetic effects of the current, as one of the methods to properly protect circuits.

Both Mr. Cutler and Mr. Sachs are very positive that "a properly designed fuse will open the circuit as quickly on heavy overloads as a circuit-breaker." From this I most emphatically differ, and upon this statement of fact hinges the whole situation. It is their argument. If granting their assumption were correct, then such engineers as Dr. Cary T. Hutchinson, C. O. Mailloux, Gano S. Dunn, etc., must be mistaken. I think the reader will draw his own conclusions as to this.

Personally, while I have no interest whatever in circuit-breakers at this writing, I took up the cudgel owing to the speciousness of the arguments advanced. In looking for the animus of the attacks I am informed that both writers are financially interested in cartridge fuses.

I believe that such fuses are better than open fuses if a uniform standard were adopted and never departed from. But Mr. Jos. Sachs is advocating a cartridge fuse which, of course, will be a different standard than the one advocated by Mr. Cutler.

Engineers will be confronted with the same multitude of different sizes, kinds of fuse blocks and infinity of design, etc., as have characterized the fuse field. Already, before the first cartridge fuse is barely established, another is proposed which is better (?).

Mr. Sachs states in connection with the cartridge fuse, in which Mr. Cutler, I am informed, is interested, that "the device above mentioned accomplishes excellent results, but, etc., and therefore still retains some of the objections of the air fuse."

The above indicates the true reason fuses will and never can be considered in the light of a proper protecting device, as the variables entering into the proper calibration or determination are so many that no two manufacturers would produce a similar type of fuse, and the same unfortunate diversity of conditions, sizes, shapes, alloy, length, position, method of enclosure, kind of contacts, character of current and age; thus the fuses placed upon the market would soon assume the proportions that now bewilder the layman upon investigating the fuse question. The magnetic circuit-breaker is a device which, by its simplicity of construction, self contained adjustment and freedom from the effects of its environment make it just what it has grown to be—an excellent and well balanced engineering device for the protection of electric circuits from abnormal current flow.

A Cyclist Did It.

The whole of the vast continent of Australia was practically cut off from European news for nearly twenty-four hours in the middle of September, in consequence of an interruption on the line between Adelaide and Port Darwin. Enquiries were made, and it was found that the wire had been cut by a cyclist who was taken ill in the wilderness and wished to summons help. It is not related how he set about it, but he had the satisfaction at any rate of being found by repairmen.

ELECTRIC-LIGHT AND POWER PLANT FOR SMELTING WORKS.

BY F. HOFFMEISTER.

The largest smelter in Canada is now running by electricity, being that of the British Columbia Smelting & Refining Company at Trail, B. C. Perhaps the most interesting feature of the plant is the water supply by which it is operated. The water comes from Trail Rock and Stoney creeks, and is emptied into a reservoir about one mile from Trail. The reservoir is tapped by two steel pipes, one 22 ins. and the other 16 ins. in diameter, which carry the water to the edge of Smelter Hill, directly above the electric station. Here the 16-in. pipe divides its flow, part going to the smelter for use in disintegrating the slag, and the remainder down the hill to the power house below through a riveted steel pipe.

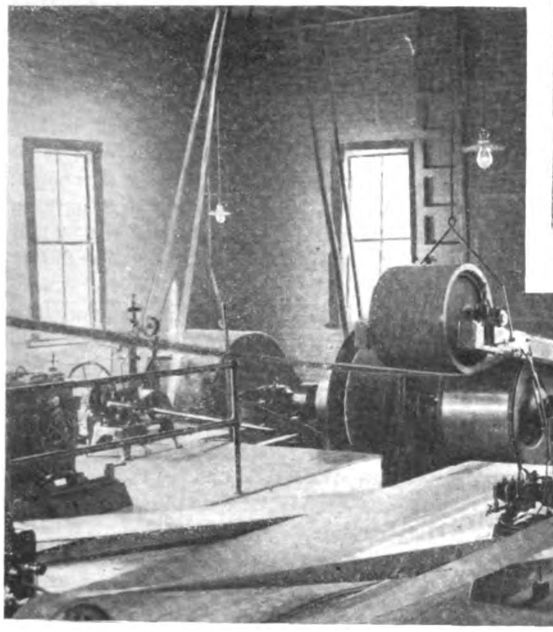

FIG. 1.—SHOWING WATER WHEELS, GOVERNOR AND SHAFTING.

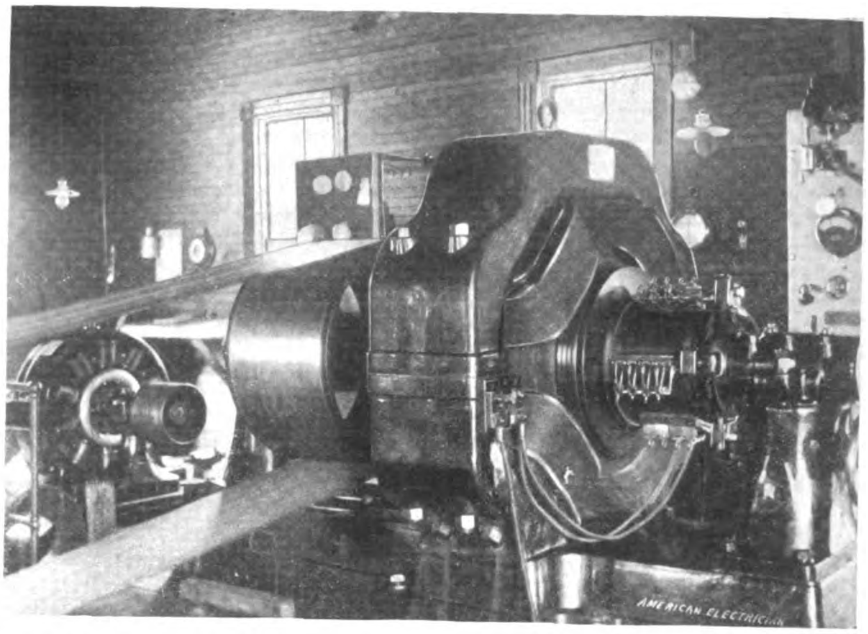

FIG. 3.—POWER GENERATOR AND ALTERNATOR.

The pipe is 22 ins. in diameter and runs at an average incline of 42 degs., with a head of about 200 ft., which gives in all a 260-ft. head at the water wheels. Just before entering the power house the pipe divides and feeds two 36-in. Pelton water wheels, which generate about 400 HP. From the Pelton wheels the power is transmitted by belts to the electric generators, which are three in number, supplied by the Canadian General Electric Company. Chief among these is the 200-KW power generator, which is the largest machine of its class in the province. This is to replace the steam engine in the smelter, which will result in a great saving of fuel expense. The current from the generator will be transformed into power by two motors of 125 HP each.

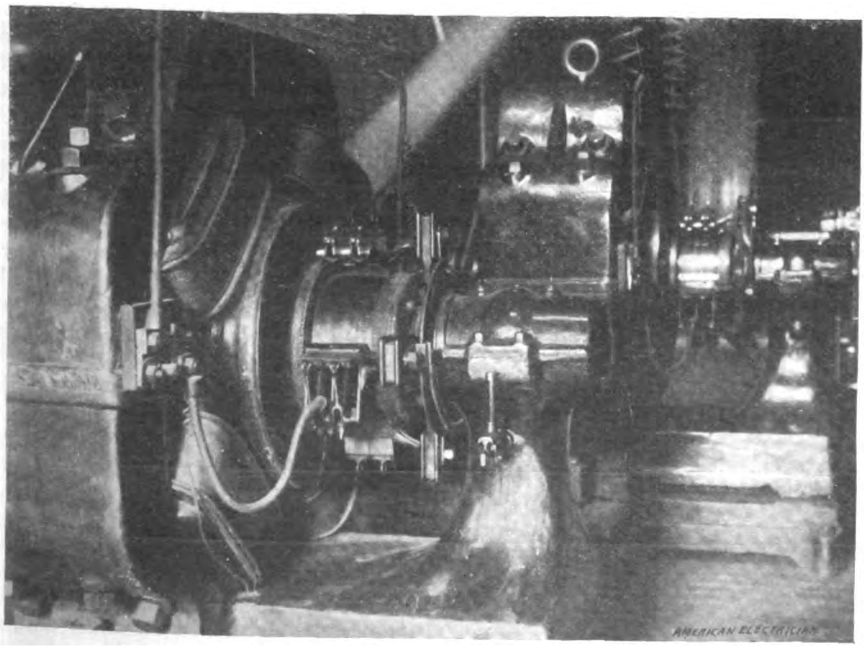

FIG. 2.—TWO 125-HP MOTORS.

The other dynamos in a power house are a 60-KW alternator T.-H. system, a 3-KW Edison type exciter, and a 15-light Wood arc machine. The switch-boards are of fine Tennessee marble, with the latest improved instruments, and finished with nickel-plated trimmings.

◆

ELECTRICAL SPECTACULAR EFFECTS,

BY C. R. PERSONS.

Some two years since the writer wired the Third Baptist Church, of San Francisco, for electric lighting, forty lights being installed in the auditorium and eighteen in the basement, including two portables. All the auditorium lights are controlled by three D. P. Hart switches placed in the front under the gallery stairs. The lights on the organ are run on the basement circuit and controlled by key sockets. Under the organ is a socket controlled by a switch, which is used for special work, as will be described later on. The current is alternating, of 114 volts.

About the time I wired the building a society of the church held an Oriental Bazaar, in connection with which I arranged an electric march and drill as follows:

Across the room were run two circuits of bare wire (No. 14 B. & S.), arranged about 18 ins. below the ceiling and run from wall to wall, each wire, of course, being on porcelain insulators. Wires of opposite polarity were about 3 ins. apart, each circuit being about 7 ft. apart. Fig. 1 will make the plan easily understood. A double-pole, double-throw knife-switch was connected in circuit in such a way that one throw would light all

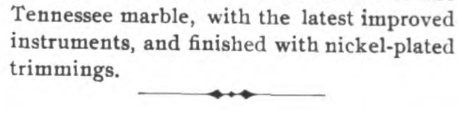

FIG. 1.—PLAN OF WIRING.

the lamps in the room, and the other send the current into the bare wires before mentioned.

The young ladies had arranged a very pretty march, in connection with which the above arrangement was used. Upon a certain bar of music being played, they would halt and salute by raising their wands in a straight line over their heads; two spring brass clips on top of sticks then made a light contact with the bare copper wires; the operator at the same time would throw the switch in the opposite direction, the lights in the room were extinguished and the lamps on top of the wands would light up, making a beautiful effect, especially as the lamps were of all colors. Before the audience could realize it, the switch was thrown in the other direction and the girls were marching away in splendid style.

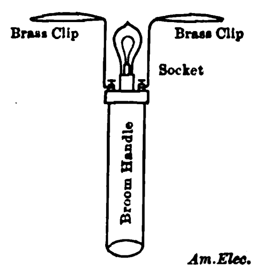

FIG. 2.—ELECTRICAL WAND.

I should mention that a third wire was run immediately in front of the copper wires; this was hung with ivy or evergreen, and served to conceal from the audience the method of lighting the lamps.

Fig. 2 will illustrate the method of making the electric wands. The wand itself was made of a broom handle, an ordinary lamp receptacle (such as is used for open work) being screwed to the top; two short strips of brass, with the ends extended, served to make contact with the wires overhead.

The entire outfit (wands and all) did not take over an hour to make up, and we had the electric drill a number of evenings with great success. It is best to rehearse about an hour, as some of the girls get nervous when it comes to making contact with the wires. The wires should be very carefully put up and connection to the switch should be made through a double-pole fuse block.

Churches generally are in debt—in fact, a church without a debt is like Hamlet with Hamlet out; the above mentioned church is not an exception, and in order to get rid of part of the debt, a performance was recently given of the well known scriptural cantata "Ruth." This gave an opportunity to introduce a number of beautiful effects, among which was a sunrise, a noon, a sunset, a moonrise, stars and a vision of two angels. The stage was wired as is shown in Fig. 3.

The method of operation is easily shown by the plan; in this case the portable stage (which is 26 ft. × 20 ft. with a proscenium opening of 15 ft. × 9 ft.) was carefully wired with annunciator wire run on porcelain insulators. Connection to the mains was made by the plug receptacle under the organ mentioned before. Any one of ordinary skill can make the switch which was used, as follows:

Procure a piece of hardwood, slate or marble, 7 ins. × 7 ins. × ½ in. thickness. At a slight cost, one can purchase from a model dealer a brass wheel 6 ins. in diameter; removing the spokes and hub, and we have a ring of brass, one face of which should be carefully turned up, and then divided into as many parts as desired (ours is in 10 sections). Mount these pieces of brass on the slate back by means of 10-24 screws, with a nut arranged to fasten tight on the rear side of switch-board. The switch will now look something like Fig. 4.

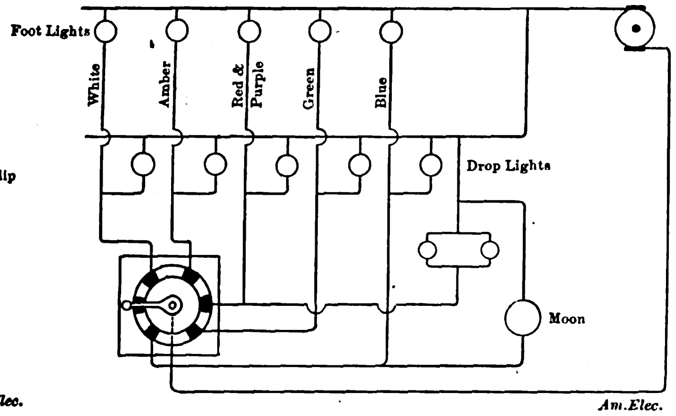

FIG. 3.—STAGE WIRING.

To make the handle and contact arm, fasten a short length of brass tubing on to a square brass plate, which tube is to contain a steel pin or shaft (a half-inch shaft will do), fitting snugly; a $\frac{1}{8}$ in. copper contact arm is made and fastened to the top of steel shaft by a nut, the upper end of shaft being threaded by a 10-24 die for this purpose. The shaft is firmly secured to the hollow brass pillar by a couple of nuts, one being, of course, a jam nut. The entire affair (pillar, shaft and all) is fastened to slate base by four 10-24 bolts, one of which is used to make electrical contact with the mains.

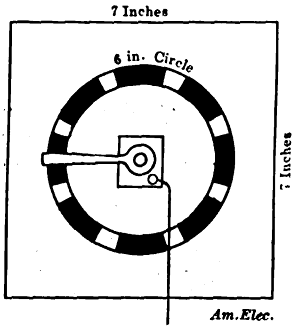

FIG. 4.—COMMUTATING SWITCH.

Of course, the contact arm must turn smoothly and easily, and make perfect electrical contact with the brass pieces. I have given no exact measurements for all the parts, as the switch can be made of any size and to carry any number of amperes. The edges of the contact arm and of the brass blocks must be slightly beveled, so that the make-and-break is easily accomplished, as otherwise vicious arcing will cause the lights to flicker in an unpleasant manner. A hard-rubber handle should be fastened to the contact arm. The arm must be wide enough to bridge the space between the brass contacts.

In "Ruth" the sunset effects were produced by the contact lever connecting red and purple lamps to the mains and cutting out the white lights. A 16-CP lamp may be connected in series to one main by an ordinary lever bell switch, which lamp can be used as a dimmer.

The moonlight effect was very easily produced by blue lamps. Arranged behind the back scene was a moon made out of a wooden box lined with tin, the face of the box having a round hole cut in it, over which was placed a piece of light blue tissue paper; a frosted 16-CP lamp in the box gave an almost perfect representation of "Fair Luna." The church was darkened during performance.

For a church entertainment, very few lamps are required; in "Ruth" were used four red, four blue, three purple, two amber, ten white and four green. A number of other lamps were used on the stage floor, concealed in boxes covered with colored gelatine. Dipped lamps may be used, but care must be exercised, as the coloring scales off easily.

The footlights and border lights must be connected on the same line running to the switch, so that corresponding colors will operate at the same time. Purple lights should be used to light the top of the back flat for sunset, with red footlights and red or amber lights over center of stage; all these lights should be fastened to a batten running over the top of the stage.

In working around churches it is frequently necessary to make something out of nothing (as churches are generally not burdened with cash), so we were compelled to use coal oil cans for reflectors—not quite so good as Frink's, but still they did fairly.

We have a powerful clock movement which fastens to the bottom of the steel shaft of switch, and during the Christian Endeavor Convention of July, we operated a large "C. E." monogram on the church tower by alternately lighting and extinguishing it every ten seconds, the clock movement operating two and a half hours each evening. During the Christmas season last year we illuminated the Sunday school Christmas tree with small lamps.

JACQUES CELL DISCUSSION.

The Jacques Cell.

To the Editor of American Electrician:

You desire to know my opinion about the "Jacques Cell" question discussed by Messrs. Anthony and Reed in the columns of the AMERICAN ELECTRICIAN. I must confess that I have not been able to find either time or patience to study very closely the various stages of the discussion which have been much confused, but as the question has finally reached a definite point, viz, the following: "Which are the electrochemical processes that are possible in this cell?" it may be perhaps of advantage if I illustrate the relations involved by a more familiar case.

Everybody knows the cell of Lalande,

which consists of copper oxide and zinc in sodium hydrate. It has an E. M. F. of 0.8 volt and, under the action of the current, the zinc dissolves on the one hand, forming sodium zincate, Na_2ZnO_2, while on the other hand the oxide of copper is reduced to copper.*

The cell becomes exhausted as soon as any one of the three substances, zinc, copper oxide or sodium hydrate is used up. In case all of the oxide of copper is reduced to copper, the cell can be restored to action by exposing the plate to the air, thus permitting the porous copper to be oxidized, this being in fact what is actually done in practice.

We possess in this cell the complete analogue of the Jacques cell. The rôle of the zinc is played by carbon, the rôle of the oxide of copper by ferric oxide, or by sodium ferrate. The cell will work until one of the three necessary constituents is exhausted. Since, in the Jacques arrangement, ferric oxide is the constituent present in the smallest quantity, the activity of the cell depends entirely upon the renewal of the exhausted ferric oxide, *i. e.*, of the amount of air or oxygen which is conveyed to the iron cathode.

If we were to construct the Lalande cell with plates of porous metallic copper instead of copper oxide, we should then be able to obtain a current from it only in proportion as fresh copper oxide is generated, say, by the blowing in of air to the cathode, or by allowing the latter to partially project in the air, and giving it a slow rotary movement, in such a manner that the reduced parts should be periodically exposed to the air.

As may be seen, in this cell as well as in the Jacques cell, the only active substance is the absorbed oxygen, and the energy which is set free by the union of the oxygen with the copper or the iron, is lost as far as the electrical process is concerned. There is practically no way known as yet for preventing this loss. If the cathode of the Jacques cell consisted of any non-oxidizable metal which would simply absorb the oxygen, as palladium absorbs hydrogen, a far higher E. M. F. might be secured, because in this case the chemical potential of free oxygen of the air, which is very high, would become effective. Free oxygen, however, is unfortunately a substance which, despite its high potential, reacts very slowly, and in order to realize practical velocities of reaction, we must put up with the loss of potential resulting from the oxidation of copper or iron.

Hence the difficulty of the problem of obtaining electricity from coal does not rest so much with the coal as with the oxygen. Theoretically it is solved in the gas battery of Grove, consisting of carbon monoxide and oxygen; the practical difficulty with this lies merely in the fact that under present known conditions these substances react too slowly, and consequently the apparatus involves too great first cost and interest. Even in the Jacques cell, it appears the oxidation of the coal takes place quickly enough; the slowest process, which determines the final result, is the taking up of free oxygen by the cathode.

When the current passes through the Jacques cell, the sodium ions move to the cathode containing ferric oxide, which thereby becomes reduced. The hydroxyl ions move to the coal, and form with the latter and the sodium hydrate present, sodium carbonate and water. As may be seen from this, oxygen is necessary only at the cathode, and every atom of oxygen which, in the free or combined state reaches the coal and burns it directly, represents a loss of electrical energy, just as does the "local" solution of zinc in the sulphuric acid of a Bunsen cell. In the computation of the total energy developed by the reaction, it is not necessary to take into account the intermediate formation of ferrate, as the assumption may be made that the cell works continuously, in which case just as much ferrate is reformed by the oxygen fed to it as is decomposed by the current. Hence we have only to consider the reaction $2\ Na\ OH + C + O_2 = Na_2\ CO_3 + H_2O$. The heat developed by this reaction is 1240 K and, as it is computed for two equivalents of the electrolyte, gives the "theoretical" value of 2.66 volts for the electromotive force of the Jacques cell. In this case the water formed is supposed to be in the state of steam, and the assumption is made, although not quite justifiable, that the heat of the reaction calculated for the reacting substances in the solid state and at room temperature, is not essentially different at the temperature of the cell.

Moreover, a more careful consideration of the reaction shows that the action of the sodium ions which have migrated to the cathode upon the iron oxide or ferrate of iron, is to form, not sodium *hydroxide*, but sodium *oxide*. At the anode *two* molecules of water are liberated by the action of two hydroxlions on the coal and the sodium hydroxide. Hence the above computation would hold good only if the air blown in at the cathode contained a sufficient quantity of moisture to allow of the formation of sodium hydroxide instead of sodium oxide. I do not know whether this fact has been taken into consideration in the practical tests of the Jacques cell; at all events, I do not doubt that by the use of moist air, especially in the case of long runs, much better results might be secured.

As for the rest, it is a known fact that the energy of cells measured thermo-chemically is never fully transformed into electrical energy; there is always a positive or negative amount of heat left in the cell, which stands in a known relation to the temperature coefficient of the E. M. F.

As you perceive, my conception of the matter is, on the whole, in accord with Prof. Anthony's views, and as a matter of fact, I do not see the slightest difficulty in regarding the Jacques cell just like other electrochemical cell. The essential point in all cells is, that the oxidizing process which furnishes the required energy, shall not take place directly, but only through the agency of an electrolytic process. It is therefore necessary that the oxidizing agent should not be brought into contact with the oxidizable anode, but with a cathode as indifferent as possible. If the reacting substances are separated in this manner by an electrolyte, and the electrodes are metallically connected, the only way by which the chemical process can take place is for the oppositely charged ions to move in opposite directions until they reach the electrodes, where they lose their electrical charge. In this manner they react in the sense of the chemical reaction, and at the same time produce a current.

If one compares in this manner the Daniell cell, for example, with the Jacques cell, they will be found to be the same in principle. There is not the slightest ground present for the assumption made by Mr. Reed of any large unknown thermo-electric forces between metals and electrolytes. The forces developed in this case are known and have been measured (for instance by Bouty) and proved to be very small.

Leipzig, Germany. W. OSTWALD.

The Jacques Cell Discussion.

To the Editor of American Electrician:

The communication of Prof. Thomson in the December number of the AMERICAN ELECTRICIAN seems to do more than "clear the air" in the discussion of the theory of the Jacques cell. If his statements are correct, they clear the air of the Jacques cell itself, as a means of getting "electricity direct from carbon" and show that it is a means of getting electricity from potash or soda.

It seems that I have given Dr. Jacques credit for more than he deserves. All of my published statements regarding the Jacques cell have been directed to an explanation of the alleged results obtained by Dr. Jacques, on which some very sensational claims of obtaining "electricity direct from coal" and promises of revolution in science and industry were launched upon the public mind about two years ago. The statements of Dr, Jacques were denied by Mr. Fitzgerald in the London *Electrical Review* of July 3, 1896. As his denial was only a statement of his personal opinion, accompanied by no experimental evidence, I did not consider it competent to wipe out the positive and apparently corroborated assertions of Dr. Jacques, claiming to be based on exhaustive experiments on a very large scale. This denial is now affirmed by Professors Anthony, Thomson and Ostwald.

If the statements of Jacques were false, we have been discussing something that does not exist. Of more importance than theory is the question of fact, in which we have on the one side Dr. Jacques and his experts, on the other, the eminent authorities mentioned above.

In the spring of 1896 a description of the Jacques cell was published in a well known and very reputable electrical journal on the authority of Dr. Jacques, from which I quote as follows:

"In this process the carbon is gradually converted into carbonic acid, which mostly bubbles up through the electrolyte and escapes. The resultant composition of the electrolyte remains unchanged, except as shown below, and oxygen of the air is consumed.

"Although the greater part of the carbonic acid, whether resulting from the union of carbon and oxygen, or already existing in the air supply, bubbles up through the electrolyte and escapes, a portion of the carbonic acid combines with a portion of the caustic soda to form carbonate of soda, and this, together with the ash from the carbon, slowly contaminates the electrolyte, and in the course of time lessons its efficiency. The efficiency may be maintained by drawing off from time to time a portion of the contaminated electrolyte and admitting a fresh portion to take its place.

---

*The active substance does not seem to be cupric oxide, CuO, but cuprous oxide, Cu_2O; this fact, however, is of no importance in the present case.

"The contamination of the caustic soda by its union with carbonic acid may be reduced and its life prolonged by adding a small percentage of the oxide of magnesium. According to Dr. Jacques the action of the oxide of magnesium is that the free carbonic acid combines with it in preference to the caustic soda, and that the carbonate of magnesium so formed is quickly decomposed into carbonic acid, which escapes, and oxide of magnesium which is again ready to repeat its action. Briefly, the oxide of magnesium serves as a carrier to convey the carbonic acid through the electrolyte."

These statements seemed to me at the time incredible, but a careful search of all the authorities at my command failed to reveal any direct contradiction. There was no authority for denying that magnesium oxide could act in the manner stated by Dr. Jacques at the temperature he employed, nor even for denying that at the high temperature employed alkaline hydrates would not combine readily with carbon dioxide. I had also been previously assured by a gentleman of unquestionable veracity and of the highest standing in the electrical fraternity, who had made investigations of the Jacques battery, that Dr. Jacques had found by analysis that the amount of carbon dioxide actually liberated corresponded exactly with the theoretical amount required by the current, and that the electrolyte suffered no apparent change after six weeks of continuous operation. In another article published by the authority of Dr. Jacques in the same paper a month after the one quoted above, occur the following paragraphs:

"The accompanying illustration (Fig. 2) shows a corner in Dr. Jacques' experimental laboratory. An early form of the carbon electric generator, which has now been in operation for six months, is seen to the left, the tops of the 100-cell battery showing with their connections * * * *. The cells consist of iron pots, 12 ins. deep and 1½ ins. in diameter.

"In a recent test made by Messrs. Stone & Webster, of Boston, the apparatus illustrated maintained 30 16-CP lamps at full brilliancy. It was found that to maintain these lights for 18¾ hours required the consumption in the pots, by oxidation, of about 8 lbs. of carbon. The average pressure during the test from the 100 cells was 90 volts, and the current 16 amperes. Messrs. Stone & Webster report that the electrical energy actually obtained from the carbon consumed in the pots was 82 per cent. of the theoretical."

It now appears, according to the authorities mentioned above, that these statements, instead of being statements of fact, were false, or at least, were cunningly devised for the purpose of deceiving the public as to the actual facts.

Who would have believed, from the statements quoted above, that no carbon dioxide is really given off in the Jacques battery? Who would have believed that each pound of carbon consumed required 9⅓ lbs. of caustic potash or 6⅔ lbs. of caustic soda? Why did not Messrs. Stone & Webster, in stating that 8 lbs. of carbon were consumed in furnishing 16 amperes at 90 volts for 18¾ hours, state that 75 lbs. of pure caustic potash or 50 lbs. of pure caustic soda were also required? Did it take Dr. Jacques and his experts more than six months of continuous operation to learn that the exhausted alkali removed from the pots weighed 12 or 15 times as much as the carbon consumed? Dr. Jacques in his illustration of a steamship (see *Harper's Monthly*, December, '96), showing how small a space would be occupied by his battery in comparison with that occupied by the steam plant, evidently forgot to show the increased size of the coal-bunkers, necessary to enable them to hold the caustic alkali that he would substitute for the coal.

The total energy evolved by the reaction,

$$2NaOH + C + O_2 = Na_2CO_3 + H_2O,$$

is 125,750 calories, and the corresponding reaction for potassium hydrate evolves 130,230. Stone & Webster's 82 per cent. efficiency was calculated on the supposition that CO_2, evolving 96,960, was formed, instead of Na_2CO_3 or K_2CO_3. The efficiency must, therefore, be reduced to 63 per cent. for caustic soda and to 61 per cent. for caustic potash. The total efficiency, instead of being 32 per cent., as given by Dr. Jacques, comes down to about 24 per cent. Mr. J. H. Helweg, Jr., has published the statement, which I do not think has been contradicted, that two-thirds of the electrical energy generated by the Jacques battery was required to operate the pump for forcing the air through the electrolyte. This is another small item that Dr. Jacques forgot to mention. If it is true, it brings down the net efficiency to 8 per cent., which compares favorably, so far as efficiency alone is concerned, with a steam engine using coal instead of caustic alkali for fuel.

Leaving now the question of efficiency for the more important question of commercial economy, we find that if the carbonate is formed, instead of the carbon dioxide, the battery ceases to have any possibilities. Its use would mean the displacement of a steam engine, using for each HP-hour one and one-half pounds of coal worth $3 per ton, by an apparatus using two and one-half pounds of caustic soda worth $60 per ton, in addition to .36 lb. of coal worth $3 per ton and .24 lb. of carbon in sticks worth at least $20 per ton. The comparison is, for raw material alone or fuel.

Steam engine................		.00225 per HP-H.
Jacques battery:		
Caustic soda	$0.075	
Coal	.00054	
Carbon	.0024......	.07794 " "

The raw material for the Jacques battery will cost at least thirty-four times that for a good steam engine and about seventy-five times that necessary for a gas engine. The weight of raw material to be handled for the Jacques battery is more than twice that used in the steam boiler, and the residue or "ash" from the battery would weigh ten or twelve times as much as that from the boiler. The figures are based on using 60 per cent. caustic soda, which would probably be the cheapest material that could be used.

The labor and expense of handling caustic alkali and keeping it in air-tight receptacles would evidently be greater than that of handling an equal weight of coal.

The figures given above assume also that all the caustic soda would be exhausted and that none would have to be drawn off until it was thoroughly carbonated. But it is evident from the nature of the apparatus that either the E. M. F. and efficiency would fall very low, or the alkali would have to be renewed before it became exhausted to any great extent, certainly before 50 per cent. of it could be utilized. Considering also the high temperature and rapid destruction of the apparatus, it is difficult to believe that this form of "electricity direct from carbon" could be practically obtained for less than about 100 times the cost of that obtained from steam, and it certainly could not compete under any conditions with a primary battery consuming zinc.

The theory of the reaction in this cell still possesses a certain scientific interest, though its possibilities for commercial or even for "promoting" purposes may be regarded as disposed of by the statements of Anthony and Thomson. The question of scientific interest is whether the chemical reaction within the cell, whatever it may be, is the cause or the result of the electric current, or in other words, whether the reaction could take place without the application and absorption of external heat.

The solution of this question depends altogether on the function of the oxygen forced into the cell. Without the energy evolved by the combination of that oxygen there is no possibility of galvanic action, the energy of carbon alone, without the absorption of external heat or electrical energy, being insufficient to decompose any constituent of the electrolyte. This fact has been brought out so often in this discussion that I shall not repeat the evidence, but refer to the recent issues of the AMERICAN ELECTRICIAN, particularly to the issue of August, 1897. Prof. Anthony has claimed that this injected oxygen acts as a depolarizing agent, that is, that it is one of the reagents taking part in the electro-chemical reaction and that the energy of its combination is given to the electric circuit as electrical energy; that this is the source and the only source of electrical energy. As evidence in support of this position, he refers to no facts, but to an alleged analogy, which he has repeatedly asked me to explain; while he has with equal pertinacity overlooked as immaterial, the most pertinent and important facts.

The object of scientific research and discussion is not to explain analogies, real or imaginary, but facts. It is for this reason that I have not thought it necessary to fill the columns of the AMERICAN ELECTRICIAN with explanations of analogies that have no real existence, hoping Prof. Anthony would ultimately come to a consideration of the facts.

It is a fact that the substitution of a rod of iron for the carbon rod in the Jacques battery gives a higher E. M. F. than can be obtained from the carbon. In that case we have two iron electrodes in contact with a fused electrolyte; one is continually receiving heat from the electrolyte, one is continually imparting heat to the electrolyte. This apparatus, without the introduction of air or oxygen, gives between the two iron electrodes an E. M. F. of 1.2 volts, and maintains it indefinitely, so long as the temperature is maintained. I will now request Prof. Anthony or Prof. Ostwald to state where this energy comes from, if it is not derived from the heat of the furnace, and how it is converted into electrical energy if not by thermo-electric inversion? It seems to me this question is sufficiently specific and definite to be entitled to a specific answer, not a parable or an analogy, but an assertive answer. Is this energy derived from the furnace or not? Until this fact is explained in some other way than by thermo-electric action, the statement by Prof. Ostwald in another column that "there is not the slightest ground present for the assumption made by Mr. Reed of any large thermo-electric forces between metals and electrolytes" would seem to be premature.

As to the "analogy" cited by Prof. Anthony of the zinc and platinum electrodes immersed in dilute acid, the observation that air coming in contact with the platinum increases the E. M. F., is correct; but the inferences and analogies that were drawn from this fact were erroneous. The inference that this increase in E. M. F. is due to the oxygen of the air "combining directly with the positive ion of the electrolyte" or "acting as a depolarizer" is incorrect. The experimental proof on this question is absolute. The only oxygen that acts as a depolarizer or takes part in the electro-chemical reaction is that which is evolved from the platinum and has been chemically combined with it in the form of a solid—oxygen that has given up combustion heat in being absorbed by the platinum. This fact may be easily demonstrated by substituting for the platinum a piece of carbon, which absorbs oxygen without combining with it. Prof. Anthony will find that with a carbon electrode, instead of platinum, the current of air produces absolutely no depolarizing effect. There is another effect that is sometimes mistaken for a depolarizing effect. It is the mechanical effect of reducing the resistance by shaking off bubbles of hydrogen gas. This effect is produced equally well by shaking the electrode, by a current of air or by a current of nitrogen or any other inert gas. If the carbon electrode be thoroughly shaken, being at the same time entirely covered by the solution, the E. M. F. will be the same, whether the current of air is employed or not. But this not the case with a platinum electrode, because platinum, as has been pointed out by Berthelot, has the power of combining with the oxygen and evolving heat of chemical combination. It is the decomposition of this compound that yields the only oxygen which takes any part in the electro-chemical reaction of Prof. Anthony's analogy-cell. That the current of oxygen has no effect whatever on the electrolyte is evident from the entire absence of depolarizing effect when carbon is used instead of platinum. The same thing may be shown also by using a well amalgamated sheet of silver, lead or copper instead of the platinum. If the oxygen acted on the electrolyte directly, as claimed by Prof. Anthony, it could make no difference whether the electrode be of platinum or not. The depolarizing effect would be the same in all cases.

Returning now from these analogies to the question at issue, the reaction of the Jacques cell, we find an amusing assortment of contradictions between authorities, which would require a tabular index for their complete enumeration.

Prof. Ostwald states in one place that the function of the oxygen is to re-oxidize the reduced iron, and that the energy of this reaction is lost so far as any electrical process is concerned. This is exactly my view and the one I have been trying for two years to establish. He then abandons that position and calculates the E. M. F. as due to the combination of this oxygen with carbon and sodium, taking particular pains to say that he agrees with Prof. Anthony.

Prof. Anthony holds that the "oxygen combines with the positive ion of the electrolyte in strict accordance with Faraday's law, and is the medium by which the current reaches the iron electrode and passes out of the cell." He believes that bubbles of oxygen that happen to strike the iron electrode enter into combination with the electro-positive ion of the electrolyte and give their energy directly to the circuit; that the oxygen "by combining with the positive ion of the electrolyte furnishes exactly the energy needed for the decomposition of the electrolyte." He consistently adheres to this delusion.

Prof. Thomson formerly stated as the result of experiments, that the function of the oxygen is to re-oxidize reduced iron. He now for some unexplained reason abandons this view and says it seems to combine directly with the carbon, and that its action is the same whether the current is flowing or not. Prof. Anthony on this point agrees with Dr. Jacques and says the oxygen used is proportional to the current.

Prof. Ostwald begins with the statement that the reaction is like that of the Lalande battery, the carbon taking the place of the zinc and the ferric oxide taking the place of the copper oxide, the electrolyte being sodium hydrate in both cases. The reaction in the Lalande battery is

$$Zn + 2NaOH + CuO = Na_2ZnO_2 + H_2O + Cu, \quad \ldots \ldots (2)$$

and that of the Jacques battery,

$$3C + 6NaOH + 2Fe_2O_3 = 3Na_2CO_3 + 3H_2O + 4Fe \quad \ldots \ldots (3)$$

These two reactions are, as Prof. Ostwald says, strictly analogous. In each case an element is oxidized by oxygen that comes, not from the air, but from the decomposition of a metallic oxide and the reduction of a metal to the metallic state, the reduced metal in the Lalande battery being copper, and in the Jacques battery, iron. The similarity of the two reactions is perfect and there is no free oxygen concerned in either of them, none appearing in either equation. The rôle of each constituent cannot be better described than in the words of Prof. Ostwald, the function of the air or oxygen being, as he says, "*the renewal of exhausted ferric oxide*," a subsequent reaction. In other words, its function is the re-oxidizing of reduced iron in exactly the same manner as the re-oxidizing of reduced metallic copper "*by exposing the plate to the air, thus permitting the porous copper to be oxidized.*" These reactions (2) and (3), are undoubtedly the electro-chemical reactions corresponding to the passage of the current in the Lalande and Jacques cells, respectively. It is further evident, as explained by Prof. Ostwald, that the Lalande "cell becomes exhausted as soon as one of the three substances, zinc, copper (oxide) or sodium hydrate is missing," and that in the Jacques battery the cell becomes exhausted as soon as any one of the substances, carbon, ferric oxide or sodium hydrate is missing. But as long as none of these substances is missing. the action goes on and there is no need of oxygen. And it is a fact that the E. M. F. is produced and maintained indefinitely whether any oxygen is employed or not, and even when any inert gas is substituted for it, the oxygen being needed only after sufficient current has passed to exhaust the ferric oxide present.

These reactions being accepted, a most remarkable question injects itself into the discussion at this point, viz., *what has the renewal of exhausted material by a subsequent and independent reaction to do with the electro-chemical reactions in these batteries?* If the exhausted material from these batteries were thrown away (as it generally is in the Lalande battery and as it seems to have been in the Jacques battery) and replaced by new material, instead of being re-oxidized, in what manner would that alter the reaction of the battery? It has never been claimed that this has anything to do with the reaction of the Lelande battery. Why, then, does the reaction of the Jacques cell depend upon the subsequent disposition of the by-products, whether they are regenerated within the cell or outside of the cell or not at all?

Is it possible that such an impertinent question as this has brought confusion upon our greatest authorities? Is it credible that Prof. Ostwald, after so clearly and admirably stating the electro-chemical reaction in the Jacques cell to be the reaction between the carbon, ferric oxide and sodium hydrate, and after also stating in unmistakable terms that "the energy which is set free by the union of the oxygen with the copper or iron is lost as far as the electrical process is concerned" and that the office of the injected oxygen is "the renewal of the ferric oxide," should precipitately abandon his position and say "we have only to conside the reaction

$$\text{"}2NaOH + C + O_2 = Na_2CO_3 + H_2O\text{"?}$$

And he says this because "the cell works continuously." *What has the continuous operation of the cell or the renewal of ferric oxide to do with the cause of the E. M. F.?* I can explain this confusion only on the ground that there is some great mistake in the translation of Dr. Ostwald's letter. In calculating the theoretical E. M. F. from this last equation a numerical error has also crept in, which is entirely excusable when we conconsider the very short time Dr. Ostwald was able to give to the preparation of his communication. The value obtained from the thermal equivalent, 124,000, is 1.33 volts instead of 2.66, carbon being a tetrad in this reaction and being electro-chemically equivalent to four atoms of hydrogen or two of oxygen.

Assuming that the regeneration of exhausted material has nothing to do with the cause or seat of E. M. F. in either the Lalande or the Jacques cell, and that the reactions in these cells are those given by Prof. Ostwald in the earlier part of his communication, we are now in a position to determine whether the reaction in the Jacques cell is galvanic or electrolytic, that is, whether the electrical energy is derived from the chemical reaction, or the chemical reaction, a result of electrolysis caused by a thermo-electric current.

Referring again to equations (2) and (3) above, we find that while they are exactly alike as far as the nature of the reaction is concerned, they differ in one important particular, viz., the energy concerned in the reaction. The reaction in the Lalande battery evolves energy (about 40,000 units), but the reaction of the Jacques battery absorbs energy instead of evolving it. It cannot take place without absorbing energy, and the only form of energy present to be absorbed is heat.

The following formation-heats are taken from Naumann's "Lehr-und Handbuch der Thermochemie:"

$$\begin{array}{lr} Na,\ O,\ H & = 102{,}030 \\ Na_2,\ O_2,\ \ C,\ O & = 271{,}080 \\ H_2,\ O\ \ \text{(as gas)} & = 58{,}700 \\ Fe_2,\ O_3 & = 191{,}130 \end{array}$$

We have, therefore, in the reaction of the Jacques cell from (2) the thermal relation,

$$3C + \left\{\begin{matrix} 6 \times 102{,}030 \\ 6NaOH \end{matrix}\right\} + \left\{\begin{matrix} 2 \times 191{,}130 \\ 2Fe_2O_3 \end{matrix}\right\} =$$

$$\left\{\begin{matrix} 3 \times 271{,}080 \\ 3Na_2CO_3 \end{matrix}\right\} + \left\{\begin{matrix} 3 \times 58{,}700 \\ 3H_2O \end{matrix}\right\} + 4Fe.$$

The sum of the formation-heats of the reagents (first member of the equation) exceeds the sum of the formation-heats of the products (second member of the equation) by 5100 units; and, therefore, that amount of energy must be absorbed or the reaction cannot take place. This is 1700 units for each of the three atoms of carbon oxidized in the equation, or a counter E. M. F. opposing the oxidation of the carbon, equal to

$$\frac{1700}{4 \times 23{,}260} = 0.019 \text{ volt.}$$

In all my previous published statements on this subject I have, in deference to the claims made by Dr. Jacques, assumed the reaction to be without the formation of carbonate, the equation being

$$3\,C + 2\,Fe_2O_3 = 3\,CO_2 + 4\,Fe.$$

If this were the reaction, the counter E. M. F. opposing the oxidation of the carbon would be about 0.3 volt, instead of 0.019 volt. In either case the electro-chemical reaction cannot take place without absorbing energy. In other words, the electro-chemical reaction is electrolysis and is caused by the electric current to which it corresponds. As the only source from which energy could be absorbed in this cell is heat, the current must comfrom thermo-electric inversion, there being no other known process by which, under the circumstances, heat can become electrical energy.

I have also found experimental proof of the correctness of this theory in a Jacques cell constructed of pure silver, instead of iron. The results were entirely different from those obtained with iron. The details of this experiment will be published later. It will be sufficient to say here that with the silver apparatus and pure caustic soda, metallic sodium was given off from the walls of the crucible and burned with explosive reports in twelve minutes after the circuit was closed, and the crucible had become alloyed with metallic sodium. The liberation of metallic sodium increased from that time until the end of the experiment, notwithstanding the fact that a strong blast of air was injected through a silver tube into the electrolyte. At the end of twenty minutes the potential of the cell had fallen to zero and reversed. In thirty minutes after the closing of the circuit the explosions from the combustion of metallic sodium became so violent that the operation had to be stopped, and the room (a large one) was filled with a white cloud of dust of sodium oxide. The crucible was 1½ ins. in diameter and 3 ins. deep. The carbon rod was ¼ in. in diameter. The lower part of the crucible was found to be so thoroughly impregnated with metallic sodium, that it became spongy on washing with water. Water which was afterwards allowed to stand in it soaked through it in twenty-four hours, as it would through porous earthenware. On slight pressure the bottom of the crucible crumbled to powder resembling a brittle amalgam of zinc.

The reduction of sodium requires a much greater absorption of energy than that of iron, and its reduction cannot be explained on any theory except that of absorption of heat and the agency of a powerful thermo-electric current.

It does not follow from this that the efficiency of the apparatus is low. On the contrary, as has been previously shown, the efficiency may be very high, certainly as high as anything that has been obtained from the Jacques cell, according to such reports as are worthy of belief.

Philadelphia, Pa. C. J. Reed.

NOTES.

Patent Office Knowledge.—Mr. James Swinburne states in a recent article that an application for an American patent for a transformer system by Bernstein, was refused on the ground that one cannot possibly get "more current out of a machine than you put in it"!

Compound Dynamos and Their Action.—In an article under this caption which appeared in our December issue, credit should have been given to a paper by Prof. W. L. Puffer, printed in the *Technology Quarterly*, of December, 1892, for much of the matter contained in the article, as well as for one of the cuts. Prof. Puffer's paper deals in an original and exhaustive manner with the action of compound dynamos when run in parallel, and we regret that proper credit was not given for the large amount of matter extracted verbatim from it.

Large Storage-Battery Plants.—The Chicago Edison Company has placed an order with the Electric Storage Battery Company for a storage-battery plant of 7436 KW-hours, which will be the largest battery installation ever made. The Buffalo Railway Company has also ordered from the same company a battery which will be the largest ever installed for railway service. By means of this storage-battery installation, the Buffalo Company will be enabled to take full advantage of its twenty-four-hour contract for Niagara power.

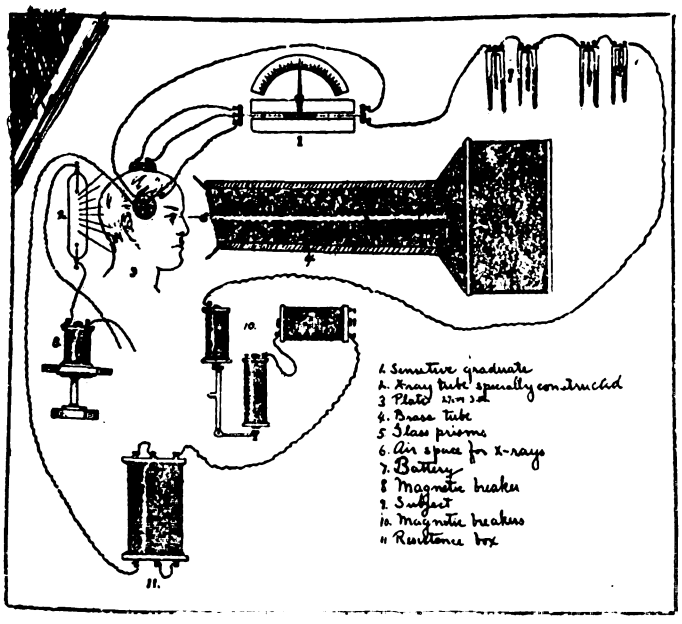
The Trans-Mississippi Exposition.—The Trans-Mississippi Exposition, which will open its gates at Omaha, June 1, of next year, and continue five months, is daily adding to the list of attractions. The many buildings to be erected will vie in architectural beauty with those of the World's Fair, and the Electricity Building, illustrated recently in our columns, is one of the most imposing. More than forty conventions are already booked to be held at Omaha during the exposition, and it is to be hoped that among the many additions that will doubtless be made to the list, the general meeting of theAmerican Institute of Electrical Engineers may be included.

Water Power Development in the West.—Among recent electrical water plants developed in the West is one of 3000 HP, about 8 miles from Tacoma, the available head of water being 115 ft. The electrical energy developed will be transmitted at a voltage of 10,000. Though the electrical machinery is not yet installed, almost the entire capacity of the plant has been contracted for, in amounts ranging from 100 to 500 HP. A water-power electrical plant of some 3000 HP has recently been developed in Montana, about 30 miles distant from Butte. The demand for current has been greater than the entire capacity of the plant when completed, and many applications for power had to be refused.

International Health Exposition.—At the International Health Exposition to be held at the Grand Central Palace for five weeks beginning Apr. 25 next, there will be a department of electricity in which will be shown the applications of electricity to health and sanitary matters and as an aid to household economies. Mr. Luther Stieringer, consulting electrical engineer of the World's Fair, Atlanta, Nashville, and Omaha Expositions, has been retained in a similar capacity for the International Health Exposition. Mr. Nikola Tesla will make a personal exhibit, and will show for the first time some novel apparatus designed for the cure of certain diseases, which will be submitted to the medical profession for critical examination, and also communicate his views as to some of the possibilities of electricity in the prevention of disease and the prolongation of human life. The phonograph will be shown in applications with which the public is not familiar, not as a toy, but as a scientific instrument which only needs to be understood to be a necessity in every well equipped specialist laboratory.

The Northwestern Electrical Association. The sixth annual convention of the Northwestern Electrical Association will be held at the Hotel Pfister, Milwaukee, commencing on Wednesday morning, Jan. 19, next. Direct and alternating current will be provided for exhibits. Papers on "Practice of Theory," "Present Efficiency for Incandescent Lamps," "Notes on Municipal Ownership," "Physical and Chemical Properties of Volatile Oils in Boilers," "Electric Lighting for Profit," "Long-Distance Transmission," and "Transformers," will be presented by John C. McMynn, of Illinois; John E. Randall, of Missouri; Fred DeLand, of Illinois; Wm. H. Edgar, of Illinois; Alex. Dow, of Michigan; Axel Ekstrom, of New York, and E. H. Abadie, of Missouri.

A New Wizard.—The sensational newspaper press is delighted at the discovery of a new electrical wizard in the person of Thos. A. Edison, Jr., the son of the original "wizard." Doubtless the sight of the columns of matter of which he is at present the subject will bring many heart-burnings to the old established "wizards," now in great danger of suffering eclipse. Within a month the new aspirant to wizard honors leaped into a fame scarcely attained by years of patient labor by the aforesaid "old established"—first as the inventor of a new incandescent lamp, and then as the discoverer of a method of photographing thought. The apparatus for thought photography is described as a closely fitting chemical bandage for the head, "whose properties are of a chemical combination, which is a jealously guarded secret; " leading from the temples and the suture of the skull are delicate conductors charged with some secret chemical to carry the most minute vibration, to which conductors are attached a graduate of secret properties and a series of disks which register the vibrations; finally, there is an X-ray apparatus, but this is of the ordinary kind and without secrets. A subject being secured, the young wizard commands him to concentrate his thoughts on some object, such as a silver quarter—but we will allow the newspaper reporter to graphically describe the process. "'Think of a quarter,' shouted Edison, Jr., 'a bright new quarter. It is to be yours.' As he spoke he whipped off the secret bandage, thrust the subject into place for the X-rays, and sent them through his brain, into a long, dark box fitted with prisms, thence to the film. Trembling with expectancy, he withdrew the film. There on the secret surface, as he tells it, was plainly discernible a round ring 18 ins. in diameter—the film was 2½ ft. × 3 ft.—and around the edge of the ring was a series of thirteen blurs like the stars which encircle the Goddess of Liberty on a quarter." The accompanying illustration (from the New York *World*) is reproduced from a sketch furnished by young Edison.



REPRODUCTION OF AUTOGRAPHIC DIAGRAM.

Niagara Power. The power-transmission line from Niagara Falls to Buffalo will shortly be doubled in capacity by the addition of three more wires. Seven new General Electric transformers will be installed, of similar size and design to the three already in the transformer house of the Niagara Falls Power Company. These ten transformers, which are of the air-blast type, are the largest ever built, each having a capacity of 1250 HP. The two-phase currents from the 5000-HP generators which are generated at 2200 volts, will not only be increased in pressure in these transformers, but changed in phase, issuing as three-phased currents at 11,000 volts. The design of the transformer is such that this voltage can later be increased to 22,000 volts. Several step-down transformers will also be placed in the station of the Buffalo General Electric Company, and from these three-phase currents will be converted into direct current by means of rotary converters, and utilized for lighting purposes and for small power units. The Buffalo Railway Company is also increasing its step-down transformer and rotary-converter capacity. In addition to the two 500-HP converters already in use, the General Electric Company has built two others of similar capacity and construction, which will bring the total converter capacity in the station up to 2000 HP. To provide for these additions, three more step-down transformers have been installed. These will be the same capacity as the three already there, each of 275 KW, reducing three-phase currents from about 10,500 volts to 375 volts for delivery to the alternating-current side of the rotary transformer, in order that it may issue at 550 volts direct current. 24,000 ft. of cable has been ordered from the General Electric Company, which will be the first used for that part of the transmission line which is within the limits of the city of Buffalo. This cable is of special manufacture, and insulated to stand the ultimate pressure of the line, which will be 22,000 volts.

Electrical Journals of the World.—A French contemporary recently printed a list of the electrical journals of the world, with date of establishment. Though quite incomplete, this list comprises 58 publications, of which 20 are printed in French, 20 in English, 10 in German, two each in Spanish, Italian and Dutch, one in Russian and one in Japanese. The oldest in date of establishment is the French *Annales Télégraphiques*, publication of which was commenced in 1858. The second in date is the American *Journal of the Telegraph*, established in 1867, as the successor of the *Telegraph Journal*, concerning which latter publication no information has been obtainable. The third in point of seniority is the London *Electrical Review*, which recently celebrated the twenty-fifth year of its existence by the issue of a magnificent commemorative number, dated Nov. 12, 1897. Eleven journals are given in the American list, of which one appears under two titles, and two are no longer published. We give herewith what is believed to be a complete list of American journals, in which are included the two street railway journals, since they now practically deal only with electric railways.

1867 (Dec. 2).—*Journal of the Telegraph.* Monthly. New York.

1883 (March 22).—*Electrical Review.* (Feb. 15, 1882, *Review of the Telegraph and Telephone.*) Weekly. New York.

1883 (April 28).—*Electrical World.* (Jan. 1, 1874, *Operator;* Jan. 6, 1883, *Operator and Electrical World.*) Weekly. New York.

1883 (June 1).—*Telegraph Age.* Semi-monthly. New York.

1884 (Jan.).—*Street Railway Journal.* Monthly. New York.

1884.—*Transactions of the American Institute of Electrical Engineers.* New York.

1885 (Aug. 1).—*Railroad Telegrapher.* Monthly. Peoria, Ill.

1886.—*Pacific Electrician.* Monthly. San Francisco.

1887.—*Western Electrician.* Weekly. Chicago.

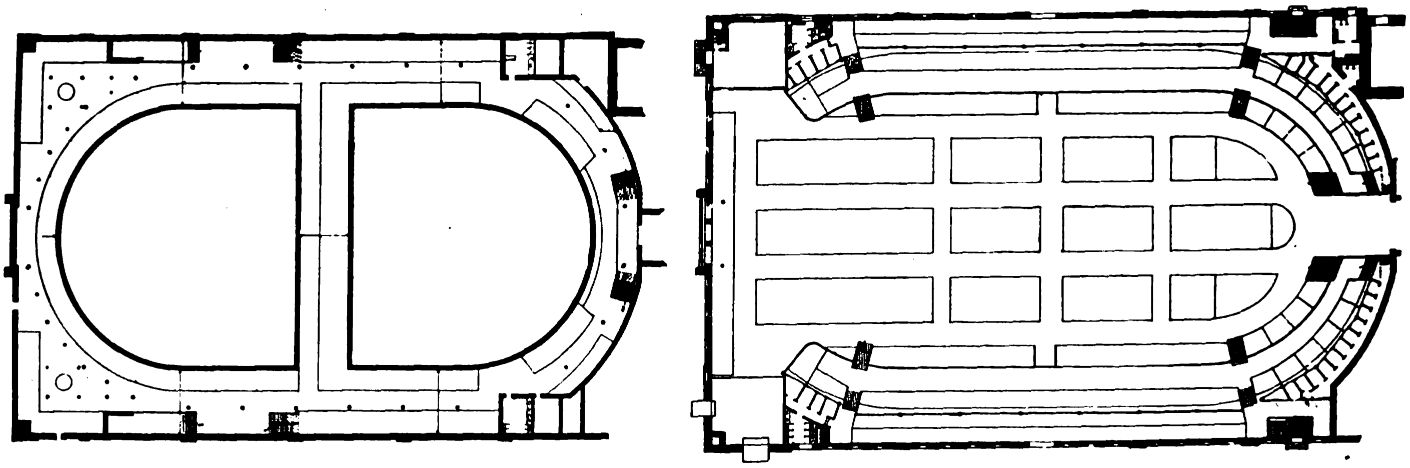
1896 (March).—*The Telephone.* Monthly. Chicago.

The date prefixed is in each instance the date of the first issue under the present name. In order, however, to avoid any occasion for re-opening the battle of the "Oldest," the date of establishment is also given of the publication which is claimed as a lineal predecessor.

Underwriters' National Electric Association.—At the annual meeting last month of the Underwriters' National Electric Association, it was voted that the break-down test of insulated wire should be of five minutes' duration, but the matter was referred to the American Institute of Electrical Engineers with a request that they express an opinion as to the propriety of this time limit. A table was reported with break distances for knife switches, up to 600 volts. The general subject of the construction of incandescent lamp sockets was referred to a committee of three, with instructions that specifications be drawn up, with which approved sockets should comply.

New York Electrical Exhibition.—The electrical show to be given in New York during the month of May promises to even exceed the phenomenal success of the 1896 show. Much of the space is already taken, in many instances exhibitors at the last show taking double or more the space they occupied in 1896. As the exhibition will be held in Madison Square Garden, it will be subject to comparison with the bicycle and other very successful exhibitions, and the electrical fraternity owes it to itself that the comparison shall not be unfavorable. Though necessarily held under the auspices of a private management, the object of the exhibition is a laudable one. Those in charge are animated more by a desire to "boom" the electrical industry than by thought of pecuniary gain, and deserve the good wishes of all for a brilliant success.



OPERATIVE EXHIBITS. NEW YORK ELECTRICAL EXHIBITION. MAIN FLOOR.

Electricity Direct from Heat.—In a recent communication to the French Academy of Science, M. Marcel Deprez promises to presently announce a method of utilizing in a practical way the magnetic properties, lately discovered by M. Guillaume, of certain alloys. A 30-per cent alloy of nickel with iron, was found, for example, to be strongly magnetic at 112 degs. Fahr., and to lose completely its magnetism at 212 degs. By the second law of thermo-dynamics, in any practical application which M. Deprez may make of this property, only 13 per cent of the heat supplied can be utilized at perfect efficiency—which is less than the percentage of heat that can now be transformed into electricity by means of a boiler, and the most efficient types of steam engines and dynamos. The working efficiency of such an arrangement must be necessarily small, and also its activity or rate of doing work, thus necessitating an extremely large apparatus in comparison with a steam engine of the same power.

Resistances in Early Days.—In a recent article Mr. W. M. Mordey says he remembers using, about 1871 or 1872, resistance coils of a few thousand ohms, weighing certainly more than 30 lbs. They were made of copper wire of quite large diameter, and required to carry, perhaps, a full load of possibly one watt. He also remembers that the mystic letters, "OHMS" on these coils were currently understood to mean "On Her Majesty's Service." The first superintendent of a cable station used to relate how, at an earlier date, in making insulation tests, the resistance in the balancing arm of a Wheatstone bridge was recorded in feet of iron wire and lengths of steel hoop-skirt, the latter being used for finer adjustments.

A Quarter-Century of Electrical Journalism.—Our very highly esteemed London contemporary, *The Electrical Review*, celebrated the twenty-fifth year of its existence by the issue on Nov. 12, of the best number of a purely electrical journal ever printed. The June, 1897, number of the AMERICAN ELECTRICIAN, had previously held the record, but we resign that claim in favor of our English contemporary, and offer our congratulations on its splendid enterprise, together with our heartiest wishes for the continuance of its prosperity. The eighty pages of reading matter are principally occupied by retrospective views of progress in the electrical field during the past twenty-five years. No less than twenty-two separate articles of this character appear, covering together every branch of electrical science and industry, each written by an authority in the department considered. It is to be hoped that these articles will be gathered into book form, as they furnish a most interesting and valuable epitome of the period covered—a period, moreover, which has witnessed the birth of the great majority of the branches treated.

The Heilmann Locomotive.—Our Paris correspondent sends us a description of the latest type of the Heilmann locomotive, which is now undergoing trials in France. The locomotive proper has a length of 59 ft. and is provided with an ordinary type locomotive boiler, a Willans compound engine of 1500 HP, direct-connected with two 6-pole Brown generators, of 450 KW each at 500 volts and 400 r. p. m. The generators are excited by a small 4-pole dynamo, giving 140 amperes at 110 volts and 550 r. p. m., driven by a small Willans engine. The current generated drives eight motors, each mounted on an axle of the locomotive. The total weight of the locomotive alone is 120 tons, and that of the tender 49 tons, making a total of 169 tons. This central station on wheels has been designed to draw trains up to 300 tons, and at speeds up to 62 miles per hour.

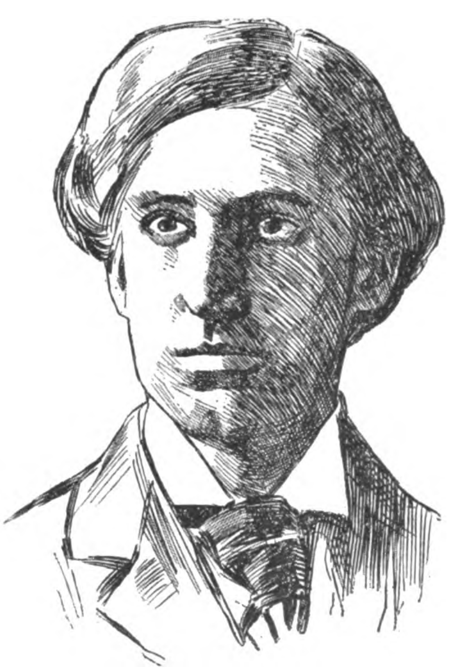
Electro-Chemistry as a Profession.—In the London *Electrical Review*, Mr. Emile Andreoli says that anyone who a few years back would have recommended a young fellow to take up electrolysis as a profession, would have been considered to be a bit eccentric, or even not to be quite right in his head. There was then, he says, hardly any future for anyone in that field, for, apart from galvanic metallic deposition, no electro-chemical industry existed. Even now, it is, of all the branches of electricity, the least encumbered, but the one in which a young man has the best chance of securing a good position. Mr. Andreoli adds, however, that he will not make much progress if, although a good electrician, he is but a poor chemist; but it will be the very opposite, he thinks, if, being a good chemist, he has no very great acquirements in electricity. Electrolysis and electro-metallurgy, he considers are, nowadays, professions in themselves. Not only are there electro-chemists and electro-metallurgists to be found at the present time, but there are also consulting engineers who confine themselves to electrolytical matters, experts who make it their special business to draw up reports on new methods, or to give advice as to the best means of applying them. Who, he concludes, even ten years ago, could have foreshadowed this state of affairs?

A Discovery Rediscovered.—The daily press has lately devoted considerable space to the alleged discovery by a Western jeweler of a method of transmitting pictures by telegraphy. As described, the process appears to be identical with the Bakewell-Caselli facsimile process, invented more than a quarter of a century ago. At each station is a synchronous mechanism, the receiving instrument duplicating the movements of the sending instrument. The picture to be transmitted is so prepared that a tracing-point at the sending end passes alternating over a conducting and a non-conducting surface, the receiving tracing point making a mark when on the former. In practice, the picture is so redrawn that the conducting surfaces are in the form of straight lines, representing in hatching the original. These lines are reproduced by closely spaced dots, which gives a semblance of the original picture in hatch-work. Gray's telautograph is a vastly more perfect facsimile device, as it reproduces continuous lines—in fact, being capable of making exact reproductions in full lines from unprepared copy, the receiving-point following the transmitting point in all of its motions as if it were one arm of a pantograph, the sending-point being the other arm.

Municipal Electrical Inspection.—At the annual meeting last month of the Underwriters' National Electrical Association, the subject of most general interest that came up for discussion related to reported departures from the National Electrical Code, of municipal codes for electrical inspection. In New York, for instance, a code is under preparation differing very materially from the National Code, and a committee of the association was appointed to confer with the municipal department on the subject. The National Code was prepared by delegates from the American Institute of Electrical Engineers, National Electric Light Association, Underwriters' National Electric Association, American Society of Mechanical Engineers, American Street Railway Association, American Institute of Architects, National Board of Fire Underwriters, National Association of Fire Engineers, and Factory Mutual Fire Insurance Companies, assisted by Kennelly and other recognized authorities. Municipal authorities who consider that they can improve upon the labors of such as these, and who are not content with fire protection that meets with the official approval of all underwriters, certainly do not lack assurance. Municipal inspection should, under any circumstances, be discouraged so far as relates to interior electrical work. The great interests the underwriters have at stake assure much more efficient inspection than can be expected from the usual city employe; and if, in addition, electrical contractors are to be harassed by having to comply with arbitrary code compilations of city electricians, a superfluity becomes an evil, which may develop into an intolerable one through the intrigues of politicians.

The Walker Company.—An important change has taken place in the ownership of the Walker Company, which recently passed into the hands of four men well known not only in the financial world, but also in public life—Ex-Governor Roswell P. Flower, Major J. W. Hinckley, Perry Belmont and Anthony N. Brady. Aside from the strength of the company financially under its new ownership, the fact that these gentlemen represent together electric railway interests aggregating $100,000,000, implies an assured market of no mean proportions for its manufactures. Prof. S. H. Short, remains as technical chief, which assures a continuance of the high standing of Walker apparatus. The growth in favor of Walker apparatus during the past few years has been so rapid, that at the present day its manufactures stand in reputation second to none, the name Walker being on a plane with that of the greatest of the electrical manufacturing companies, at home and abroad. This success has undoubtedly been largely due to the ability of Professor Short as a designer, coupled with a long experience in the electrical field, which has made him thoroughly conversant with all the practical and commercial problems involved in the production of electrical machinery. The new Walker alternator may be pointed to as an example of this union of qualities, the introduction of all the latest principles of alternating-current machinery design in this case not meaning an experimental apparatus, but a commercial machine fitted when placed on the market, for all the demands of practical service, however varied or severe. With its present strong financial backing, and with the technical policy of the old company continued under the new management, there is every promise of a development that will make the Walker Company an increasingly great factor in the electrical field.

Edison, Jr.—The son of Edison has entered the electrical field as an inventor, the first evidence of his inherited talent being an incandescent lamp, called the "Thos. A. Edison, Jr." which is claimed to be the most economical lamp thus far made. The filament, which is of the coiled type, differs in shape from other coil filaments in having three loops with a straight common axis. The young inventor, who has just attained his majority, says that to improve the incandescent lamp as he found it was necessary to increase the candle-power and efficiency, and also use a much higher vacuum in exhausting. To accomplish these ends without increasing the cost, he invented a new form of air pump, and uses a filament made of a chemical combination carbonized at 4000 degs. Fahr. The inventions and processes involved in the manufacture will not be patented, the young man believing that a patent furnishes no real protection.



Thomas A. Edison Jr

Transformers and Theorists. — Mr. James Swinburne, though considerable of a theorist himself in a non-mathematical way, has little use for theorists who deal in symbols. Writing of the transformer in the London *Electrical Review*, he says that by the time that apparatus was practically thrashed out and in general use, it was time for "so-called theorists" to tackle the subject. "Everyone, from those who just knew how to differentiate the sine and cosine with respect to the angle, up to some of the ablest mathematicians of the day, seems to have turned himself loose on the subject. The victim was attacked from two sides; one section of the invading force made clock-face diagrams, which were so absurdedly wrong in scale that they give no idea of what goes on in a transformer; and the others attacked it analytically, and wrote strings of equations. The transformers that were subjected to attack by analytical methods, generally had resistances, R and r, and self-inductions, L, and sometimes, L', and even mutual induction, M. They seldom had all these recommendations at once, and even now people will talk about the "self-induction of the transformer." I remember as late as 1890 trying to explain to a pure theorist that the transformer designers did not work in that way, and that none of my assistants would know what the self-induction of a transformer was. He said 'it is a shocking state of things.' So it was, but I do not know even yet what the 'self-induction of a transformer' is, and I fear I never will know. All these calculations, geometrical not to scale, and analytical with letters instead of numbers, have been almost absolute waste as far as information goes. They occupied a great deal of room in the technical papers, often involved very advanced mathematics, were generally considered very deep and learned by those who did not take the trouble to see what they were all about, and they must have been very expensive to print. The yearning for publishing elaborate calculations on insufficient or wrong data seems to be almost a disease. It is going on still." Referring to an investigation he made, which was later confirmed by Prof. Ryan, showing that the magnetizing current could not possibly vary harmonically—this, he says, "did not daunt the attacking force a bit, but only gave them more to work upon, for they seized upon Fourier's series and have reveled in it ever since. There are still papers and books coming out on the so-called theory of alternating currents, and multiple-current work has given it a new lease of life lately. As far as I known, it has never had the least influence on the design or manufacture of any practical electrical apparatus." Mr. Swinburne qualifies his remarks by saying that he does not mean that engineers do not make use of a certain amount of calculation involving harmonic currents and pressures, but that the elaborate and complicated calculations of theorists, with letters instead of figures, or diagrams not to scale, have been practically waste paper.

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED

Electrital Industries.

W. D. WEAVER, Editor.

Diagrams of Electrical Connections.

Beginning with this number, subscribers to the AMERICAN ELECTRICIAN will receive with each issue a supplement, consisting of a sheet of diagrams of electrical connections. The matter for the supplements will be prepared by Mr. Jos. Sachs, and will include diagrams of every kind of electrical connection met with in practice. The sheets will all be uniform in size and paged consecutively. A convenient portfolio for their better preservation may be obtained from the publishers.

◆

Electric Power.

The article printed elsewhere in this issue on the electrical plant of the American Lithographic Company, describes one of the most notable electric power factory equipments yet made, both with respect to extent and the thorough manner in which all of the details have been worked out. In this latter connection the plant is in striking contrast to many others, even of recent date, and, as an example of thorough electrical engineering, is decidedly creditable to Messrs. Ford & Bacon, under whose specifications the work was performed. It will be noted that the equipment is fireproof throughout. Iron-armored conduits are used entirely, and the construction is everywhere not only permanent, but essentially mechanical, this latter, in fact, being one of the notable features of the plant in in all of its various details.

No less than 141 motors are used throughout the building, and all are direct-connected, either to the larger machines or to the line shafting, in the former case excellent electrical provision being made for press control. Among other interesting points are the switch-board design, the details of the wire runs, of the distributing centers and of the cable runs in the generating room. The lighting by means of enclosed arc lamps has given particular satisfaction. Much of the press work of the establishment is in colors, and the distribution and character of the illumination is such that the pressmen are thereby enabled to mix and match their colors as if working in daylight. As to economy of operation, the data from carefully kept records show this to be extremely satisfactory, an electrical horse power at the switch-board being obtained on 4.45 lbs. of coal per hour, with a low load factor. In the mere item of coal alone, and aside from economy resulting from the enhanced quality and quantity of the output, the new plant has produced a saving of 44 per cent. over the former system of light and power supply. These figures speak eloquently of the advantages of electric equipment which, in all large establishments, will probably soon entirely displace the older, more expensive and less cleanly and convenient methods of power distribution.

◆

Polyphased Armature Windings.

In another column will be found an interesting article by Mr. J. P. Stone on the windings of polyphase armatures, which should go far toward dispelling the idea held by many that such windings are especially intricate. As will be seen, the Y-winding consists merely of two ordinary alternator windings in the case of two-phased machines, or three such windings in the case of three-phased machines. Two-phased windings are entirely disconnected on the armature, an analogy to such a machine therefore being two simple alternating-current machines with their shafts rigidly connected, and corresponding wires displaced with reference to the poles, by half the distance between poles. A similar analogy to a Y-wound three-phased machine would be three simple alternators with their shafts rigidly connected, with corresponding wires displaced a third of the distance between poles, and with three collector rings—one ring of each of the three pairs of rings—connected together.

The delta winding is merely the usual direct-current winding, tapped at four equidistant points for two-phased working, or at three equidistant points for three-phased working. As pointed out by Mr. Stone, the selection of either type of winding for polyphased machines is merely a matter of convenience. Where a neutral wire is to be run from a three-phased machine, the Y-winding must be used, the neutral running from a fourth collector ring being connected to the common point of the three windings. Such a neutral will supply three additional circuits of a lower voltage than that of the main circuits; that is, if the voltage between the neutral wire and the three main wires is 1000, the voltage between the three mains will be 1732. By placing three rings on the commutator of any direct-current machine, the rings being electrically connected to three equidistant bars, the machine will be a three-phased, delta-wound alternator, so far as generating alternating current is concerned.

◆

Alternating-Current Patents.

Three patents were granted on December 21 to Mr. Rudolph M. Hunter, of Philadelphia, which were heralded in the newspaper press as covering fundamentally the principles of alternating-current distribution, and the transformation from high to low tension and *vice versa*. The dispatch in which the information was given adds that should the Supreme Court of the United States uphold these patents, millions of dollars royalty must be paid under them by electrical companies manufacturing alternating-current apparatus. An examination of the patents, however, does not indicate that these comprehensive claims can be borne out. There are three patents, the earliest date of application being a division of an application filed in February, 1883; the drawing of this patent shows a telephonic arrangement, but the claims are apparently broad and intended to cover the transmission of electrical energy in general. The other two patents relate to the step-up and step-down systems with translating devices in parallel, the original application for these patents having been filed in 1887.

Mr. Hunter, whether justly or not, is widely known as a "paper patent inventor," and with no other evidence at hand than that presented by the claims of the patents here referred to, this designation would seem to be not far removed from the truth. There is nothing new in the transformer principle, which was embodied in the apparatus whereby Faraday demonstrated the principles of electro-magnetic induction. Almost a half century ago the principle of stepping up and stepping down voltages was described in a text-book—Hall's "Manual of Magnetism"—which has a number of illustrations showing how, by means of the induction principle, a low voltage may be transformed into a high voltage and *vice versa*. Berliner, in the first telephone patent issued to him, described the principle with reference to the telephone, his application being dated 1877. Rosetti in 1880 patented a similar electrical arrangement; and in 1881 English and French patents on step up and step-down transformers were issued to Deprez. In 1882 Gaulard & Gibbs gave a demonstration at Westminster Aquarium, of their series transformer system, from which time alternating current working may be considered to take its origin; and the Zipernowski-Deri patents on the arrangement of transformers in parallel date from about 1885.

If there is anything at all patentable in the alternating-current system of distribution, it would appear to be on the placing of transformers in parallel. Such a claim might possibly, however, receive no greater weight in court than did the Edison claim for the ordinary parallel incandescent lamp system of distribution. This is not the only series of patents issued to Mr. Hunter with apparently broad claims covering an entire art. It will be remembered that he also claimed to cover with patents many of the fundamental principles of electric traction. This claim, if patents were accepted at face value and not subject to adjudication, would probably have to be pronounced well founded. It is somewhat significant, however, that the company owning these railway patents has not made any use of them in the extensive litigation of the past several years which has resulted so disastrously to fundamental electric-traction patents.

The Past Year.

While the year 1897 has not witnessed any startling innovations in the electrical field, it has nevertheless been marked by solid achievements in almost every branch. The only new development heralded in a manner that brought up recollections of early years, was the Marconi system of wireless telegraphy. As pointed out in these columns, however, this so-called system contains no new elements, being merely an almost obvious practical application of the Branly tube and Hertz resonator. In electric lighting the most notable occurrence has been the definite triumph of the enclosed over the open arc. At the present time the enclosed arc may be said to have entirely driven out the open arc for constant-potential work, and has also recently begun to enter into use for out-door lighting. The past twelve months have also witnessed great encroachments by the alternating current in the field at one time thought by many to be peculiarly that of the continuous current, the recent action of several Edison Illuminating Companies in adopting alternating currents being a reversal of the policy of these former great champions of the direct current and low voltages.

Another notable advance in the central-station field has been the adoption by the larger companies of rational systems of charges, similar to that which Mr. Arthur Wright has advocated so successfully in England. As will be seen from a note in another column giving the latest tariff of the New York Edison Company, benefit is now given to the long hour user, the rate going as low as 3¼ cents per HP-hour where the consumption is large and distributed over many hours per diem. A reference should also be made to the enclosed fuse, which during the past year has been under process of development. As this type of fuse is claimed, and apparently with good reason, to obviate most or all of the serious defects with brought the open fuse into disrepute, the promise for its future is good. The electrical transmission of power has proceeded with steady strides during the year, the most notable plant being that now in process of construction at Massena, N. Y., and the transmission from Niagara to Buffalo One of the most notable features of the Niagara development has been the somewhat unexpected use to which the power there generated has been applied, and which has resulted in making Niagara a great center of electro-chemical manufacture.

The friends of the storage battery can look back upon a year of successful achievement, and congratulate themselves that at last this important auxiliary has had its merits generally recognized, and is now in a stable position with respect to the future. The many applications made for central-station use and on the distributing systems of electric railways during the past year and several preceding ones, have thoroughly demonstrated the claims that had been made as to its advantages for these purposes. The electric cab also promises to furnish another great opening for its application, as there appears to be no doubt as to the success of the experiments with such cabs during the past year in large cities. In machinery the most important event has been the adoption by the leading manufacturers of the inductor type of alternator, which promises before long to displace the older types of alternating-current machines.

The successful trial of the new Sprague multiple-unit system and its adoption for use on Chicago railways, were perhaps the most important occurrences of the year in the electric railway field. The year has also witnessed the passage of heavy railway electric traction from the experimental stage, and the astonishingly good results obtained on several roads will undoubtedly lead to very great extensions. The growing use of the rotary transformer in the distributing systems of electric railways should also be noted. There is little doubt but that this apparatus will before long be considered a necessary feature in every extensive distributing system.

In telephony the two events of most importance were the confirmation by the Supreme Court of the validity of the Berliner patent, and the organization of the independent telephone companies. The adverse decision of the Supreme Court has affected somewhat the spread of the independent telephone movement, and it is to be regretted that no effort has been made to bring the Berliner patent up for retrial—this time on its merits as an invention. In the general commercial field, there was a steady improvement during the year, and while business has not yet gotten back to its old basis, the advance over the several previous years has been quite marked, and the outlook for the future is bright.

CONSTRUCTION OF A THOMSON ASTATIC GALVANOMETER.

BY H. S. WEBB.

While the Thomson astatic galvanometer has been more or less superseded by the D'Arsonval instrument, it is, nevertheless, an excellent instrument for the detection of feeble currents where great sensitiveness is required. It is, therefore, used for null or zero methods, such as measuring resistance by the Wheatstone bridge; Rayleigh's and Bosscha's methods of comparing the electromotive force of primary cells; Thomson's method of comparing the electrostatic capacities of two condensers, etc. It requires, perhaps, more skill and patience on the part of the user, than the D'Arsonval, and cannot, like the latter, be so easily used in the neighborhood of dynamos or wires carrying strong and variable electric currents.

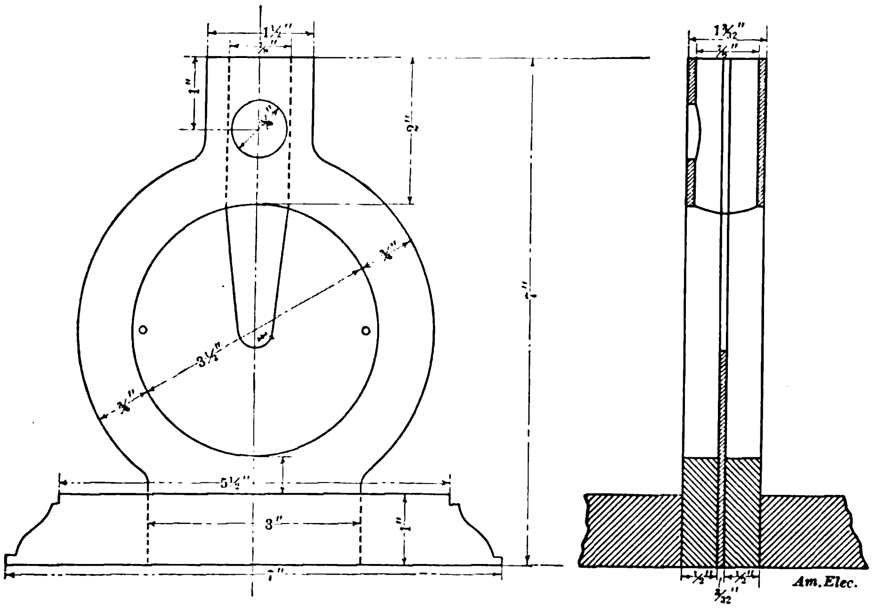

FIG. 1.—FRAME OF GALVANOMETER.

The galvanometer about to be described, has proved a very useful instrument for laboratory work and may be made very sensitive if desired.

The wood-work, as shown in Fig. 1, is made up of four pieces. Into the base is mortised and glued the upright portion, consisting of a thin central sheet or diaphragm, 1/16 in. thick, glued between the two cupcarrying supports. This thin partition holds the two coils apart and is cut away, as indicated in Figs. 1 and 2, to give sufficient room for the suspended system. A hole, 1/8 in. in diameter and 2 ins. deep should be drilled from the top, and another hole in the front, ¼ in. in diameter, as shown in Figs. 1 and 2.

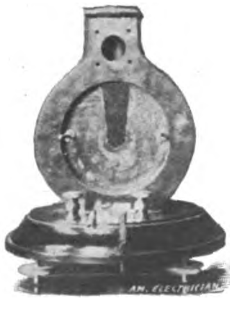

FIG. 2.

This front opening is to be covered with a clear piece of perfectly plane glass, ground round or square, as shown in Fig. 10. To make this glass fit air-tight and yet not break when the screws are tightened, put a washer of rubber, felt or chamois skin under the edge. Fig. 2. is a half-tone of a similar instrument after the two main binding posts, three leveling screws, two spirals of No. 26 silk-covered copper wires, soldered to the under nuts or washers of the binding posts, and two rods for holding the coil cups, have been put in place. Set the binding posts well apart and near the edge of the base to allow plenty of room for subsequently putting in place and removing the front coil cup. These cups should fit snugly into the uprights in order to be as air-tight as possible. Fig. 3. is a scale drawing of the wooden cups for holding the coils.

Well seasoned, hard maple is a very good wood to use and polishes nicely. The inside surfaces of the wood-work should be treated to a coat of shellac. To give the outside a fine polish, proceed as follows: After making the outside surface as smooth as possible with very fine sand-paper, coat it with hard oil. When perfectly dry, rub it down well with powdered pumice stone, using a soft rag and boiled linseed oil thinned with kerosene. Repeat this several times and, the last time or two, use powdered rotten stone in place of the pumice stone.

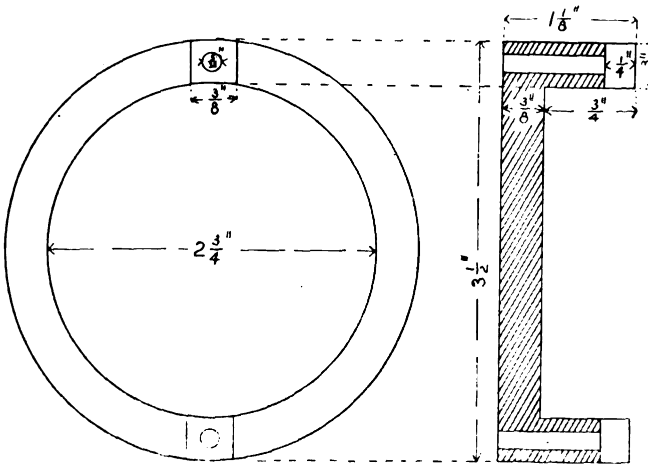

FIG. 3.—COIL CUPS.

Fig. 4 shows one of the leveling screws and Fig. 8 the tapped rod and nuts for holding the cups in place. There are two of these rods, threaded their entire length, eight washers, four small square nuts and four larger ones which show on the outside, (Fig. 11.) Fig. 2 shows how these rods are fastened in place by the small square nuts, one nut on each side of the thin partition.

Fig. 5 shows a form on which the coils are wound. The one from which this drawing was made was constructed of iron because a large number of coils were wound upon it, but, where only two coils, as in the present case, are to be wound, it could be made of some hard wood by slight modification. Before winding the coil, cover that part of the form which is to be filled up with wire, with two or three thicknesses of paraffine paper to facilitate the removal of the coil when finished. The wire coil should fill the form to within ¼ in. of the edge. To make a coil with a resistance of 200 ohms, making a 400-ohm instrument when the two coils are connected in series, will require about 13 oz. of No. 30 B. & S. double-silk-covered copper wire. By connecting the two coils in parallel, instead of in series, the galvanometer will have 100 ohms resistance. In winding these coils it is well to first wind on a single layer of No. 26 wire, to which the No. 30 is soldered, and to terminate the winding with a layer of No. 26. This protects the finer wire and furnishes a more suitable wire for making soldered connections to the binding post washers.

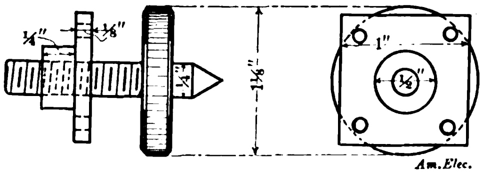

FIG. 4.—LEVELING SCREW,

In soldering wires and connections use resin and not soldering fluid, as the latter, unless completely neutralized and dried off, may later corrode the metal and cause trouble.

The coil, when wound, should be well treated with shellac and allowed to dry before attempting to remove it from the form. To do this, it is necessary to heat the form until the paraffine paper softens enough to allow the removal of the coil from the form. The shellac should hold the coil in shape. The ends of the coil are soldered to washers which are firmly fastened in counter-sunk holes in the inside of the wooden cup by the binding-post screws. After placing the coil in the center of the cup, pour a mixture of melted paraffine and resin into the cup, around the coil, to hold it there. Fig. 6 is a horizontal cross-section of cup and coil complete. Fig. 10 gives an inside and outside view of the same. When the coils are in place, the hollows at the centers of the coils should come exactly opposite each other and just above the bottom of the cut-away portion of the separating wooden partition in the middle of the upright supports, and the surface of both coils should press against this separating partition.

A more sensitive instrument, having the same resistance, can be made by winding the two coils as follows: Over a single layer of No. 26, wind 136 ohms of No. 36, heaping up the wire slightly toward the face of the coil which is to be nearest the needle—that is, on the side of the form where the conical spindle has the smallest diameter. Over this wind 52 ohms of No. 31, and finally, put on 12 ohms of No. 26.

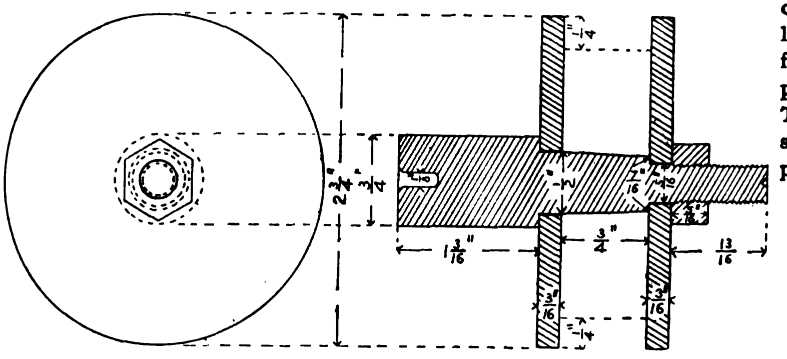

FIG. 5.—FORM FOR WINDING COIL.

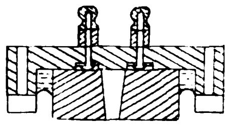

FIG. 6.

The two coils are to be so connected, when in series or parallel, by spiral wires running through and under the wooden base so that the current, flowing through both, will tend to deflect the needle system in one and the same direction; that is, one coil must not oppose the other in its action upon the magnetized needle. The proper ends should be soldered to the under part of the main binding-posts. Two main binding posts, similar to Fig. 14, and four smaller ones, for the coil cups, similar to Fig. 15, will be needed.

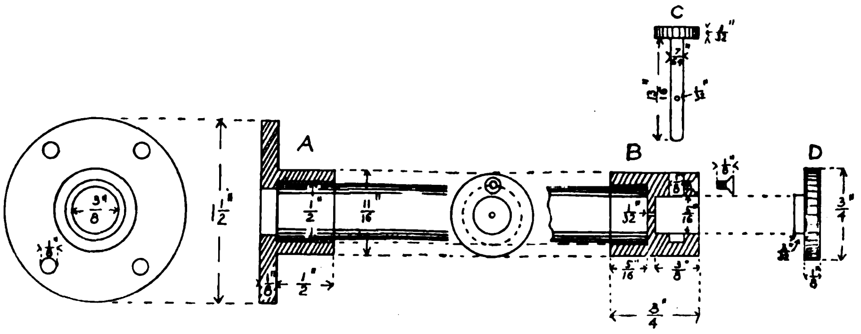

FIG. 7.—DETAILS OF SUSPENSION TUBE.

Fig. 7, shows two brass pieces which are to be connected by a stout piece of glass tubing, 6 ins. in length. The outside diameter of this glass tube should be enough smaller than ½ in. (the diameter of the hole into which it is to go), to allow a piece of chamois skin to be wrapped once around the tube and thus make the two ends fit snugly into the two brass pieces, *A* and *B*. In order that it may not turn, the bottom one is to be firmly secured, with shellac or LePage's glue, on both sides of the chamois skin; but the top piece of the skin is glued on only one side to allow the top brass piece to be revolved around the glass tube to remove torsion from the suspending fibre, whenever necessary, in adjusting the instrument to give zero reading. By using a longer glass tube and, consequently, making the suspending silk fibre longer, the sensitiveness of the galvanometer may be increased.

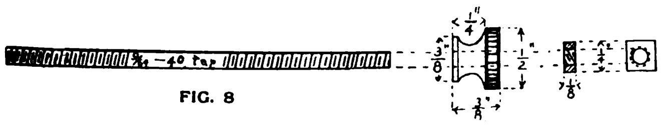

FIG. 8

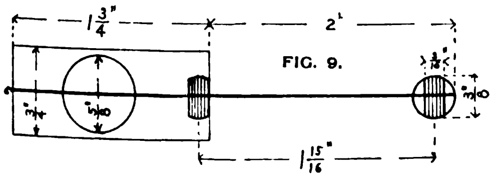

FIG. 9.

FIGS. 8 AND 9.—DETAILS OF SUSPENSION.

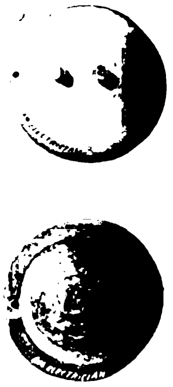
The bottom brass piece, *A* (Fig. 7), is fastened to the top of the wooden framework by four brass screws; but, between the wood and metal, a piece of felt is interposed. This is in the form of a circular disk of 1⅜ ins. external diameter and cut away at the center to allow passage for the suspending fibre. This felt serves two purposes: First, it prevents air currents passing through and disturbing the action of the needle system; secondly, it affords a means of adjusting the suspension tube into perfect alignment with the rest of the instrument by tightening or loosening the proper screws.

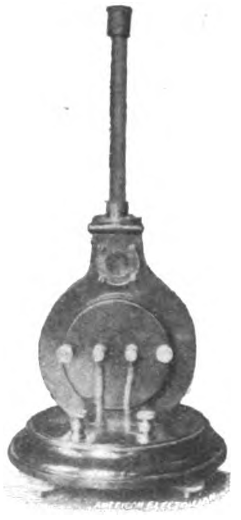
It is, perhaps, needless to remark that no iron in any form, except for the needles, must be used in the construction of this form of galvanometer.

The astatic needle system is shown in Fig. 9. It consists of a very thin, rectangular piece of mica, ¾ ins. × 1¾ ins., to which are fastened, by shellac, a plane glass mirror, from ½ in. to ⅝ in. in diameter, the upper set of steel needles, and a thin glass fibre about 1/50 in. in diameter. The object of the mica vane is to dampen the vibrations and help bring the needle system to rest and, for this purpose, it should be as large as the space, in which it swings, will allow. The space which contains the needle system and the silk suspending fibre should be made as air-tight as possible to prevent external gusts of wind or currents of air from entering and causing the needle system to vibrate and shake. When finished and set up ready for use, the mirror should come opposite the glass-covered hole in the front of the instrument. It is difficult to make a good mirror and is more satisfactory to purchase one from an electrical instrument maker. However, if the reader desires to make one, he will find the necessary directions on page 169, AMERICAN ELECTRICIAN of May, 1897.

The glass fibre, used to connect the lower set of needles to the mica vane on which the upper set of needles is fastened, must be perfectly straight and very light. By a little practice, a good one can be made from a small glass tube by heating it over a fish-tailed gas burner and drawing it out. Make a number of these and select the best one. To the top of this secure, by shellac, a minute hook made of No. 36 or No. 38 bare copper wire, and to the lower end glue a very thin circular piece of mica upon which is glued one set of steel needles. The two pieces of mica must be in the same plane. This needle system should be as light as possible (not over ten grains), to make its moment of inertia small. Other things being equal, the smaller this moment of inertia, the quicker it will come to rest.

The steel needles may be made from steel piano wire about 1/40 to 1/50 in. in diameter, or No. 8 guitar string. The temper should first be drawn and the wire straightened and cut into convenient lengths—about 6 ins. long. These pieces must then be tempered glass hard. This should be carefully done, as the entire piece should be of the same hardness. From this wire cut or break off twelve pieces of the proper length (as indicated in Fig. 9) for the needles and secure them in place with shellac, six above and six below, being careful to have a thin air space, about 1/50 in. between each needle, so that they will not touch each other.





FIGS. 10 AND 11.

The best way to magnetize the needles and obtain an astatic system,—that is one set magnetized equally but oppositely to the other,—is to magnetize the set by an apparatus shown in Fig. 12. *A* and *B* are soft-iron rods, $\frac{7}{16}$ in. in diameter. *C* and *D* are soft-iron pole pieces between which the needles to be magnetized are placed, as shown. *G* and *H* are two coils, each consisting of 350 turns of No. 18 B. & S. copper wire. The coils must be connected in series so that the magnetic flux produced by each will produce poles, as indicated in the figure. The trough is merely a variable liquid resistance containing some liquid, such as salt water or a solution of washing soda, and two metal plates or electrodes, one of which can be moved from one end to the other, so that the current may be varied from 0 to about 5 amps. Any other convenient variable resistance which will do this may, of course, be used.

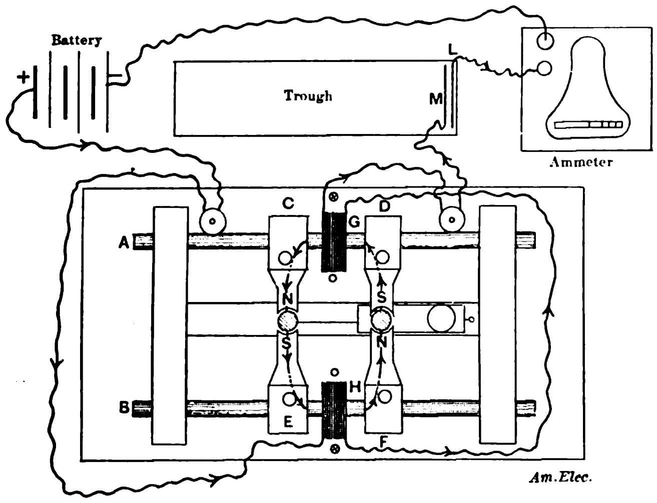


FIG. 12.—METHOD OF MAGNETIZING NEEDLES.

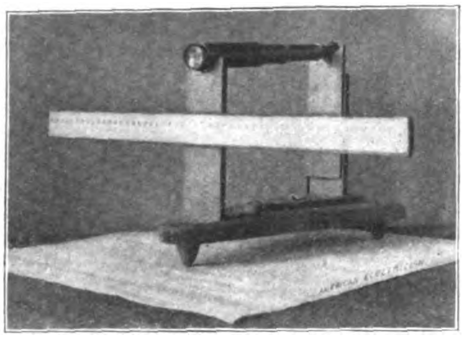

FIG. 13.—TELESCOPE AND SCALE.

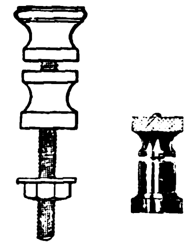
After making connections and adjusting the strength of the solution so that the proper current can be obtained, place the needles between the pole pieces, as in Fig. 12, and put on the full current of 5 amps. and then gradually and slowly reduce the current to zero. Repeating this process several times should magnetize the needle sufficiently, and, if the steel was properly hardened, they may never need remagnetizing.



FIGS. 14 AND 15.—BINDING POSTS.

For suspending the needle system, get a single fibre of unspun silk at least 10 ins. long. To remove all initial torsion, hang this up for a day or so, having fastened to its lower end a small weight of non-magnetizable material, such as a brass screw. Pass this silk fibre through the $\frac{1}{32}$ in. hole in *B*, Fig. 7, and secure one end to *C*, by tying it through the $\frac{1}{32}$ in. hole in that piece. One of the coil cups being removed, work the free end of the silk fibre down through the glass tube. Fasten this free end to the small hook on the upper end of the needle system with shellac. When the shellac is dry, wind up the fibre on *C*, until the lower needles hang in the center of the coils. Then level the galvanometer until the lower needles hang midway between the two coils and turn perfectly free. Replace the coil cup, and if properly leveled, the needle system should still vibrate free and smooth. It will depend upon the resultant polarity of the astatic system whether the instrument should be set facing East or West. This can only be determined bytrial.

If a plane mirror is used, a telescope and scale for observing the deflection of the needle system is more convenient than a lamp, scale and lens. A telescope, suitable for this purpose, can be purchased for $1.80 or less and a one-half meter scale on cardboard can be obtained for twenty-five or fifty cents. If a terrestrial telescope is used, it may be greatly improved, for this purpose by removing the set of rectifying lenses, in which case the figures on the scale must be reversed and inverted. Fig. 13 shows a suitable stand, for this purpose, which may be easily made. It is customary to place the telescope and scale just one meter from the mirror. The rear support for the telescope and the board upon which the paper scale is fastened are arranged to slide up and down for adjusting. The scale should be as much below the level of the mirror as the object glass of the telescope is above it.

Quite a number of galvanometers of the above type with the telescope and scale have been in regular use in the electrical laboratory at Lehigh University for the past two or three years. We have also a number of four coil galvanometers of a similar design, whose resistances run up as high as 5000 ohms, but for general use the two coil instruments are sensitive enough. Considerable of the work on these galvanometers was done by students taking the electrical course during their third year.

◆

Permanent Magnets.

In experiments made by Preece on different kinds of magnet steel, it was found that steel of the best magnetic quality would retain as high as 2540 lines of force per square centimeter; ordinary steel retained from 1100 to 1700 lines. The working density of wrought-iron and soft steel is about 15,000 lines, and of cast-iron, about 9000 lines per square centimeter, which numbers will serve for comparison.

PRINCIPLE OF THE WHEATSTONE BRIDGE.

Owing to several typographical errors in letters of reference, a note on the principle of the Wheatstone bridge which appeared in the December issue in answer to a query, is here reprinted with the necessary corrections.

To better fix ideas, we will take electric-light currents and voltage, as indicated in the diagram below. If no current flows through the galvanometer circuits, *B D*, it follows from Ohm's law, $C=\frac{E}{R}$, that, the current in *A B C* is $110 \div 55 = 2$ amperes; similarly, the current in *A D C* is $110 \div 110 = 1$ ampere. The drop ($E = C R$) from *A* to *B* is therefore $2 \times 45 = 90$ volts, and from *A* to *D* is $1 \times 90 = 90$ volts. Consequently, the drops to *B* and *D* being the same, the potentials at those points will be equal, and no current will flow through the galvanometer, *G*. That is, it will be seen that when $a \times d = c \times x$, the bridge is balanced. This may be expressed,

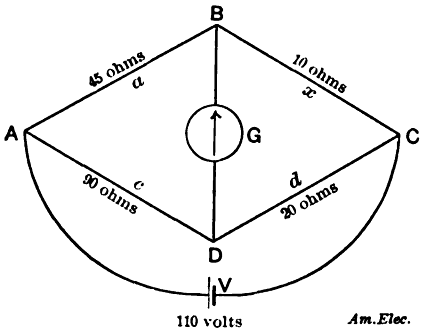


FIG. 1.—DIAGRAM OF WHEATSTONE BRIDGE.

$$x = \frac{d}{c} \times a.$$

In practice, the resistances of the two arms, *c* and *d*, are fixed in a certain ratio for a given measurement (in this case, 20 : 90, but usually as 10 : 100 or a multiple of 10), and the value of *a* is then varied until a balance is obtained.

A plan view of a commercial Wheatstone bridge is shown herewith, having the parts lettered to correspond to the above diagram, *x* being the resistance under measurement. In this case, *c* is the left hand part of the upper row, *d* the right hand part, and the two lower rows correspond to *a*, If *c* were plugged for 1000, and *d* for 10, and if 1425 plugged in *a* brought a balance, then the value or *x* would be 14.25 ohms. As the above type of bridge is actually made, the *withdrawal* of plugs throws in the resistances.

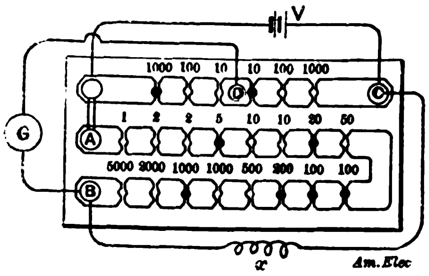

FIG. 2.—WHEATSTONE BRIDGE.

ELECTRIC RAILWAY PRACTICE.

BY EUGENE C. PARHAM.

INSTALLING A TRIAL EQUIPMENT.

Having considered in a previous article, complete in itself, and under the same heading, the precautions to be observed in equipping a truck, and having pursued the course of car wiring from the trolley wheel to the hood switches, we resume our discourse at the point where these important devices become active.

The hood switches are provided as a means of breaking the circuit should accident disable the controller; hence are safety devices. They are also used to "deaden" the motor circuit for working purposes, when pulling down the trolley would put out all lights. These switches are placed in the hood above and a little in front of the motorman's head, and must be so hung that the handle, when "on," can, by the most involuntary motion, be thrown "off." If it is mounted on its board before being hung, unless some thought is used, it will go up backward. The screw holes in the board are laid off, bored, and countersunk; the board is then screwed to two of the hood ribs, the screw heads puttied and the whole painted. The switch is then placed.

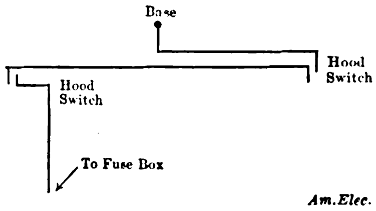

FIG. 1.—SWITCH CONNECTIONS.

We next wire the roof; this consists in running a wire from the base through the switch on one end to the switch on the other, as shown in Fig. 1. The second switch reached will be regarded as on the front end of the car. If the base is not provided with a terminal, the wire must be secured between two washers on one of the base bolts, from around which all paint has been cleaned. Leaving the base, the wire hugs the deck to the end, bends under to avoid the deck sash, runs along the hood to a point just over the switch terminal, and goes through a hole bored to receive it. From the negative terminal a second wire passes up to the hood roof, runs along to the side of the deck and hugs this to the other end, where, as before, it passes through the hood to the rear switch. The wire is held by wood, canvas or leather cleats, and is painted the same color as the car roof. All holes are stopped with putty and a coat of stiff paint. It is a good idea to mark the positive switch terminals, as it saves time when it is desired to connect in instruments. We now pass to the car floor.

On new cars a wire is found sticking out of one side of one of the hood roofs; the other end of this wire sticks through the floor just under the bulkhead. If this wire is missing, or if it is necessary to replace it with a larger one, proceed as follows: On a closed car having swinging end windows, a special moulding between the bulkhead linings conceals the wire, and this moulding must be removed. On an open car the wire runs in a groove in the window post, whose moulding must be removed to show the groove. Passing down the bulkhead, the wire goes through the car floor and connects to one side of the fuse box, which is generally placed on the outside platform stem just behind the car step.

The next device to place is the lightning arrester, of which there are so many types, calling for different conditions, that its position cannot be generally defined. The important condition to fulfill is that the lightning arrester and fuse box connect by a *straight* wire. Some wiring diagrams show the arrester to be tapped on the trolley wire before it enters the fuse box, and others show it tapped on afterwards; neither seems to affect the arrester's efficiency. Fig. 2 shows the latter connection. This completes the wiring up to the point where the controllers are active, and it is well now to place the controllers and resistance to facilitate the laying out of the cables.

The controllers go on the platforms, and are so placed as to be conveniently operated by the left hand, while the right retains a hold on the brake handle. The motor cables pass up to the controller through holes bored in the car floor. In standing the controller up to lay out the position of the cable holes and holes for the bolts or lag-screws which fasten it to the floor, the following must be observed·

The controller must stand out from the dash rail to allow a motorman's gloved hand to clear the vestibule; all controllers must be placed alike, so that a single pattern of dash-rail angle-iron will serve as a model for making any number of them; the cable holes must not be bored through an end sill or platform stem and the cable must clear the coupling bar, sand box, snow-scraper, gong and brake rigging. Lag-screws are preferable to bolts for fastening the controller to the car floor, because in case of an end-on collision, the lag-crews give and save the controller.

Before finally placing the controllers it is well to test them for grounds. On single-shop. This consists in cutting the wires to reach from one controller to the other and in splicing on the taps to receive the motor leads, etc. If the wires are cut 5 ft. longer than the distance from one controller to the other, they will do for any controller now on the market. Fig. 2 shows a cable made for a car 29 ft. over all and 26 ft. between controller centers. The wires were cut 31 ft. long, and 6 ins. were lopped off each end. The wires cut, they are sorted into two bundles to be run in separate hose on opposite sides of the car. The trolley-resistance, and trolley-motor wires run in one hose, the ground and ground-motor wires in the other.

There may be three sizes of wire used in a motor cable; on a 30-HP equipment the trolley and ground wires are generally No. 4 B. & S. rubber-covered cable; the motor wires and the highest numbered resistance wire. No. 6 rubber-covered solid wire, and the remaining wires a No. 7 or 8, according to the service. The wires are to a degree distinguishable by their size. Fig. 2 shows a cable of 13 wires, 9 of them trolley, Nos. 1, 2, 3, 4 resistance and motor No. 1 wires go in No. 1 hose; motor No. 2 wires and the ground in hose No. 2.

The two sets of wires are drawn through their respective hose and tagged. The trolley and ground are tagged, for should they become interchanged on both controllers, the result would be not only to oppose the weaker parts of the controller insulation to trolley potential, but to render the motor cut-outs useless under certain conditions liable to obtain. We next select a No. 6 wire and tag it, say, plus field; the other end is found by pulling the wire and is tagged minus field. Selecting another No. 6 wire, it is tagged plus field and its other end minus field. The idea in making the ends of the same field wire of opposite polarity is to have the motion of the car obey the reverse switch indications on both ends. Either the field or armature wires are marked reversely. but not both; all other

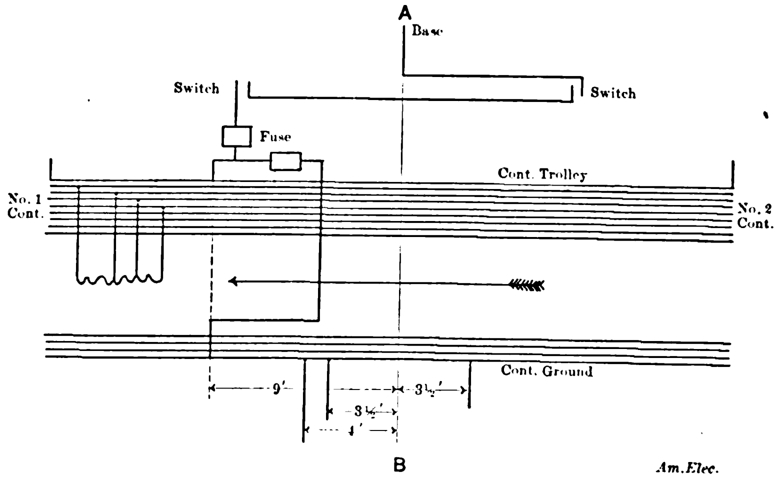

FIG. 2.—MOTOR CABLE.

The next step is to make up the motor cables, if they have not been sent from the end cars the resistance coil is put under the front end to economize on wire, but on double-enders it is immaterial under which end it goes, so long as it is on the same side of the car as the resistance cable. It is a simplifying convention to put the No. 1 end of the coil towards the front of the car.

wires are tagged the same on both ends and as blue print calls for.

The wires all tagged, they are pulled even and so that they protrude 9 ins. beyond the hose on both ends. The hose is straightened and its center and ends plainly marked on the floor, and the center marked on the hose. In all subsequent measurements the centers must coincide. In fixing the points at which the wires are to be tapped, the center line, *A B*, of car, truck and hose is used.

Now, to proceed with the splicing, begin with the trolley wire. The distance from *A B* to the fuse box is 9 ft., so that 9 ft. from the hose center and towards the front end, we cut the hose open and splice onto the trolley wire, a wire of the same size long enough to reach the fuse box. Taking the ground wire next, we see it must have four splices—one for the arrester, 10 ft. front; one for the ground-motor armature lead, 4 ft. back; and a ground wire for each motor frame, 3½ ft. ahead and back of the center line. The rest of the wires have each one splice, to be made opposite the device to which it goes. Splices should never be made alongside of each other, as there is some danger of abrasion. To identify any wire to be spliced, it is only necessary to pull one of its tagged ends and observe it move where the hose is split. As soon as the tap is spliced, it receives a tag similar to that on the wire to which it is spliced.

The splices are made as follows: The cable wire is skinned about 4 ins., and the tap about 10 ins.; both are well cleaned with sand-paper; by means of a pair of connectors and pliers the tap is snugly twisted around the hose wire. If the taps are of stranded wire, the strands are separated, straightened, cleaned, made into two bundles and one bundle twisted to right, the other to the left around the hose wire. When all the joints are made, they are well cleaned with acid and soldered. This is best done by melting solder in two ladles and pouring from one to the other over the joints. If both ladles are heated, the solder does not cool so rapidly. Cooling solder should not be poured, as it forms snags which may pierce the insulation. No molten solder must be allowed to run down into the hose. All splices should be tried for rigidity and inspected for snags and, if necessary, dressed with a file. They may then be given a layer of okonite, two layers of black Manson and a coat of shellac.

The wires are then pulled straight and even and the hose adjusted. A piece of rubber hose, 1 ft. long and split 2 ins. on one end, is slipped on every tap except the trolley tap, so that the two split ends enter the hose and lap around the cable wire. The jaws of the opening in the canvas hose are then drawn together and well taped, after which the hose is given two coats of thick asphaltum and hung up. When dry, it is ready to go under the car. The hose is strapped up by means of leather or canvas straps to the intermediate sill just inside the wheel boxes.

In placing a hose, sight must not be lost of the fact that upon receiving a load the car body lowers three or more inches. Before the hose is tacked up, its center is drawn immediately under the center line of the car, and if a good job has been done, every tap will fall opposite the device to which it connects. The easiest and quickest way to hang the hose is to first tack up one end of all straps along the route selected, poke the two ends of the cable up into the controllers, then begin at the center and work towards the ends; swinging the hose into place, strap by strap, straight and taut and avoiding kinks and corners. If the car is a closed one and the railway people insist on having the cable run under the seats inside the car, the wires and hose must be cut 4 ft. longer. In this case both cables are run on the side that does not contain the stove, and pass to the under side of the car through two holes bored for that purpose under the seat and up as near as possible to the bulkheads. The hose need not be painted except where it runs underneath the car. To place it, it is taken inside the car and its center fastened over the center of the car. The two ends are then passed down through their respective holes.

When wiring a car having radial trucks, care must be had that the hose is placed where the car wheels cannot reach it when turning a curve. Also the motor taps must be left long enough to allow for the displacement of the motors. When a brake is put on the brake rods rise, and all wires must be well out of their way.

The hose swung, the body is lowered and bolted to the truck. The hose is rung out with a magneto and all connections temporarily made; the controller wires are cut off, skinned and put in permanently, except the field wires, which are left long enough to reverse should it be necessary to do so. The trolley is now put on and the lamps should burn if the lamp circuit is all right. If they do not burn, try the test lamps; if they burn, put in the hood switches and try the motors one at a time.

Should both motors run in the same direction and according to the indication of the reverse switch, all connectors can be permanently made. Leads that are a little long can be given a few turns around a screwdriver handle. They are then skinned, dipped in solder, and connected to the cable by means of two-way connectors. As the resistance coils, fuse box, etc., have terminals of their own, they require no terminals. The trolley wire, wherever exposed beneath the car and where it comes up into the controllers, is encased in soft-rubber tubing like that used on the taps. The canvas hose is brought well up into the controllers and its ends are closed with tape and paint.

It was intended that this article should include a consideration of the lighting and heating circuits, as well as a dissertation on lightning arresters, their connections and principles; but this will be deferred to a future article, which will resume where this article leaves off, and take the reader out on the car's trial trip.

◆

HANDY TOOLS IN A GENERATING STATION.

It is often extremely convenient in power house manipulation to be able to make substantial temporary connections on the switchboard promptly, and such connections may be utilized for many purposes; for instance, an engine may get stuck on a dead point, and a little current turned into the generator would assist wonderfully in turning it over. It is easily possible, where an engine is connected to a pair of generators, to drive one very slowly as a motor, and thus obtain the required speed for turning down the commutator of the other machine.

It may be desirable to take current from the switch-board for many other purposes. Nothing is more convenient in making such connections than a set of jumpers which may be fitted into the switch-jaws and led off in any direction. Sheet-copper of proper thickness should be cut into a shape like that shown in Fig. 1.

The sharp shank, *A*, may be fitted into a handle. The broad flat piece, *B*, should be filed with the edge, *x y*, on a double bevel, as shown in the section, so that it may be easily driven into the switch-jaw. Care must be taken that the thickness of this copper does not exceed that of the switch-blades, for otherwise the jaws would be spread and the good contact of the switch destroyed. The lug, *D*, should be wrapped about the end of the cable, which leads away the current, and should be generously soldered thereto. It is easy to see that a number of such devices will find a use; some should have switch-jaw plugs at both ends, while others would be more convenient if one end only were so provided, the other being adapted to connect in the binding posts of a measuring instrument or a similar device.

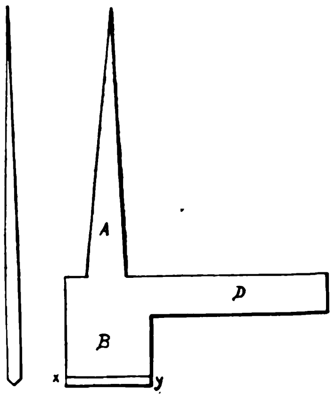

FIG. 1.—JUMPER.

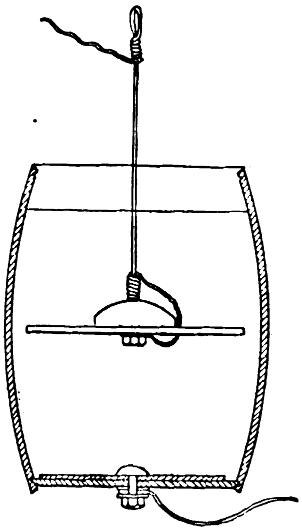

FIG. 2.—WATER RHEOSTAT.

One of the most convenient devices about the power station, is the water rheostat. It is almost as handy as a pair of pliers, and will serve almost any purpose. It is essentially necessary whenever a *little* current is required to be drawn from the mains.

If, for instance, it were desirable to turn over one of the machines as a motor, if the main switches consisted of two single-pole switches, as they should, it would be the easiest matter imaginable to bridge one of the switch-jaws with the water rheostat, by means of a pair of jumper connections described in a previous paragraph. By manipulating the rheostat, the current which the machine received could be varied at pleasure. Indeed, without an equivalent device, the operation would be an impossible one.

For testing arc lamps, shunting circuit breakers, operating railway motors for temporary power, and similar devices, the water rheostat finds a use. Its most convenient form is a barrel, arranged as in Fig. 2. It should be placed out-doors, for the reason that the boiling and bubbling causes offensive fumes. The lower plate is preferably connected to the wire which passes through a water-tight joint in the bottom of barrel.

A good arrangement is to bolt an iron plate, ¼ in. or ⅜ in. thick, to the bottom of the barrel, the bolt being very tightly fitted to the holes in the first place. An additional security against leaks is provided by painting the bottom of the barrel and the interior of the bolt holes with very thick asphaltum. The lower wire should then be secured to one of the bolts by appropriate washers, and setting up the nut tightly compresses the joint together.

A most convenient terminal for letting down into the barrel may be made of an ordinary hitching weight, to the bottom of which a circular ¼-in. plate is tightly screwed. These screws should be at least ⅜ in. in diameter. A large ½-in. cap-screw in the middle is very satisfactory.

The wire connection should loop about the staple, in the middle of the hitching weight, and return on itself a number of times, and then pass through the plate and loop about one of the screws, holding the latter in place. A good strong wire should be selected.

The wire should be the sole support of the weight. If it should break and allow the latter to fall, the circuit would be automatically opened, which would not be the case if the weight were supported by a rope, and the wire merely the flexible connection. The latter connection in the matter mentioned, would cause a serious short circuit.

The lifting of the weight should be accomplished by means of some arc-lamp cord passed over pulleys and wound up on a ratchet reel, such as is common with arc-lamp out-riggers.

This ratchet reel should be within convenient reach of the switch-board attendant, and, of course, the terminals of the rheostat should be conveniently at hand for any connection that may be desired.

The barrel should be mounted on a pair of beams, so as to clear it from the ground, and it should be filled with water, acidulated with 6 oz. of sulphuric acid. The exact amount of acidulation is best determined experimentally. The greater the acidulation the lower the resistance will be, up to a certain point.

A bung should be provided in the bottom of the barrel by which the water may be changed, if it is desirable to change the resistance, and the barrel located conveniently near a tap, so that it can be filled by means of a length of hose.

If these directions are carefully followed out, the result will be of a permanent character, and will be found to be highly satisfactory. Such a rheostat ought to absorb, without very much trouble, 30 or 40 HP.

REPAIRING A "BURNT-OUT" COMMUTATOR.

BY NORMAN H. CROWELL.

If the dynamo-tender understands his business and has suitable instruments at hand, it may be but a matter of a few minutes' time to discover the cause of a "break-down" and set about its repair. If, however, he happens to be a good steam engineer, but a novice at the practice of the electrical art, and tends dynamo by "throwin' her in gear" and trusting to luck, he may as well sit calmly down and wait for reinforcements.

Under the supervision of a competent electrician, a serious break-down is of rare occurrence. There can be little trouble with the machine with a firm foundation, steady power, tight screws, evenly ground brushes, and the constant application of a good big "rag" to the parts where dirt, grease and copper dust collect.

In the case in hand the dynamo had gone on for months grinding out its existence with no attention from the tender. He never knew whether the brushes bobbed, the commutator cut or sparked, or where to oil the journals. This state of things could not continue long without something giving way, and the lights suddenly winked out one night leaving Mr. Engineer "up a stump."

By the aid of a dim and flickery lantern we hastily inspected the dynamo, field magnet, wall attachments, ground wire and even the friction clutch. As far as could be seen everything was tight and in order. Now we must roll up our sleeves and hunt for the "trouble." A small boy eagerly grasps the opportunity to turn the "magneter" handle while we poke around feeling for shocks, and we find a good many.

Everything is found all right until we test the exciter, and here we find a grave condition of things. By placing one wire against a segment of the commutator and the other firmly against the end of the armature shaft, we get a merry tinkle from the bells. By testing the segments one by one we discover that about every third one is in connection with the shaft. We have located the difficulty, and now proceed with the treatment.

We first remove the armature from its chamber and by testing it again we prove our theory to be the right one. Then we make out a little list of articles needed and send the small boy away with it. The list reads as follows: Twenty pieces of heavy mica, 4 × 5 ins.; can of shellac and brush; strip of heavy duck cloth 6 ins. wide; needle and saddler's thread.

While he is in quest of these things, we place the armature in the lathe to facilitate matters and unscrew the burr that holds the cap over the ends of the commutator segments. Next, we remove the "cap," and the cause of the short-circuit is visible to the eye. In several spots the thick mica layers are charred through and when we peel them off we find the copper has a "worm-eaten" appearance.

Take a flat file and cut through the band of wires about the armature head. If the cover is badly worn or torn, file both bands and take the cover off entirely, saving the eyes for use on the new cover. This exposes to view the twenty pairs of wires leading from the armature to the lugs of the segments. Now comes the delicate task of spreading the segments. It is delicate for the reason that they are worn to the thinness of an ordinary pasteboard and require careful handling. However, by pulling gently with the pincers they are lifted from their bed and the charred insulation is scraped and blown away.

At this point, we test the connections between the armature wires and the lugs and find them good. Now carefully inspect the insulation of the base-cap, and if you find it unimpaired, proceed to the laborious task of cutting the mica into strips.

These strips we make ½ in. wide, 4 ins. long, and cut one end off at an angle of 45 degs. Care must be taken to keep the mica from flaking, otherwise you will be greatly hindered in the work to follow. After enough strips are cut, we lay them in a place convenient to our reach and turn our attention to the dismantled commutator. Make sure that no small pieces of insulation adhere to the segments, and then carefully return them to their original position. Slip a heavy rubber band over their base to keep them in their place.

Now we insert the shaft in a vise, with the commutator end uppermost, giving us the most convenient position for handling the ticklish job we now undertake. The next step is to put a strip of the mica between each segment and its fellow, making sure that the pointed end fits the V-shaped recess in the base cap closely. Take a strip and swab it with shellac, then gently pry two segments apart and slip in the strip. The job increases in difficulty as it nears completion.

A small wooden mallet may be used to tap the strips down into place, and this is the place to exercise patience as long as possible.

Now, with the task half done, the mica strips stick out ¼ in. from the normal surface of the commutator, and should project at least an inch beyond the ends of the segments. The ends that thus project are now carefully clipped off close to the segments with a pair of sharp shears, care being taken to make good, clean cuts. When this is done, drop the mica ring behind the strips to hold them from the shaft. Now take an extra thick and fine sheet of mica, and cut out a circular piece with a hole in the center. This is to take the place of the old insulation on the "cap," and must fit accurately, and be thick and solid.

Fit this ring to the cap and put the cap on the shaft in position. Now start on the burr. Unless you have access to a special vice for holding the cap firm, it will be very liable to turn, thereby twisting the segments out of position and perhaps destroying the insulation. This must be avoided, but the burr must be set on so tightly that there will be no probability of its loosening, although the direction of the armature's rotation may tend to unscrew it, which is unfortunately the case with many machines.

With the cap and burr in place, we proceed to remove the superfluous mica that confronts us. This is done best with a very sharp knife point. When the most of it has been cut and pared away with the knife, take the file and finish it.

Now, if you have succeeded in getting

the commutator round or approximately so, you may be assured that your job has been well done, but if it presents an oval shape or a very uneven surface, you will probably have the pleasure of going over the whole process again. If it is oval the brushes will bob and dance until the bulging part wears thin and caves in. If uneven, the chances are that it will not permit lathing, and you may have to loosen the burr and spend an hour adjusting it. The commutator should be so nearly circular that a small amount of light filing will complete it.

Having removed the rubber band, you are ready to put on the drum or canvas coating on the armature head. It is a good idea to have some one who is handy with tools attend to the making of a duplicate of the old cover, which is a simple matter, while you are engaged on the other work. Wrap the cover tightly around the head and sew with the saddler's thread. Put on a liberal coat of shellac. Then cut some long strips of medium thin mica to support the band wires. Next wrap some No. 16 (B. & S.) wire around the edge of the drum over the strips of mica at a strong tension. Make a band about ½ in. wide and solder in several places. Care must be taken that no part of the cover or solder bulges out so that it will touch the chamber when the armature is placed in position.

Now everything is completed, and you are ready to slip the armature back into its chamber, adjust the brushes and start up. It will take a minute for the magnet to pick up, but if you have been thorough in your work you will have the satisfaction of seeing the pointer begin to dance, and when you turn the handle, realize that you have saved your company time as well as expense.

◆

AMERICAN TELEPHONE PRACTICE.

THE MULTIPLE SWITCH-BOARD.

BY KEMPSTER B. MILLER.

When the number of subscribers in an exchange exceeds 500 or 600, the switch-boards so far considered, become inadequate; for in order to afford room for the number of operators needed to properly handle all the connections, the board must be made of considerable width, and is thus too wide for the operators to reach across them with their cords.

The multiple switch-board, which is designed to enable each operator to make any connection required without the aid of any other operator, and without the use of unduly long cords, is used in most of the large exchanges in this and other countries. The idea underlying the construction of multiple boards is very simple. In practice, however, the greatest complexity is met, but this is due entirely to the great number of repetitions of one comparatively simple circuit.

The boards are divided into sections, each section usually affording working room for three operators. Each line, instead of being provided with a single spring jack or terminal, as on the boards used in small exchanges, is provided with a spring jack on every section of the board, and with a drop or other visual signal on one section only. Each section, therefore contains a spring jack for every line entering the exchange, and also a number, usually 200, of line drops. Suppose an exchange to have 300 subscribers. The multiple board would then probably have 15 sections, each containing 3000 jacks, that is, a jack for each line. Each section would also contain 200 drops belonging to the 200 lines whose calls would always be received on that particular section. An additional jack, called an answering jack, is usually provided for each line on the particular section at which that line's drop is located. These answering jacks are placed in a separate panel at the lower part of the switch-board.

Before considering any particular form of multiple board in particular, it is probably well to describe in a general way the operation of the multiple board. When a subscriber calls the attention of the operator at whose section his drop is located, the operator plugs into the answering jack, of that line with an answering plug, and having switched her telephone into the cord circuit of that plug, ascertains the number of the subscriber desired. She then completes the connection with the subscriber called for by inserting the calling plug into the multiple jack of that subscriber's line, one of which is, of course, on her section.

As each section contains one multiple jack, for every line in the exchange, it is evident that an operator will always be able to complete a connection with any subscriber who may be called for by any of the 200 subscribers whose drops are located at her section. During the least busy portions of the day, one operator at each section usually suffices to handle all of the calls originating at that section. As the number of calls increase, two operators may be placed at each section, and during the busiest part of the day three are usually required.

When three operators are seated at a section, the center one can reach all of the jacks on the section at which she works. The operator at her right cannot well reach the jacks on the extreme left hand portion of that section, but she has within her reach a similar portion of the section at her right into which she may plug when necessary. In a similar manner, the operator at the left cannot well reach the jacks on the extreme right of her own section, but can reach with her left hand the jacks on the extreme right of the section at her left. Thus every operator has a multiple jack for each of the entire number of lines within her reach, the right hand operator controlling the right hand two-thirds of her own section, and the left hand one-third of the section at her right; the center operator controlling her entire section, and the left hand operator controlling the left hand two-thirds of her section, and the right hand one-third of the section at her left.

In order to prevent two or more connections being made to one line at different boards, some sort of a test system is necessary. It is therefore usually provided that when a line is "busy" that is, when it is connected to some other line for conversation—that an operator at some other board than the one at which the connection is made, in trying to connect another party to that line, will in some simple way be notified of the fact that that line is already busy. This is known as the "busy test" and on its efficiency to a great extent depends the operativeness of the multiple board.

In the accompanying figure is shown diagrammatically three lines passing through three separate sections in a multiple board. One side of each line—for instance, of line 1—passes in multiple to all the contact rings, *b*, of a jack on such section. It then passes to one terminal of the line drop, d^3. The other side of the line passes to the spring, *a*, in the jack belonging to that line at section 1. This spring rests against an anvil, *c*, to which a wire is connected which runs to spring, *a*, of the jack belonging to that line on the second section. The anvil from this jack is connected to the line spring, *a*, of the jack on the third board, and so on the connection of the line is continued through a jack on every section and finally to the other terminal of the drop, d^3. Lines 2 and 3 pass successively through the sections in a similar manner.

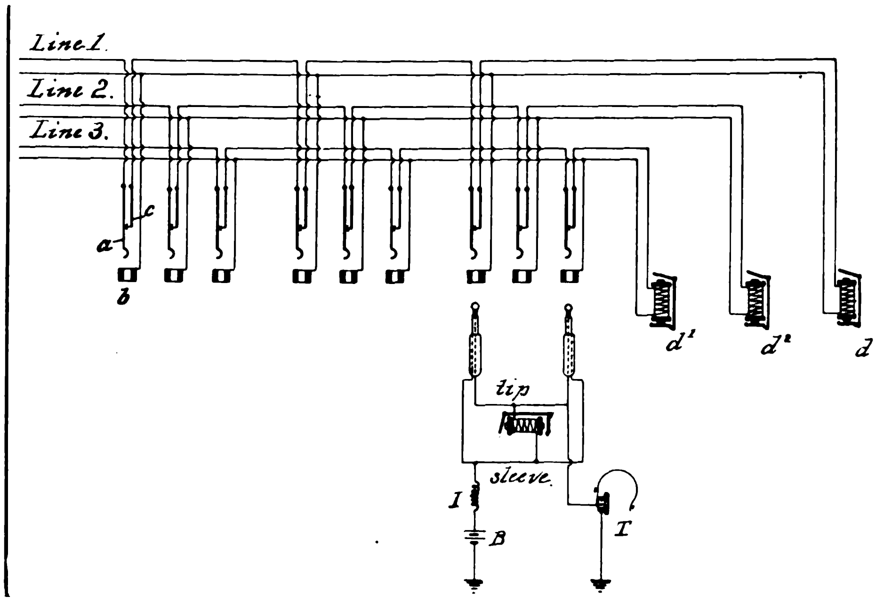

DIAGRAM OF MULTIPLE SWITCH-BOARD.

When a subscriber operates his generator, the current passes over the line wire through all of the contacts, *a* and *c*, in series, through the drop coil, and back over the other side of the line. When an operator inserts a plug into a jack, the spring, *a*, is lifted from contact to the anvil, *c*, by the tip of the plug. The sleeve of the plug makes connection with the test spring, *b*, and thus the tip and sleeve strands of the plug are connected, respectively, into the metallic circuit of the line, while the circuit through the drop is cut at the anvil, *c*.

The operator's telephone, *T*, may be then bridged across the cord circuit in order to enable the operator to converse with the subscriber who has called. Means for connecting the operator's telephone in the circuit in this manner are not shown in this figure, but will be discussed in a later article. This telephone is shown grounded from the tip side of the cord circuit in order to better illustrate the principles of testing in this system.

The sleeve strand of each cord circuit is grounded through a battery, *B*, and in order that this ground may not produce serious effects in unbalancing or crossing the circuit of two connected lines, an impedance or reactance coil, *I*, is placed in this circuit. Whenever any plug is inserted into a jack, one side of the test battery, *B*, is thrown on to all of the test rings, *b*, of the line to which that jack belongs. If now, an operator at another board desires to make a connection with that line, she touches the tip of her answering plug to the test ring, *b*, of that line. This will connect the test ring, *b*, to ground, through her telephone, *T*, and a click will be heard, due to the passage of the current from battery, *B*. The operator will therefore know that that line is busy, and will refrain from making the connection.

In the figure the three lines have their drops located at section 3. It must be remembered that other lines would pass through jacks on the various sections in a similar manner, but would have their drops located on sections 1 or 2. The operator at any section will, of course, answer calls on lines terminating or having drops on her section only, but she may be required to connect one of these lines to any other line in the exchange by means of the multiple jack. The calling and listening in may be performed by substantially the same form of keys as those described in connection with smaller boards.

The arrangement of circuits here shown is that used in what is termed the series-multiple board, the name series being derived, of course, from the manner in which the line passes through the contact springs and anvils of the multiple jacks. This system, although widely used, is subject to grave defects, and is being rapidly replaced by another form of multiple board known as the "bridging" or "branch terminal multiple." In the series-multiple an open circuit may be caused in any one of the jacks by a particle of dust or other foreign insulating matter becoming lodged between the line spring and its anvil, or by virtue of one of the springs becoming weak and failing to bear upon its anvil. The liability to open circuits, therefore, is very great, especially in large exchanges.

Another serious objection to the series board is that when a plug is inserted into a jack, one side of the line is cut off at the anvil of that jack, but the test side is not cut off, and is continuous through the drop of that line and back to the anvil of the jack which is plugged. This, in a large exchange, means that to one side of the line is attached an open branch, perhaps several hundred feet long and containing the drop coil. This destroys to a certain extent the balance of the line, and is liable to produce cross talk.

A MAGIC CLOCK—I.

BY NEVIL MONROE HOPKINS.

Numerous mechanical devices for secretly moving the hands of timepieces have been worked out, producing more or less magical effects. Timepieces as well as magic, date back to the early stages of civilization, and their combination is therefore not untimely. The magic clock herein described may be sealed up under a glass shade and made to run for years without breaking the seal, which adds greatly to the mystery, and forms a most suitable clock for a magician's table, or even his library mantle.

Glass shades usually come with wooden bases provided with little ball feet, and it will be readily seen that the electrical contact system can be duplicated in the glass shade and stand, in the manner it is used in connection with the clock base and table.

Fig. 1 represents the general appearance of the simplest design of clock which may be built on this plan, having only one hand to point out the time. A clock can, of course, be put together having two hands, but it will require another set of wheels in the base with additional gearing and a second moving glass plate.

If the clock is constructed with only one hand it had better be large and of an ornamental design cut from bone or ivory, as some will suggest that the working of the hand is dependent on magnetism if the hand is iron or steel.

Fig. 2 represents a section of the clock from behind. All the mechanism is shown here with the exception of the electromagnet and ratchets which move and control the ratchet wheel, *a*, which turns in a horizontal plane. This ratchet drives a set of bevel gears, which in turn, through the medium of a little cog-wheel at the back, drives the large wheels, *b*, *b*.

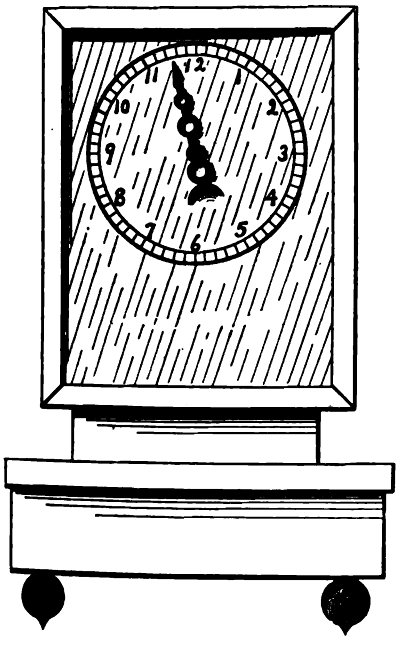

FIG. 1.—ELEVATION OF CLOCK.

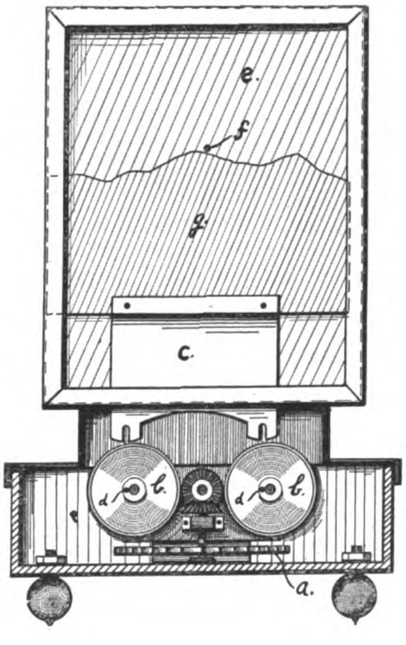

FIG. 2.—FRONT VERTICAL SECTION.

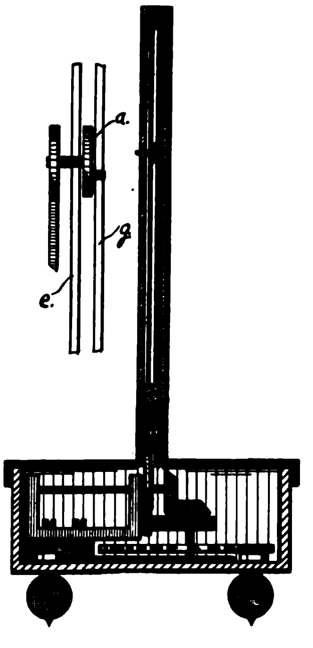

FIG. 3.—SIDE VERTICAL SECTION.

This mechanism will be made clearer by referring to Fig. 3. The brass plate, *c*, in Fig. 2 has the slotted projections cut to engage two small eccentric pins or cranks, *d*, *d*. These slots are filed up until the top of the plate, *c*, is hidden by the frame of the clock when the little pins are at their highest point. The stroke, or throw of the little pins must, of course, be small, in all cases, a trifle less than the thickness or width of the frame.

The frame holds two pieces of thin clear glass, one stationary and the other movable. The stationary plate is represented by *e*, and fits tightly into the frame. The little hole, *f*, which is drilled through the stationary plate, serves to mount the little spindle and hub which carry the hand. The second plate, *g*, is a little smaller than the frame; that is, it is cut free to move back and forth, as well as up and down, through a distance fully equal to the throw or stroke of the little eccentric pins, *d*, *d*. The movable plate is shown at *g*, partially cut away for the sake of clearness. This is represented in the illustration at its extreme left position.

This movable plate also has a little hole drilled through (the plate being cut away here, the hole is not shown) at such a point that it will describe a tiny circle about the hole in the stationary plate. It will be readily seen that the circumference of the little circle which this hole describes will be equal to the little circles described by the little eccentric pins when the wheels are revolved.

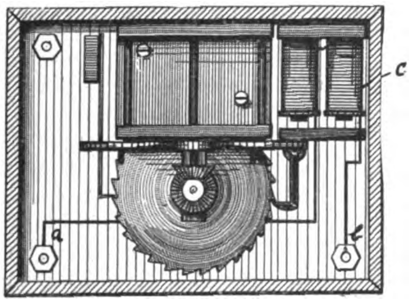

FIG. 4.—PLAN OF BASE.

Fig. 3 shows a side section of the clock mechanism, with a diagram of the glass plates and hub at the left. The working of the plates and hub will be made clear by reference to this sketch, where *a* is the hub carrying the hand on a little spindle, with a little crank pin at the back, with *e* the stationary plate, and *g* the movable plate, turning the little crank pin on the hub, as it is moved by the little crank pins of equal stroke in the base.

Fig. 4 shows a plan of the mechanism with an electromagnet and ratchets in position. The little nuts, *a* and *b*, in this figure, are the terminals of the winding on the electro-magnet, *c*.

Fig. 5 illustrates the clock being driven by battery power to a swinging pendulum in combination with a little mercury cup which completes the circuit through mercury at every beat. This arrangement is only intended for exhibiting the clock before an audience, as the hand is made to travel fast enough to be noticed. The hand should be attached so it may be taken off at any time and passed around. Of course, the circuit can be closed through a telegraph key and the clock run by hand. If the clock is intended to keep time on a library mantle, the connection with a regulating timepiece will have to be different. Here the number of teeth on the ratchet wheel in the base will have to be taken into account as well as the reduction in gearing between the ratchet wheel and the little wheels which carry the crank pins. By making electrical connections with projections on the escapement wheel of a large clock, the hand on the magic clock can be made to follow the hour hand of the regulator clock, if the problem of teeth and gearing is correctly worked out.

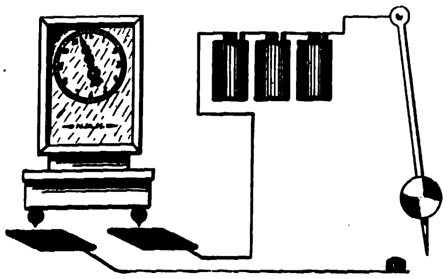

FIG. 5.—DIAGRAM OF CONNECTIONS.

Of course, the magic clock can be placed a long distance from the regulator if good battery power is at hand. For a real timepiece a large battery of bluestone cells, or telegraph battery will give the best service. The base plates which make contact with the sharp points of the bolts can be covered with almost any table or mantle covering, as the clock is heavy enough to pass the points, if sharp, through very heavy material.

◆

ROTARY VALVES.

There is at present considerable difference of opinion among makers of engines regarding the manner of making rotary valves, as may be gathered from the statements made in the preceding article. Still another point of difference is whether to use the "original" Corliss valve, as shown by Fig. 1, or to use the "through" stem, in preference to the "T head" stem illustrated in the engraving. The cross section shows very plainly the manner of putting in the springs, where such appliances are used. The engraving also shows the manner in which the valve is attached to the stem, a top and a bottom view of the latter being shown.

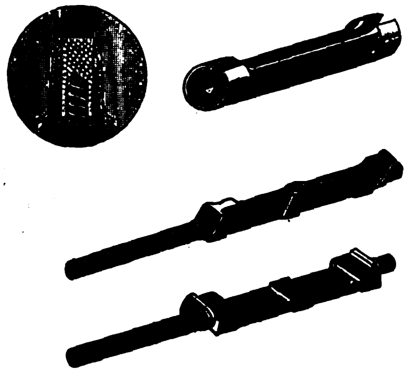

FIG. 1.—"ORIGINAL" CORLISS VALVES.

A number of engines use valves of the rotary type for exhaust purposes, while the admission is controlled by ordinary slide valves, or by those of the piston variety. Fig. 2 presents a form used in connection with double-faced slide steam valves. In this engraving, the small arrows indicate the direction of flow of steam, while the large arrows show the direction in which the valve is moving. Really, this form consists of two double-ported valves with arc-shaped faces fitting the bore of the valve chest, and placed loosely on a central stem which drives them both, and allows each to be held tight to the seat by steam pressure.

Steam is admitted from the valve chest over the edge of valve, and also through the port in the valve, thus giving a very rapid and wide opening. At the same time, the exhaust from the other end of the cylinder has a very direct, though curved passage from port to the condenser. This valve is driven by a rocker arm, and if used as an intermediate, it can be actuated by a wheel governor, although not so connected in the engraving here shown.

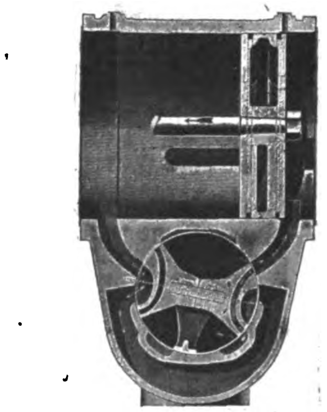

FIG. 2.—ROTARY EXHAUST VALVES.

In the vertical compound engine illustrated by Fig. 3, the valves are actuated by a rocker arm, and controlled by a connection between the arm and a wheel governor. It will be noted that the steam valves are hollow and placed on the ends of the cylinders, thus securing extra short ports and consequently small clearance space. The action of the wheel governor is transmitted by means of a compound connection something after the style of that used on the Porter-Allen engine. This, and some other typical valve connections, will be described in a future article.

Another rigging with slide steam, and rotary exhaust valves, is shown in Fig. 4. Here, the exhaust valves are actuated by a separate eccentric which is connected to both valves by means of a single rod. Or, I might say that the valves are each connected to a short rocker arm, the arms being connected together with a parallel rod. The rod from the eccentric is connected to the first of the short rocker arms, which thus works both valves with a single motion, one being open while the other is closed. The steam valves are actuated from a wheel-governor eccentric, which works the regulation by changing the stroke of the valve in a manner described in the September issue, under the title of "Wheel Governors."

A queer arrangement, which, while it may not be called a distinct form of valve, still possesses very distinctive and interesting features, is shown in Fig. 5. Any form of regular Corliss valves may be used, and the structure itself consists of an auxiliary steam-chest which may be bolted to the cylinder of a plain slide-valve engine. It is intended to give the distribution secured by a regular Corliss valve, and it will do so with the ad-

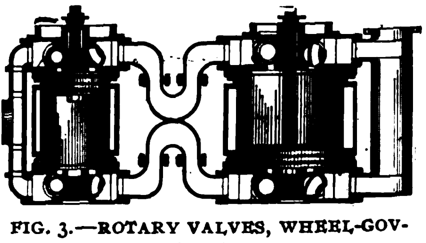

FIG. 3.—ROTARY VALVES, WHEEL-GOVERNED.

dition of a considerable percentage of clearance, and the use of long steam passages. How these losses would figure up against the saving derived from automatic regulation, I am not able to state, but it seems to me that after the time of making and fitting the new steam-chest, and the putting of it on steam-tight, has been summed up, it would be found to amount to fully as much as the cost of a new Corliss cylinder for the engine. If this is the case, or if the cost comes anywhere near the cost of a new cylinder, the saving in steam by the use of the smaller clearance of the new and regular Corliss cylinder, would more than pay the interest on the extra cost of the "full-blooded" cylinder, whatever that might amount to.

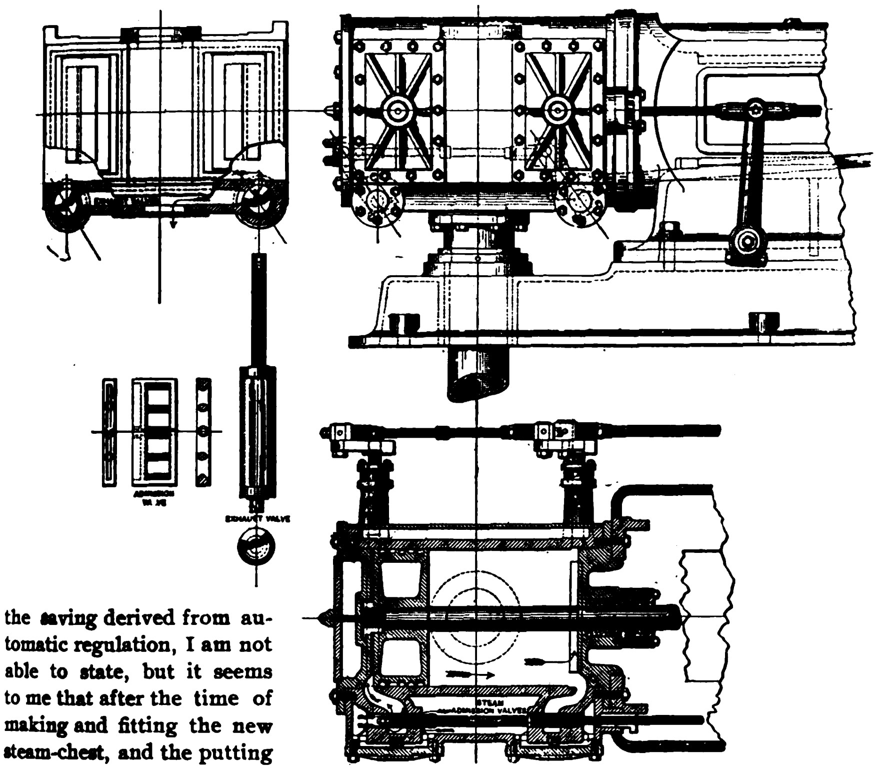

FIG. 4.—DIRECT-CONNECTED ROTARY VALVES.

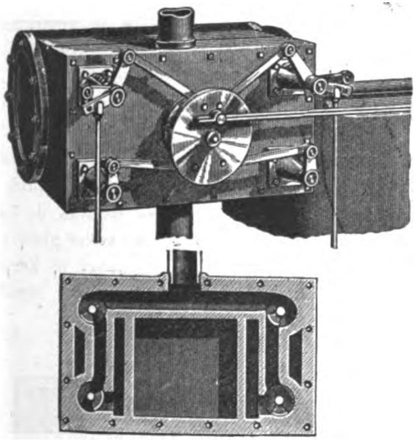

FIG. 5.—A CORLISS 'VALVE CHEST."

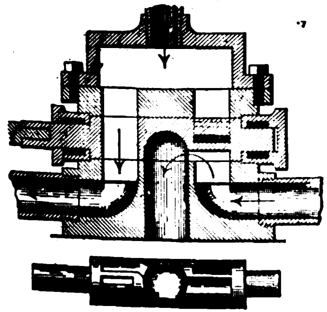

FIG. 6.—ROTARY STEAM-CHEST VALVE.

Another steam-chest valve is shown by Fig. 6. This valve is to take the place of the plain slide form of construction, and may be worked by motion from a wheel governor if desired. The upper engraving is a section through steam-chest and valve. The lower one is a perspective view, looking down on top of the valve, which has steam ports at different angles, one at each end, with an exhaust port between.

From the latter, channels lead in opposite directions, these channels being out of line with each other, but each being in alignment with the steam port on the opposite side, so that when one port is admitting steam the other is exhausting the steam from the other end of the cylinder. By this construction, the area of pressure upon the valve is reduced to that of one of the steam ports, and the valve movement is consequently very easy. It requires but little power to operate the valve, as there is very little friction.

◆

LESSONS IN PRACTICAL ELECTRICITY

CAPACITY.

In alternating-current working the subject of capacity is of minor importance to that of inductance, but is yet one of much interest and has some practical applications.

The simplest form of a condenser consists of two parallel plates separated by a non-conducting medium, usually spoken of in this connection as a *dielectric*. In the case of condensers used in telegraphy and telephony, the conductor consists of alternate layers of tinfoil and of paper treated with paraffine or other non-conducting substance, as shown in Fig. 1.

As to the effect on the capacity of a condenser of different dielectrics, suppose we have two parallel plates separated merely by air, in which case we will call the capacity unity; then if paraffine wax is placed between the plates the capacity of the condenser will be increased from 2 to 2½ times; with vulcanized rubber about 3 times; with sulphur about 3½ times; with shellac from 3 to 3½ times; with gutta-percha 4 times; with mica 5 times and with different varieties of glass, from 6 to 10 times. That is, with glass as a dielectric, from 6 to 10 times as much electricity will be held for a rise of one volt than if air were used.

The above ratios between the value in this connection of air as a dielectric, and of other dielectric substances, is called *specific inductive capacity*.

Suppose we take two plates of tin, place them close together, but without making contact, and connect one plate to one side of an alternating-current circuit and the other plate to the other side, in the same manner that an incandescent lamp would be connected up. As the voltage changes, the two sides of the condenser become unbalanced; with an increasing voltage a current will therefore flow into the condenser, and with a decreasing voltage a current will flow out. For each change of voltage between the two plates, a definite quantity of electricity will flow in or out; if, for example, there were a uniform rate of change from 20 to 50 volts, a current of uniform value would flow into or out of the circuit in order to supply the difference existing between the charge of the condenser at 50 volts and the charge at 20 volts.

By definition, a condenser which when charged with 1 coulomb of electricity has a difference of potential of 1 volt between its terminals, has a capacity of 1 farad. Since an ampere flowing for one second will deliver 1 coulomb of electricity, we see that to charge a condenser of 1 farad capacity requires only a very small amount of electrical energy.

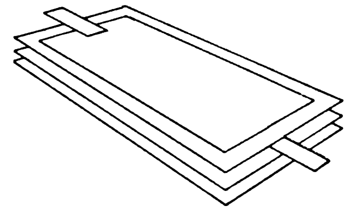

FIG. 1.—TIN-FOIL CONDENSER.

Though this would make it appear that a farad is not a large capacity, it is nevertheless enormously larger than is met with in practice, and consequently for practical work the term *microfarad* is always used, meaning a millionth of a farad. Even a condenser of 1 microfarad capacity forms a large piece of apparatus. For example, if a condenser is to be made of sheets 6 ins. square, and consists of tinfoil between paraffined paper, more than 150 sheets of foil 6 ins. × 6 ins., will be required.*

In order, however, to deduce the law of the condenser as applying to alternating currents, we will assume a condenser of 1 farad capacity. If such a condenser is charged with a coulomb of electricity, or the quantity that would be supplied by a current of an ampere flowing for one second, there would, as stated before, be a difference of potential of 1 volt between its two sides. If the condenser were of 2 farads capacity, then the same amount of electricity would only, we may say, "half charge" it, and consequently the difference of potential would only be ½ volt; if the condenser were ten times as large the potential would be only $\frac{1}{10}$ volt, and so on. We thus see that the voltage at the terminals of a condenser will, for the same charge, be less as the capacity of the condenser is increased, so that if increased K times, the voltage will be only $\frac{1}{K}$th as great; conversely, if the capacity is reduced K times, for the same charge the voltage will be increased K times.

---

*The formula for such a condenser is $A = \frac{15458 \times t \times M}{K}$, where A is the area in square feet of one side of the foil; t the thickness of the dielectric in inches; M the capacity in microfarads, and K the specific inductive capacity.

Suppose our farad condenser is on an alternating-current circuit, having a frequency of one period per second. Then the condenser will in each period be, 1°, charged positively; 2°, discharged; 3°, charged negatively; 4°, discharged. That is, in each period there will be two distinct charges and discharges.

If, now, an ampere (coulomb-per-second) of current is flowing as measured by an ammeter in the condenser circuit, one coulomb of current corresponds to two charges and to two discharges, or to one-quarter coulomb per charge or discharge; consequently, the voltage at the terminals will be but one-quarter volt. That is, as the periodicity is increased the voltage is decreased at the rate of four times the number of periods, n, or as $4n$.

While we have used the term alternating current above to fix ideas, the reasoning applies to a uniform flow of current into the condenser. When the flow is alternating, the quantity delivered in a given time is less with respect to the value in the above case, by $\frac{2}{\pi}$, and therefore the voltage at the terminals will be reduced in the same proportion.

We can now apply the above principles to the solution of a problem. Suppose we assume a condenser of one microfarad capacity, a frequency of 100 and a sine wave alternating current of 5 amperes flowing in the condenser circuit (Fig. 2).

Five amperes correspond to $5 \times \frac{2}{\pi} =$ 3.18 coulombs-per-second. But this quantity per second must be divided among 100 periods of four distinct charges or discharges each, or into 400 parts, making $3.18 \div 400 = .00795$ coulomb for each charge. If one coulomb were put in a condenser of one microfarad capacity (one-millionth of a farad) the voltage between its terminals would be one million; and for a charge of .00795 coulomb the voltage would be $1,000,000 \times .00795 = 7950$ volts (which would puncture any ordinary condenser). If one-half ampere flowed, the voltage would be one-tenth less than that corresponding to 5 amperes, or 795 in this case. That is, in order in this case to obtain a current of one-half ampere in the circuit in question having in it a condenser of one microfarad, 795 volts would have to be applied to its terminals.

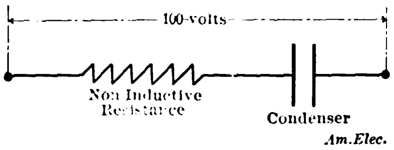

FIG. 2.—CONDENSER AND RESISTANCE IN SERIES.

If we denote the condenser capacity by K, the current by C, the frequency by n, and the E. M. F. by E, necessary at the condenser terminals to produce the flow of current, C, then the above operation may be represented by the simple formula

$$E = \frac{C}{2 \pi n K}.$$

Substituting the above values, $C = .5$, $n = 100$, and $K = .000001$, we have

$$E = \frac{.5}{2 \times 3.1416 \times 100 \times .000001} = 795.$$

The curves and bipolar diagram relating to capacity E. M. F. have been given in previous lessons, and as all of the considerations with respect to such curves and diagrams developed in the last lesson with reference to inductance, apply equally to capacity, they will not be here repeated.

It was shown that all problems relating to inductance and resistance in series can be solved by reference to a right-angled triangle such as that shown in Fig. 3, in which the vertical, OB, represents the CR or free E. M. F.; the horizontal line, AO, the inductive E. M. F.; the hypotenuse, AB, the impressed E. M. F.; ABO, the angle of lag; and the ratio $BO \div BA$, the power factor.

Similarly, all problems relating to capacities and resistances in series can also be solved by reference to a right-angled triangle, such as that of Fig. 4, where ob represents the free E. M. F.; $a\ o$, the capacity E. M. F.; ab the impressed E. M. F.; abo the angle of lead (capacity throwing the current in *advance* of the impressed E. M. F., and inductance the reverse); and $bo \div ab$, the power factor. It is always well to draw the capacity triangle to the right of the perpendicular if the inductive triangle is drawn to the left, as inductive and capacity E. M. Fs. act opposite to each other, as explained in a previous lesson.

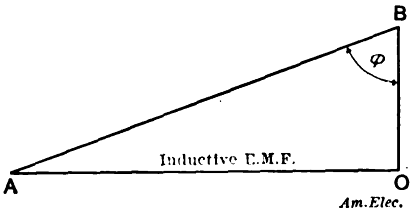

FIG. 3.—INDUCTANCE TRIANGLE.

As an example, we will determine what current will flow in a circuit having in series with each other a non-inductive resistance of 100 ohms and a condenser of two microfarads, the circuit being connected across alternating-current mains of 100 volts and a frequency of 100.

From Ohm's law, $E = CR$, the drop or free E. M. F. for 1 ampere will be $100 \times 1 = 100$ volts.

By the formula just deduced, the E. M. F. at the terminals of the condenser will be

$$\frac{1}{2 \times 3.1416 \times 100 \times .000002} = 795.$$

In Fig. 4 we will have $ob = 100$, and $ao = 795$; solving the triangle, we have

$$(ab)^2 = (100)^2 + (795)^2 = (812)^2.$$

The voltage of the main circuit, however, is only 100, but since the impressed E. M. F. varies directly at the current passing (as will be seen from the formulas) we merely have to reduce the current of 1 ampere that was assumed in the ratio of 100 : 812, which gives .12 ampere. That is, .12 ampere will flow in the circuit of given resistance and capacity in series when connected across 100-volt mains of the given frequency.

The power factor is the ratio of the free to the impressed E. M. F., or $ob \div ab$, or $100 \div 812 = .12$. (It is merely a coincidence that the current and power factor have here indentical values.) This means that while the line voltage is 100 and the current flowing is .12 ampere, the energy in the circuit is not $100 \times .12 = 12$ (volt-amperes), but $.12\ (100 \times .12) = 1.44$ watts.

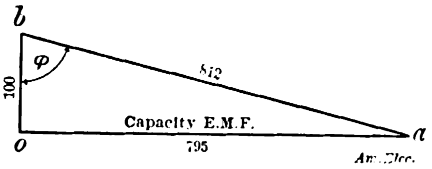

FIG. 4.—CAPACITY TRIANGLE.

This follows for the reason that the condenser absorbs no energy (leaving aside dielectric hysteresis), but gives back on discharge what it receives on charge, in this respect acting like a spring. The only energy used in the circuit in this case is, therefore that dissipated as heat in the resistance, or the C^2R less. As the resistance is 100 ohms and the current is .12 ampere, this loss amounts to $(.12)^2 \times 100 = 1.44$ watts, as found above by means of the power factor.

The above triangular diagrams are not drawn to scale. In practical problems, capacity E. M. F. is usually so small in comparison with the free E. M. F., that the perpendicular and hypotenuse are extremely close. In these lessons exaggerated values of these quantities have been taken, so that the shape of the triangles has been reversed. In working out problems, however, it is always well to do so with reference to a triangle, however greatly it may depart from scale, in order to keep the principles in mind and thereby avoid error.

Letters on Practical Subjects

Magneto for Firing Blasting Fuses.

To the Editor of American Electrician:

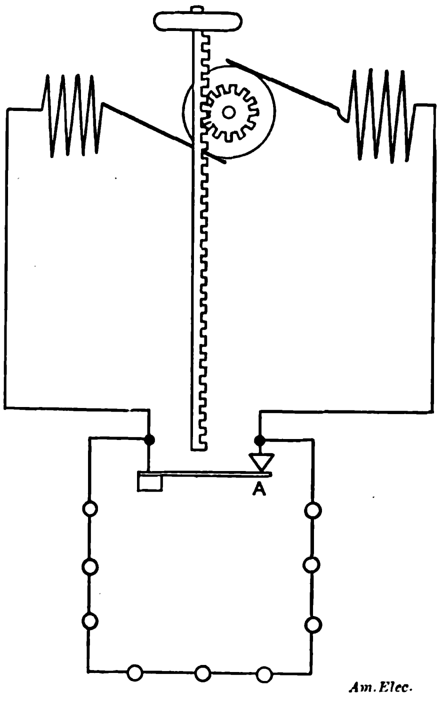
Replying to the inquiry of Mr. James L. Francis in your November issue, as to how a magneto firing machine is connected up and operated, and why his apparatus failed to work, I will say that the more modern blasting machines are small series-wound dynamos with a two-part commutator and connected with firing mechanism, as shown in the accompanying diagram. If the machine is connected as shown in the engraving in his letter, whether it be a magneto or not, his trouble probably lies in the quality of current developed; for, if his magneto were made originally, as he states, to actuate an alphabetical telegraph instrument, it probably does not give out amperage enough to bring to incandescence the fine platinum wire which ignites the powder surrounding it in the exploders.

He will attain better results if he discards his permanent-magnet fields and attaches to the pole pieces instead, heavy soft-iron cores; cast iron will answer.

The fields for a machine capable of igniting 12 to 15 fuses at one discharge should be about 6 ins. long, 5 ins. wide and 1½ ins. in thickness, wound with 6 to 7 layers of No. 14 B. & S. magnet wire, and the armature wound with No. 21 B. & S. wire, preferably silk covered, which will permit of a greater quantity being wound on; the current, of course, is to be commutated.

In operation, until the rack bar, which revolves the armature, strikes the trigger at the end of its stroke the dynamo is short-circuited on itself, and, from the fact of its being a series-wound machine, builds the fields up to full saturation and the whole dynamo into full operative condition by the time the current is switched in the blasting circuit by the bar striking the spring lever, or trigger, at the end of the stroke, and opening the short circuit at the point *A* in the diagram. R. H. STERLING.

Durango, Col.



FUSE-FIRING MAGNET.

Switches for Intercommunicating Telephone Stations.

To the Editor of American Electrician :

The accompanying sketch shows a pair of switches by which independent communication may be held between two telephones, both of them connected with central by the same wire and occupying but one drop on the switch-board. Either can call up the other without calling central, either can call Central without calling the other, but when Central calls both stations ring.

There are many places where such a system is desirable. I have been using it for two years, and for my purpose, between office and residence, I prefer it to having two telephones connected with central by different wires. It is necessary, however, that the two stations be connected by two wires.

To make the switches, a brass circle cut, as shown, is screwed to a hard-wood board about 4 ins. square, and the wires connected to the switch points as indicated.

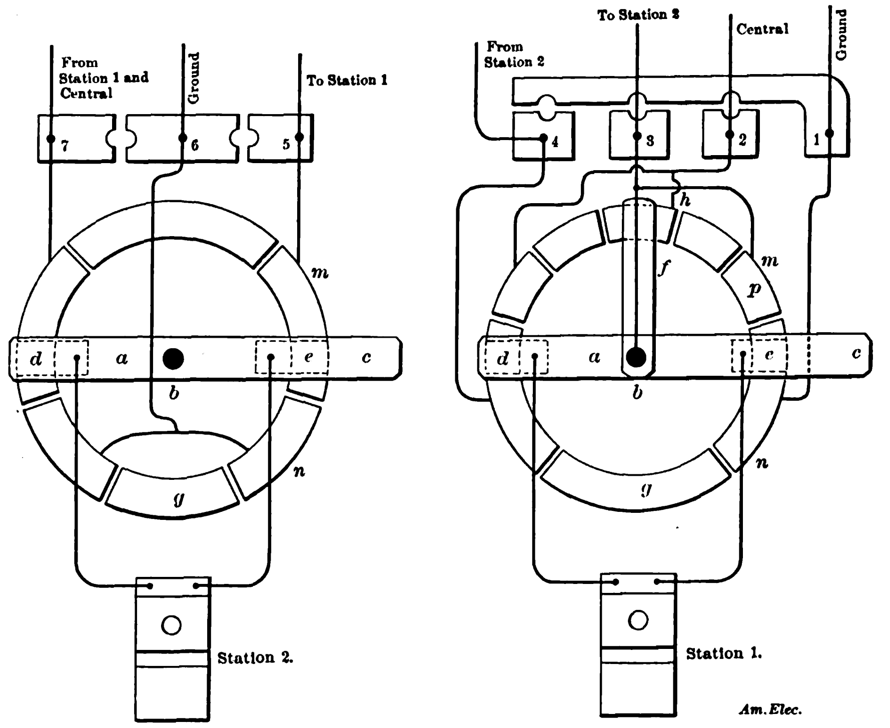


DIAGRAM OF TELEPHONE CONNECTIONS.

The horizontal bar, *a*, extending across the circle, is a wood lever pivoted in the center at *b*, so that the handle at the right at *c*, may be moved up or down. To this bar on the side next the board are secured by binding screws, two brass pieces, *d* and *e*, which slide around on the circle as the handle is moved up or down. These binding posts are connected by wires to the binding posts on the telephone.

To the middle of the bar in station 1 is attached a brass lever, *f*, extending upward at right angles with the bar, to the brass circle. To the pivot *b*, with which this lever is connected, the wire from station 1 to station 2 is connected by way of binding post, 3. The switch point, *p*, is also connected to it.

This brass lever cuts out central when the lever at station 1 is raised. The cut in the circle at *h*, is essential only to prevent either from switching in when the other is communicating with central.

1-2-3-4-5-6-7-(stations 1 and 2) are binding posts on the switch-board to which the line and ground wires are attached, as indicated. 1, station 1, is the ground wire; 2, station 1, is connected to central; 3, station 1 is connected with 7, station 2; 4, station 1, is connected with 5, station 2.

The levers should be left standing horizontally, then both telephones are connected in series with central and grounded at 1. When the handle at either station is lowered to the point *n*, that station is connected with central and the other is cut out. When the handle of either switch is raised to the point *m*, the two stations are in communication and central is cut off.

When the handle of station 1 is raised, the two stations are on metallic circuit. When either handle is raised or lowered it is presumed that the other remains horizontal.

To cut out the telephones and ground the wires, the handles are lowered to the points *g*, and the holes plugged in the lightning arrester.

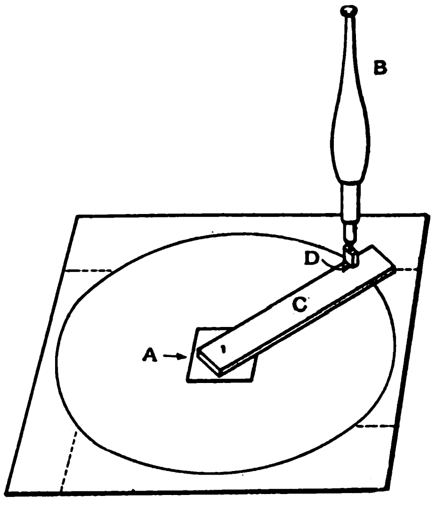
The mechanical construction of the switches may be modified as the maker may desire, so long as the proper connections are preserved. P. F. LANGENOUR.

Statesville, N. C.

Cutting Glass Disks.

To the Editor of American Electrician :

In the belief that some of your readers might be glad to know of a simple way of cutting out glass disks for static machines, I take the liberty of handing you herewith a description of my method.



CUTTING GLASS DISKS.

Referring to the enclosed sketch, a piece of thin wood or heavy card-board, *A*, is glued over the centre of the pane of glass from which the disk is to be cut. The mounting of a glazier's diamond, *B*, fits tightly into a notch, *D*, cut into a flat wooden rod, *C*, near one end; the point of the diamond being allowed to protrude a little. The point of a brad is made to project below the other end, and at a distance from the diamond point equal to the radius of the desired disk. The point of the brad is then pressed slightly into the wood or card-board, and held in this position with one hand, while the other does the cutting with the diamond—the rod acting as a radius arm.

It is important that the cut extend clear through the glass; if it does not do so in any place, it must be tapped locally with a light instrument, on the reverse side, until the cut is continuous. Then the outside pieces can be snapped off by cutting along the dotted lines; this is better than cutting tangents to the circle. After the disk is cut out, the sharp edges can be taken down by means of a course file moistened with turpentine. ANDRE J. PICOLET.

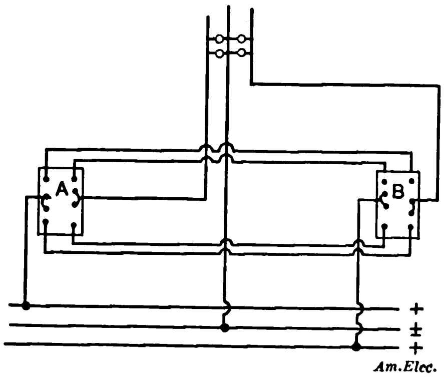
Control of Lamps on Three-wire Circuit.

To the Editor of American Electrician:

In your October number Mr. James L. Francis asks for a sketch, showing how a group of lamps on a three-wire system can be controlled from two or more places. Accompanying this is such a sketch, showing how, with the use of two double-pole, double-throw switches, *A* and *B*, a group of lamps may be turned on or off from two places.



THREE-WIRE DOUBLE-END SWITCH.

This might be used for surface wiring or for temporary wiring where it is desirable to control a group of lights from two different places.

Portsmouth, N. H. A. W. LEE.

◆

Electrical Sport.

To the Editor of American Electrician:

Being an interested reader of the articles on "Electrical Sport" published in your paper during the past few months, but preferring to have my sport with men who are my equals, and having more of a chance to get even than innocent animals and children, I will describe a method I used at a car house with the night-men for victims.

I procured an old tin pail and filled it with tin cans, bolts and stones, and suspended it from the rafters by a fine wire, from which I ran another wire, and connected it to the trolley.

Then I put another wire on the pail in such a manner that it made a contact and remained up in the air when the pail dropped. This wire I ran to a clock some distance away. I then took the alarm key off an alarm clock and covered it with tape.

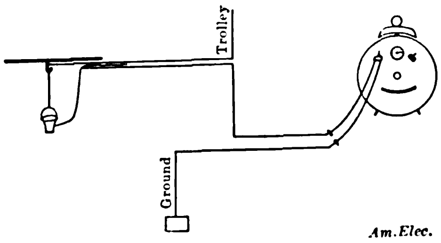


DIAGRAM OF CONNECTIONS.

Around the tape I wound the ends of two No. 18 bare wires so they were insulated from each other and the clock; these were cut about 6 ins. long, and the other ends tacked to the floor or board on which the clock rested.

One of these I ran to the ground and the other to the pail as above stated. I then put the key back on the clock and took off the bell and wound the alarm and set it for 3:30, at which hour night-men are working (?) the hardest.

At the time set the key unwinds, twisting the two bare wires together, which closes the circuit. The fine wire holding the pail fuses and down comes the pail, etc., with enough noise to keep the men away for a week. The accompanying sketch shows the arrangement described.

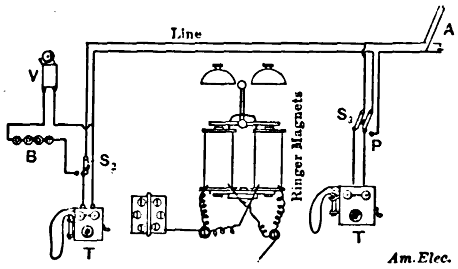
◆

Special Telephone Connections for Burglar Alarm Circuits.

To the Editor of American Electrician:

It often happens that a person living in a small town has his store or business place connected with his residence by burglar alarm wires; should he also wish to add a telephone, the arrangement shown in the accompanying diagram will be found to work very satisfactorily, and it is inexpensive to install.

V is a vibrating bell for the alarm, *B* is the battery, S_2 is a two-point, single-lever switch, *T T* are the telephones, S_3 is a three-point two-lever switch, and *P* is one side of the alarm circuit to the alarm springs, A.



SPECIAL TELEPHONE CONNECTIONS.

If the telephone at the store is left in circuit accidentally, it will ring the vibrating bell as soon as the switch in the house is thrown on. The switch, S_2, at the house end cannot be left in circuit with the telephone, as the telephone is cut-off when the bell is "turned on."

In order not to run down the batteries, it is necessary to use a multiple system of connections in the ringers, as shown in the drawing. The laterals that connect both coils are untwisted and one side of each coil connected to one wire leading through generator to line. This connection has also been found satisfactory on long grounded lines for telephone exchange work.

If the telephone ringer coils are not connected in multiple with each other, as illustrated, they will not always ring the alarm if the telephone at the store should be left on the alarm circuit at night, the resistance of the coils in series being too great. In this case the battery is on a closed circuit all night, and after a few such trials it will be run down.

Bridgeport, Conn. G. E. RUTHER.

◆

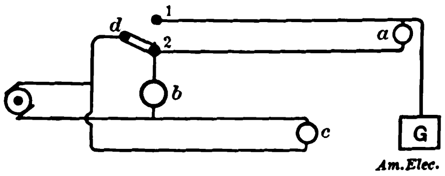
Switch-board Ground Detector.

To the Editor of American Electrician:

A day or two ago I had occasion to place a ground detector on a switch-board where it was not desired to have the device in circuit all of the time. It was also desired to have one of the lamps so arranged as to use it for the illumination of the switch-board cabinet, and to use a third light on the same circuit for the purpose of illuminating the rear of the board.

I arranged the wiring according to the above diagram and obtained good results.

The lamps *a* and *b* were attached to brackets fastened to the upper corners of the switch-board, and the lamp, *c*, was suspended from a cord in the closet at the rear of the board.



GROUND DETECTOR.

One wire from the bus bars was led to a "three-way" switch, *d*, and connected to the double post. A wire was carried from one of the single posts of switch *d* to lamp *a*, and from there to a water pipe and grounded at *G*.

From the other single post of the switch, *d*, a wire was carried to both lamps, *a* and *b*. The wire from the other bus bar was carried to lamps *a* and *c*, and the other side of *c* was connected to wire No. 1.

When switch *d* is set on point 1, lamp *b* burns brilliantly, and when set on point 2 lamps *a* and *b* are put in series and both burn dimly, providing there be no ground on the system. If there be a ground on any part of the system, the lamp on that side of the line goes out and the other lamp burns brilliantly.

All that is necessary to use the system is for the person in charge of the switch-board to turn switch *d*, which is usually kept on point 1, to point 2 momentarily, to ascertain if the system is free from grounds.

By this simple device many break-downs on account of poor insulation may be eliminated. S. E. SANBORN.

Manchester, N. H.

Testing Extraordinary.

To the Editor of American Electrician:

That there are "tricks in all trades but ours," is a foregone conclusion among the members of the various crafts, and the thought and ingenuity expended upon some of the tricks and dodges, would, if expended in true work, increase the salary and standing of the trickster to a notable degree. A case in point: The engineer of a small isolated lighting plant not a thousand miles from New York City was informed that a test of his plant would be run to determine the cost of lighting the building, after which, current from Edison street mains would be turned on, and the cost of thus lighting for a similar period be ascertained.

The engineer knew that if the Edison service cost less than it did to make the current by the plant he was in charge of, that his occupation would be forfeited. Therefore, when the trial run was made, never was boiler, engine or dynamo in better condition than his, and the coal burned was very small.

When the Edison trial was made, he had figured out the cost of everything and knew to a dot what current could be received, and still retain his place. A cunningly concealed water rheostat in the adjoining building was connected by concealed wiring, and the economy of the Edison current received so severe a set-back during the test run that the engineer is sure of his job for some time to come, unless he gets found out.

While not speaking well for the trustworthiness of the engineer, it speaks still worse for the skill of the Edison "expert" who conducted the test for his company. He should have detected the fraud immediately.

S. L. CORSON.

Pittsburgh, Pa.

◆

Operation of T.-H. Arc Dynamos.

To the Editor of American Electrician:

As I have never seen anything in print about caring for Thomson-Houston arc dynamos, I venture to send a few suggestions about these troublesome machines.

In the first place, the commutator, brushes and brush holders should be well cleaned after every run. Adjusting the machine with too short a spark will cause "flashing." The spark can be lengthened by turning the commutator slightly forward on the shaft. This weakens the machine, however, and if it is well loaded, care should be taken not to weaken it so much as to cause the regulator to rest on the stop. The commutator should not be moved more than $\frac{1}{16}$ in. at a time.

Much trouble is sometimes caused by the air-blast being worn out. The hubs should fit snugly in their bearings in the sides of the air-blast. I have seen them with as much as $\frac{1}{16}$ in. play. The General Electric Company will repair them much more cheaply than new ones can be obtained for.

I have obtained the best results by adjusting the air jets so that the blast will strike about ¼ in. in front of the brushes when the regulator is down. Of course, if the machine has to work with a light load, this cannot be done. If the load is very light the armature will get quite hot. This can be remedied by connecting a rheostat between the binding post and connecting-rod post on the right hand leg of the machine. This weakens the field and causes the regulator to run lower. The height at which the regulator runs can be adjusted by turning the rheostat. It should not be more than ½ in. from the top.

When the rheostat is in use, the spark will be longer than usual and may be a little harder on the segments and brushes, but these are cheaper than armatures. The rheostat should have not less than 60 ohms resistance.

Omaha, Neb. CARL C. GILES.

◆

Hydraulic Pumping.

To the Editor of American Electrician:

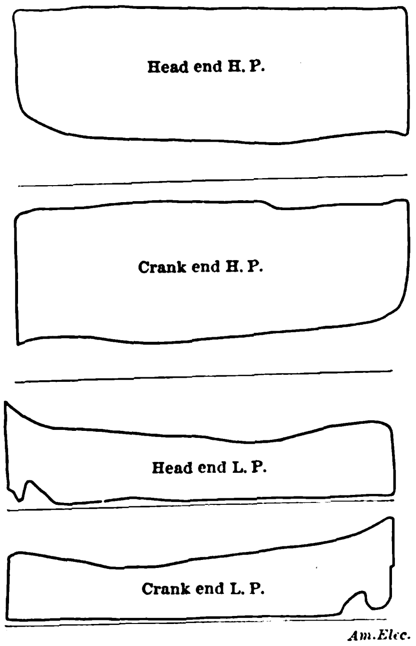
The accompanying cards were taken from an elevator pumping engine, and they furnish a good object lesson as to the relative economy of generating power for hydraulic and for electric elevators. The data are as follows:

High-pressure. Scale,* 60 lbs.; cylinder, 16 ins. × 15 ins.; r. p. m., 28.

Low-pressure. Scale,* 30 lbs., cylinder, 25 ins. × 15 ins.; r. p. m., 28.

With this type of elevator service, the engines generate approximately the same power empty as when loaded—in this respect also differing from electric elevators, and rendering any comparison still more unfavorable. I should be glad to have some reader give from the above cards the I. HP and pounds of water per I. HP. hour.

New York. M. L. TROWBRIDGE.



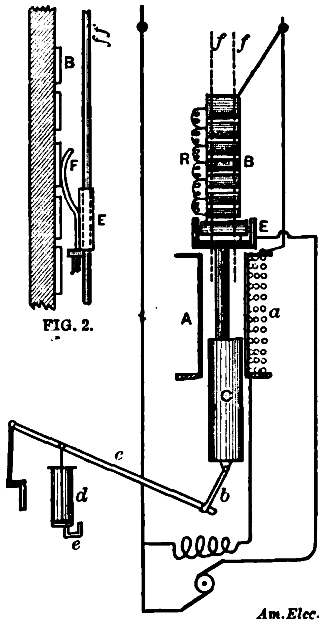
CARDS FROM HYDRAULIC ELEVATOR PUMPING ENGINE.

◆

An Automatic Rheostat.

To the Editor of American Electrician:

The accompanying sketches show the principles of an automatic rheostat, the mechanism of which can be mounted on any of the usual forms of rheostats now in use. The rheostat will automatically start the armature current when the switch is closed, and can be adjusted to move slow or fast at will. The gravity movement employed avoids trouble from the sticking which sometimes affects the working of spring movements.



AUTOMATIC RHEOSTAT.

In Fig. 1, *Aa* represents a magnet in series with a motor field, the winding being on a brass cylinder; *B*, are rheostat contacts or steps; *C*, a plunger that raises the contact shoe, *E*; *R*, resistances; *b* and *c*, lever arms; *d*, a dash pot, and *e*, a check valve. Fig. 2 is a side view of the shoe movement, *E* being the shoe, and *F* a contact spring. *ff* in Figs. 1 and 2 are rods on which the shoe slides, and which also form one pole for the current.

That Magneto Firing Machine.

To the Editor of American Electrician:

Noting the reply, under title of "Blasting Fuses," of Mr. Van Deth in December issue, to my letter of inquiry published in November, I desire to advise the writer that experiments had already been made in the direction he suggests, and that I found a single cell of LeClanché battery capable of exploding one of the "electric primers," for which I desired to construct a firing machine. In the experiment, the cell was connected direct to the wires (about 6 ft. long) to which the exploders were attached.

It seemed to require about one second for the current to get in its work when thus attached, but when the magneto provided for that purpose is used, there is no appreciable time between the pushing down of the handle, and feeling of the jar of the explosion, even when six or eight exploders are connected in series.

I am not able now to measure the resistance of one of these exploders, not having one at hand, but it must be very small. Still, Mr. Van Deth does not meet the main question, which is to give a diagram showing how to connect up a magneto for firing one of these exploders. It is done on every large blasting job (the firing) and a magneto is used as stated in the first letter, but when I tried to so connect up a telephone magneto to do the work, I could not make the thing operate.

---

* The scales refer to the cards as they are here reproduced.

I have several times fired an exploder at the ends of 50 ft. of wire immersed in fresh, and even in brackish water, with no insulation except that afforded by the cotton winding on ordinary office wire. With a magneto, even this is not necessary, the bare wires immersed in water carrying current enough to fire the shot.

On several occasions, while exploding dynamite at the bottom of driven wells, I have had trouble from lack of insulation where the water was pretty salt, in firing from a 110-volt circuit, but on connecting to a 500-volt railway circuit near by, the charge went off at once. Once, the charge went off, with only one wire attached to the negative wire of the 110-volt circuit, probably from leakage from the 500-volt circuit.

Brooklyn, N. Y. James L. Francis.

ELECTRICAL CATECHISM

178. How can the instantaneous values of the current and E. M. F. be measured when the whole cycle is completed in less than one-sixtieth or one-hundredth of a second?

By means of photography and galvanometers having very light, rapid and sensitive moving parts, the curves may be printed automatically. The more common method is to measure the instantaneous values directly and then plot the curves from these.

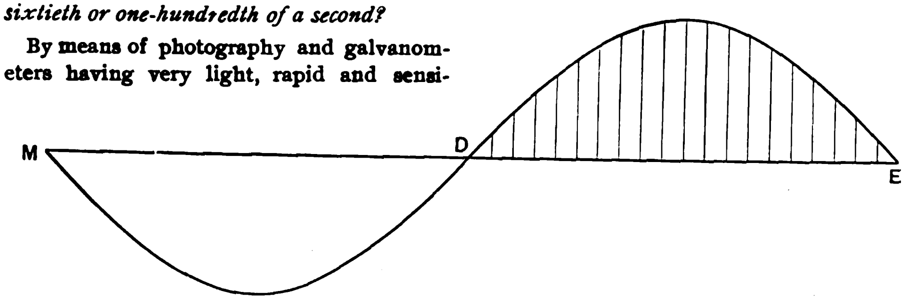

FIG. 2.—SINE CURVE.

179. Explain more fully how the curves can be made to print themselves?

A galvanometer is required having a very light needle swinging in a very strong magnetic field, as suggested by the diamond-shaped needle in Fig. 1. When no current flows through the coils, the needle points in the direction indicated, taking its position directly in the path of the magnetic lines of force between the poles, *N* and *S*. Current through the coils tends to place the needle in the direction of the line *A B*, at right angles to its other position. When the needle is under the influence of both forces at the same time, it will take an intermediate position. Now if the current varies in amount or direction or both, the needle will respond and take a position at every instant corresponding to the relative strength of the current. A beam of light reflected from the needle or from a small mirror attached to it, will take a record upon a photographic plate which is moved at a regular speed in a direction perpendicular to the motion of the light. For this purpose a very sensitive instrument is required and the amateur had better not waste time in trying the experiment. This is outlined simply to give a general idea of how it is done. The more common method is more tedious, but more easily applied.

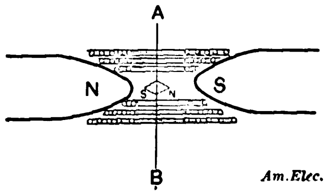

FIG. 1.—MAGNETIC EXPLORING NEEDLE.

180. What is the more common method of determining the instantaneous values of an alternating E. M. F. or current?

There are a number of methods, all being dependent upon the fact that no matter how rapidly the current or E. M. F. passes through a cycle, each cycle is exactly like those preceding and those following. For example, if in the curve in Fig. 2, the distances above and below the line, *M D E*, represent the variation of an alternating current through a single cycle, the current will pass through exactly the same set of values many times each second. In the armature of an alternator there are usually as many coils as there are poles in the field. These are connected in series and are placed symmetrically with reference to the magnet poles, so that the E. M. Fs. in the various coils are all in the same direction and equal at any instant, that is, so that the E. M. F. in each coil is zero at the same time. Now suppose that an insulated metallic disk is mounted upon the armature shaft so that a brush can make continuous contact with it, and having a projection from one side so as to make contact with a wiper or spring once each revolution. It is plain that the wiper will make contact with the projection from the disk at the same point in the revolution of the armature, no matter how rapidly the armature may be rotating. Now suppose that a sensitive voltmeter is connected on one side to one of the mains carrying current from the machine, and on the other side to the brush making continuous contact with the insulated disk, and that the wiper brush is connected to the other main, as suggested in Fig. 3. The wiping brush completes the circuit through the voltmeter once every revolution of the armature and at identically the same point in the revolution. The voltmeter will therefore receive current from the mains for an instant, and the needle or pointer will be deflected—a certain amount depending upon the voltage between the mains at the instant the contact is made. By moving the wiper to other positions, the corresponding voltages may be determined for various positions. By properly calibrating the voltmeter, the actual voltage between the two mains at the instant of contact may be determined for each position, and a curve may be plotted using the successive positions of the wiper as horizontal distances and the corresponding voltages as the vertical distances. There are many details to be looked after for accurate results and many different arrangements of the apparatus have been used, but they are all essentially the same as outlined above.

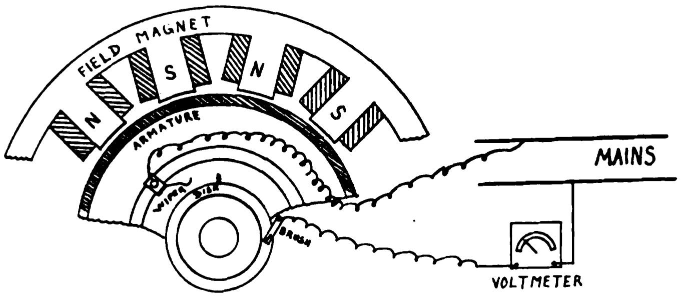

FIG. 3.—DETERMINING INSTANTANEOUS VALUES OF ALTERNATING E. M. F.

181. How can the curve for the alternating current be obtained by such a device?

A small non-inductive resistance may be placed in series with one of the mains so as to carry the current to be measured. By Ohm's law, the fall of potential through the resistance is directly proportional to the current. Pressure wires run from the end of the resistance to the contact device and voltmeter as before, enable us to measure the drop through the resistance at different points and so to calculate the current and to plot a curve for the current in the same way as was done for the voltage between the mains. For measuring the current by this method, it is necessary to have the voltmeter sensitive, since the drop in voltage through the resistance will not be large.

182. How can the relative positions or the difference of phase between the current and voltage be determined?

By having suitable switches, the wires to the contact device may be connected first to one circuit and then to the other, so as to determine the current and then the voltage corresponding to each position before the wiper is moved to a new position. In this way corresponding values for primary current, primary voltage, secondary current and secondary voltage may be determined.

QUERIES AND ANSWERS

What percentage of the total current generated is used in the field of modern dynamos? M. P. C.

From 10 per cent. in small machines to 1 per cent., and even less, in very large ones.

Are alternators ever connected in series? J. H.

No. With alternating currents voltages are raised by the simple means of transformers.

At what point on the sine curve does the E. M. F. change from plus to minus? J. J. G.

When a wire of a generator is midway between two poles, it is at zero potential and on the point of changing to plus or minus.

Would a greater amount of iron in a field core reduce the number of ampere-turns of the shunt winding? M. P. C.

Yes, but as the amount of iron in the field cores of a dynamo is calculated for a definitely fixed point of saturation, the question has no practical bearing.

How can I heat a tailor's goose iron by means of a 100-volt alternating current? E. H. T.

It will be cheaper to buy such an electric iron. The data will have to be determined experimentally. Use resistance wire zigzagged, but not coiled; have a choke coil in circuit while experimenting.

How is the rated candle-power of arc lamps fixed? W. C.

A 2000-CP (nominal) open-arc lamp is one taking 450 watts—usually 10 amperes at 45 volts at lamp terminals. A 1200-CP open-arc lamp is one taking 300 watts—usually 6.8 amperes at 45 volts.

Will hard-wood spools saturated with paraffine be as good for use in an induction coil as rubber or glass? C. J.

No. The value of the spools will depend upon the amount of paraffine absorbed. Hard rubber and glass both offer a much higher resistance to disruptive discharge than paraffine.

I wish to run a dynamo of 15 volts from a windmill. What should the power of mill be? W. E. R.

For how many amperes is the dynamo designed? The question as put can no more be answered than the similar one: What is the horse-power of a water-power whose head is 15 ft.

What is the estimated voltage of a Tesla coil giving a 10-in. spark? H.

It has been claimed that a large Tesla coil will give 200,000 volts. The effect of such coils does not depend upon the mean voltage that is measured with ordinary instruments, but upon the highest voltage attained, which is an unknown quantity.

How can the motor, whose construction is described in the February number, be altered for use on a 52-volt alternating-current, or 550-volt railway circuit? C. N.

The motor will not work on an alternating-current circuit, and it would be impracticable to adapt it for a 550-volt circuit. For windings of battery motors, see page 358, September, 1897, issue.

How are the resistance and the size of wire of a field rheostat determined? M. P. C.

The difference between the voltage at the terminals of the shunt at full load and at no load, divided by the maximum field current, gives the resistance. For carrying capacity of different wires in different forms of rheostats, see March issue, 1897.

Can a storage battery be made of lead and copper in a sulphuric acid solution? S. T.

Yes, but a very poor one. The lead plate will be peroxidized and the copper electrode dissolved on charge; on discharge, the peroxide will be reduced and copper redeposited on the copper electrode. Almost any primary battery is a storage battery in this sense.

1°. Can a water rheostat be made to absorb 12 KW at 115 volts? 2°. What E. M. F. is necessary to produce electrolysis of water? H. N. L.

1°. Yes; see articles on water rheostats in the December issue. 2°. Chemically pure water is not an electrolyte nor a conductor. 1.482 volts are necessary to electrolyze water rendered conductive by the introduction of some impurity.

How may two holes in the insulation between the commutator bars of a G. E. compound alternator be plugged permanently? S.

Fill the holes with sizzling hot melted shellac, dip fibre wedges cut to fit the holes in this, drive the wedges in and pare down flush and polish. It is probable that the only satisfactory cure will be a new mica segment.

1°. Would good soft steel castings do for the motor described in the February number? 2°. In this case, should the dimensions of the field-magnet core be increased? 3°. What are the windings of the motor for a 50-volt circuit? G. L. B.

1°. Yes. 2°. Not if first-class soft steel is used. 3°. Use No. 25 wire on field, winding it twenty nine layers deep, and No. 21 wire on the armature, putting on as many turns as can be gotten in the slots.

What is a "teaser coil"? F. C. M.

In early days a compound coil used on electroplating machine was called the teaser coil. In the monocyclic alternating-current system, the auxiliary armature winding is sometimes called the teaser winding, the line wire leading from it the teaser wire, and the voltage between the latter and either of the main line wires, the teaser voltage.

What should be the size of the core and secondary winding for an induction coil to give a 3-inch spark? R. F. A.

A core one inch in diameter by 10 or 12 ins. long will answer. Use No. 36 wire; if the coil is properly designed after the principles given on pages 18–21, January, 1897, issue, 3 lbs. of wire will be sufficient—otherwise the old rule of 2 lbs. per inch of spark had better be followed.

How may a storage battery by charged from a railway circuit? J. H. S.

It is impracticable to charge a few cells from a 500-volt circuit. For example, to charge 5 cells, 97½ per cent. of energy would be wasted to 2½ per cent. utilized in the cells. If 10 amperes passed through the cells, but 125 watts would be utilized while 4875 watts or more than 6½ HP would be wasted in the resistance necessary to cut the voltage down.

We have four D 62-KW, two M. P. 90-KW and one M. P. 225-KW generators running in parallel on a 550-volt circuit, but in starting up meet with trouble from the 225-KW machine running as a motor. The machine ran all right for a few weeks, but lately the commutator blackens and sparks badly?

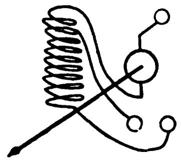
The trouble may lie in the equalizer or in the series coil, but is probably due to a difference in characteristic. See that the contacts are good at the equalizer connections, and that the equalizer conductor is of low resistance. The series coils may be shunted too heavily by the German silver resistance, or one of the coils may be faulty.

I have a T.-H. shunt wound motor, of 250 volts, 45 amperes and 1500 r. p. m., which I wish to use as a dynamo to supply current for arc and incandescent lamps. What changes will be necessary? D. B.

By using two incandescent lamps in series and five open arcs or two enclosed arcs in series, no change will be necessary. To change to 125 volts, rewind the fields with wire of half the present resistance, but using the same number of turns; or rewind with any size of wire, but keep the ampere turns the same. Short-circuit the commutator bars by pairs and reconnect in parallel to the adjacent coils, the armature coils thus thrown out.

What is a calibrating coil on a voltmeter? D.

When a voltmeter has two coils, as in the accompanying sketch, that for low reading is frequently called the calibrating coil. By means of a single cell of storage battery and a water resistance, a 150-voltmeter, for example, can be calibrated by means of such a coil over the entire scale. Instructions are given for calibration by this method on page 232, June, 1897, issue.



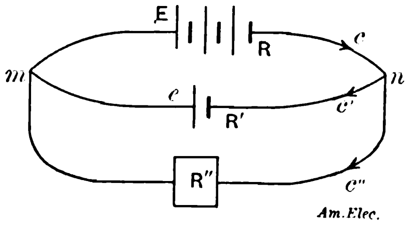
Am. Elec.

I have charge of a 75-KW, 4-pole, 500-volt Westinghouse railway generator, the commutator of which sparks badly at two diametrically opposite bars. If turned down, the sparking and blackening begins a few days after. I have changed the armature, but the new one acted the same. What is the matter? S.

Blackening like that described is ordinarily caused by a loose coil connection at the bars affected. It may be that the machine vibrates, causing the brushes to jump at certain points, thus starting the trouble, which will rapidly grow. To test the field, take a voltmeter and measure the voltage of each of the field coils, both shunt and series; if the voltage of any of these is not practically equal to that of its mate carrying the same current, that coil is probably faulty, which would distort the field and thus possibly cause sparking.

In the accompanying sketch, how are the currents in the three circuits calculated? D.

Let R, R' and R'' be the resistances of the circuits, containing R'', E and e, including the internal resistance of the cells; let V be the difference of potential between m and n, The current in the upper branch will be $C = \frac{E-V}{R}$; $C' = \frac{V-e}{R'}$; and $C'' = \frac{V}{R''}$. But $C = C' + C''$ or $\frac{E-V}{R'} = \frac{V-e}{R'} + \frac{V}{R''}$. Substituting the values of E, e, R, R' and R'', we get the value of V, and from that the values of C, C' and C''.



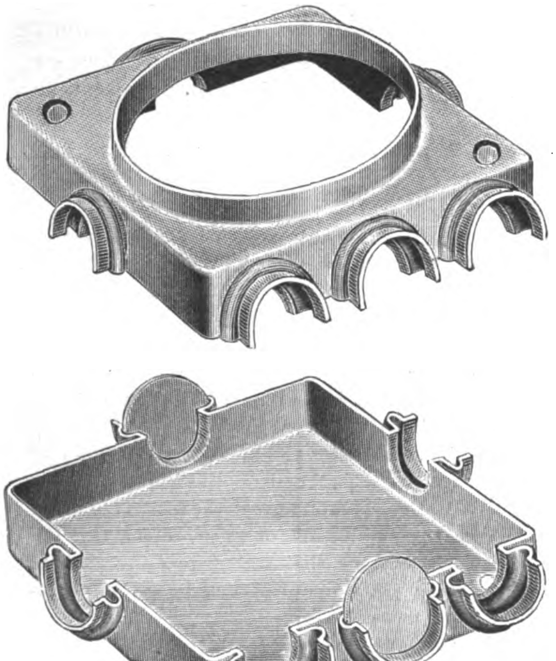
Am. Elec.

New Apparatus and Appliances

A STEEL "SPLIT BOX."

Outlet and switch boxes drawn of steel for use with iron-armored conduit are superior to the cast-iron box generally used for this purpose, both in conception and practical application, and are coming widely into favor. The latest addition to these steel boxes is that shown herewith, known as a "split box." It is very convenient to install, as the cut shows, and is more nearly water-tight than the ordinary split box, because of the unusual length of the lugs encircling the conduit.

An ingenious feature will be noticed on examining the inner edges of these outlet lugs. The openings at that point are smaller than the outside diameter of the conduit, with the result that the conduit cannot be thrust too far into the box. The steel disks shown are removable, but when in position render the openings practically water-tight. The box weighs only 21 ounces, is strong and practically indestructible. The manufacturers lay stress on the desirability of screwing the conduit into the box in order to form a thoroughly water-tight and fireproof combination, and they inform us that in the higher class of work boxes arranged in this manner, with threaded lugs on the sides and bottom for the conduit, are meeting with great favor.

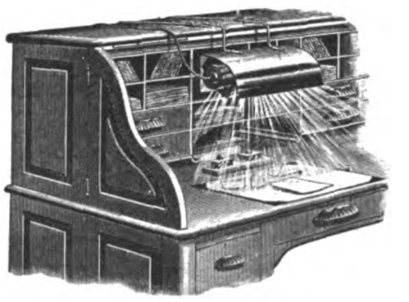


STEEL "SPLIT" BOX.

The Bossert Electric Construction Company, of Utica, N. Y., owns the patent and controls the manufacture of the box illustrated.

ELECTRIC DESK LAMP.

The desk lamp illustrated in the accompanying engraving is applicable to roll-top, flat-top and book-keepers' desks, typewriters' tables, etc. The light is soft and abundant, and so well distributed as to leave no shadows or dark corners on the desk; yet the lamp itself is entirely shaded from the eyes. In appearance it is ornamental and attractive, and in no way interferes with the opening or closing of a roll-top desk. For flat-top desks an upright mounting is used.



DESK LAMP.

All of the parts are of polished brass or nickel. This desk fixture is made by the Wareing Supply Company, 136 Liberty Street, New York.

COMMUTATOR COMPOUND.

The sparking of commutators has long been a source of serious thought and one that has caused the dynamo tender probably more trouble than anything he has had to contend against. It has reduced the working capacity of his motor or dynamo; it has worn out his commutators, wasted power, and in some instances destroyed thousands of dollars worth of machinery. Mr. K. McLennan, for a great many years chief electrician for Swift & Company, gave considerable thought to this question, and after four years of experimental work with machinery and brushes of all kinds, he invented Gale's commutator compound. The material is put up in convenient form, as shown in the accompanying illustration, and is claimed to prevent sparking and cutting of commutators; to save wear and tear of brushes, and to put a high finish to the commutators, without gumming the brushes. The compound is sold by K. McLennan & Company, 1128 Marquette Building, Chicago.

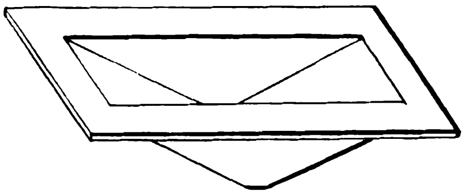
GALE'S
COMMUTATOR COMPOUND

COMMUTATOR COMPOUND.

BRAZING CRUCIBLE.

A new form of brazing has recently been perfected whereby a joint to be brazed is merely immersed in a crucible of molten spelter; the joint not only brazes in a few seconds of time, but comes out of the bath entirely free from scale, a brisk cleansing with a metal brush being about all of the treatment required.

The surfaces to be brazed are painted with a flux, and the adjacent parts with an antiflux. On account of the high degree of heat required, a special crucible for the molten metal is necessary, one of which is shown in outline below. It is 24 ins. × 6 ins. inside, the bottom forming an angle, and 10 ins. deep in the middle. It has a 3-in. flange to support it in a furnace, and can be used in a coke, coal, gas or oil furnace.



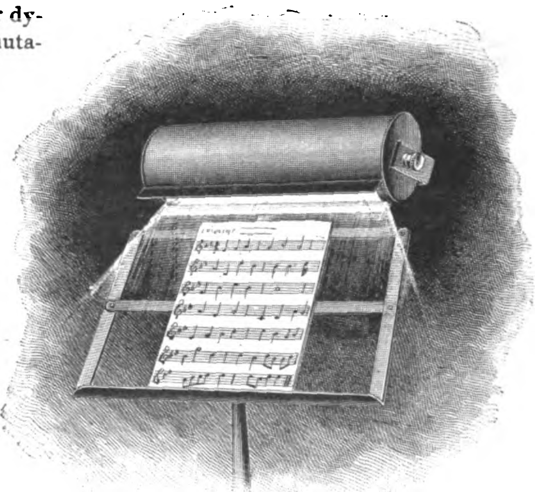
BRAZING CRUCIBLE.

The Joseph Dixon Crucible Company, Jersey City, N. J., manufactures the above described crucible and brazing fluxes.

ORCHESTRA LAMP.

As will be seen from the accompanying illustration, this new type of fixture is cylindrical in shape, the socket being inside the cylinder. The standard fixture is made to take a 16-CP lamp. The cylinder is pivoted on the ends and may be revolved in any direction. The cylinder is composed of two pieces, one of which revolves inside the other so that any desired opening may be obtained, depending on the volume of light required. It is fitted with an adjustable clamp for attaching to music racks.

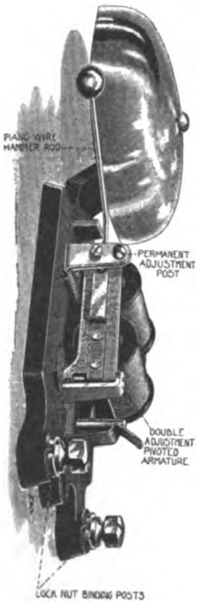
This device, although called an orchestra lamp, is just as valuable for lighting pulpits and pictures. The rector of St. Thomas' Church, New York, it is stated, experimented with several devices for lighting his pulpit, but did not find anything satisfactory until one of these lamps was installed. The fixture, which is known as the Ward Orchestra Lamp, is made by McLeod, Ward & Company, 27 Thames Street, New York.



ORCHESTRA LAMP.

IRON BOX BELL.

The principal feature in the electric bell herewith illustrated is in the mechanical construction, which is such that the various parts once assembled and adjusted, it is impossible to lose the adjustment. Instead of the usual contact post, the present one is made of two pieces of heavy metal placed under different tensions; a screw is provided which puts a tension on the binding contact screw and makes it impossible for either to loosen. Adjustments, however, can be easily and quickly made.



IRON BOX BELL.

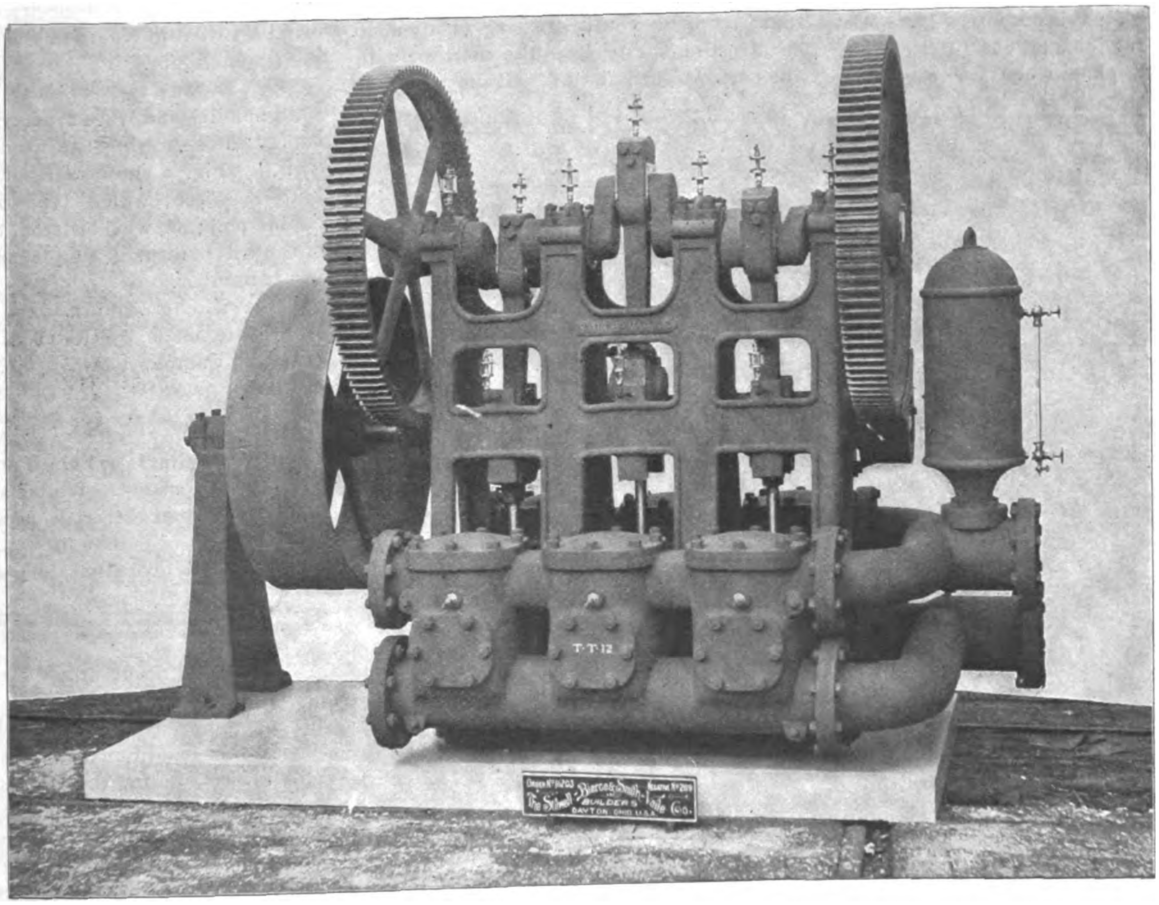
The armature is pivoted on a brass pin, which passes through holes drilled in the armature and into brass supports; this gives an easy positive movement, a clean stroke free from any wabbling, and always keeps the contact rivet against the contact screw point. This construction, also, allows the heel of the armature to be brought very close to the core without touching it, thus utilizing the full power of the magnets, and at the same time preventing the possibility of the armature sticking.

The contact and adjusting spring is made of one piece of phosphor-bronze spring. This gives a perfectly balanced armature movement, and a simpler and more positive adjustment than can be otherwise obtained. The gong cannot turn or loosen, and is therefore always in striking position. The hammer rod is formed from spring wire, always retains its shape, and will not get loose either in the armature or hammer. The cover is made of cast-iron neatly japanned both inside and out, and is held firmly in place by a German silver spring.

The bell above described, known as the "Improved B. B. Iron Box Bell," is made by the Central Electric Company, Chicago.

ELECTRIC PUMPING.

The application of electric power to pumping service is coming more and more to the fore. Thus far most of the electric pumping plants have been installed in the West, where their advantages were early recognized, but knowledge of these advantages and of the opportunities which electric pumping offers for leveling the load line, is becoming more general, and there is every prospect that this application of electric power will soon become widely extended. In New York City it has been found profitable to sell electric power in large quantities at less than four cents per HP-hour, notwithstanding the enormous cost of the underground distributing system. In localities where coal is cheap, and with a rational system of charges instead of the usual system that makes no allowance for long-hour heavy service, even small plants should be able to sell current during hours of light load at a cost which would enable it to be used for pumping purposes.



TRIPLEX PUMP.

Manufacturers of pumps have been awakened to the possibilities of electric pumping, and one of the newest designs of a triplex pump specially applicable to such service is illustrated herewith. Among the features in this pump which are new is the use of four standards, giving four bearings for the crankshaft—in other words, giving the piston connections a bearing on each side. The piston rods are guided by cross-heads with adjustable brass shoes, in this way preserving a perfect alignment at all times and insuring that the stuffing boxes will not cut.

Another feature is that the cylinders are cast separate from the pump, thus being removable and enabling a new cylinder to be supplied at any time. The frame is raised high enough above the pump so that the parts are easily accessible for packing; a piston packing is used with this type of pump, as it is believed to be the best for the service. The valves are given a very large area, which allows a high speed without any undue fluctuations or hammering. All the valves seats are made of composition and are screwed in place. Where thick liquid is used and in "stuff" pumps, the valve chambers are altered somewhat, and ball valves are used. The gear is cut gear, and for pressures of 150 lbs. and above are beveled gears; for 80 lbs. and below a single gear is used.

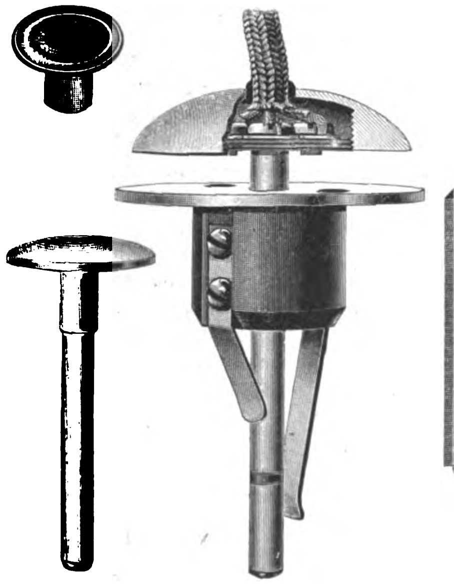
The motor is mounted on a base flanged and bolted to the pump base, thus making an alignment which is perfect. The shaft is provided with ring oilers, and the crossheads have oil packings. The cranks are of steel, and the piston-rod boxes are of the regular engine type.

FLOOR PUSH.

Among the class of electrical appliances known as "electrical house goods" there is no article which has given as much trouble to user and electrician as combination floor pushes. In the position where they are generally used, under dining room tables, they are very liable to be broken when the table is moved to one side to clean the rug.

To obviate this liability, the push shown in the illustration has been devised, its special advantages being that it is impossible to break the top, owing to its rounding shape, which allows a table leg to roll over it without doing any damage. If the cord is pulled hard, it will not break the small conducting wires, because a knot can be made in the flexible cord under the cap, or a special cord used, as shown in the illustration.

Only one hole is required in the floor plate for both plugs, which in use pass through an eyelet that has been pressed through and easily fastened in the carpet or rug without breaking the strands, by a tool made specially for this purpose. The eyelet used in the rug enables one to easily find the floor-push plate when the rug is replaced after cleaning. The portion inserted in the floor is securely held, as it exactly fills the hole. The distance between floor plate and top is adjustable, and a rubber bushing is used where the cord passes through the cap.

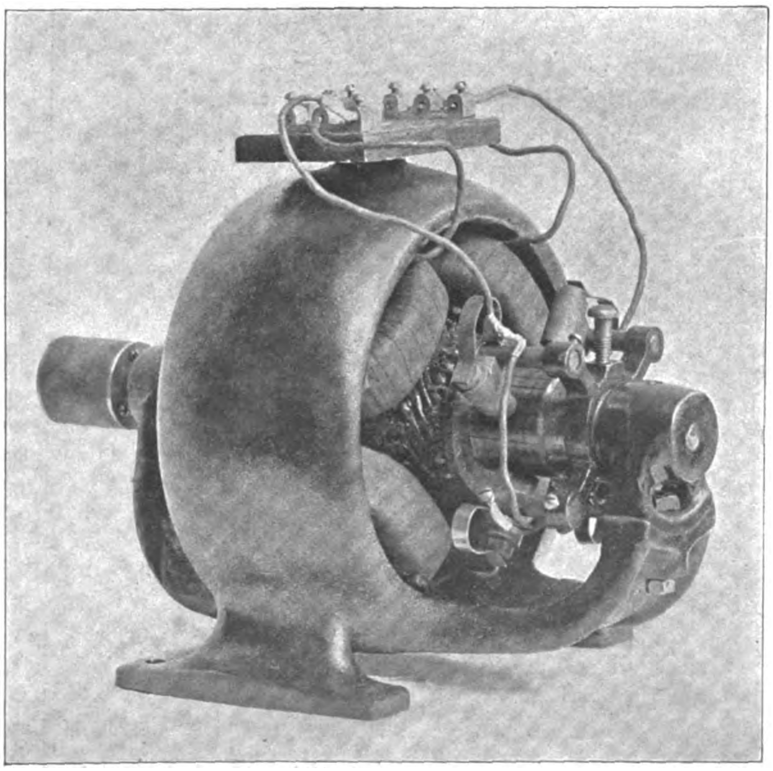


FLOOR PUSH.

This push, known as the "Dandy Floor Push," is manufactured by The Electric Gas Lighting Company, 195 Devonshire Street, Boston.

A DYNAMO FOR EXPERIMENTAL PURPOSES.

The illustration herewith shows a new design of dynamo for experimental purposes, manufactured by the Institute for Home Study of Engineering, of Cleveland, O., for its students. Though especially adapted to experimental work, it is also a commercial machine, the idea in furnishing such an apparatus being that after the student has finished his course he can use it for a practical purpose. When the student reaches that part of his course treating of dynamo construction, he receives the machine with the parts finished and with all the materials for winding; the work of making the armature complete, putting on and connecting the field coils, is a part of the electrical course of the Institute. When completed, the student uses the machine experimentally during the remainder of his course.



DYNAMO FOR EXPERIMENTAL PURPOSES.

The illustration shows the machine complete. The armature is of the drum type with laminated core. The commutator is long in order that collector rings for taking off currents uncommuted, and in from one to three phases, may be slipped on it, together with the new set of brushes required. When operated as an alternating-current machine, it excites its own fields.

The range of experimental use is wide, and teachers of electricity find that the practice of winding and connecting the machine is of great value to the students.

FLUSH SWITCHES.

The accompanying illustrations show several types of flush switches that during the past year have been finding much favor among contractors and electricians who demand a switch in regard to whose reliability there is no doubt.

Fig. 1 shows a type of flush switch with solid handle, and Fig. 2 a key switch with an indicator showing the words "on" and "off." Fig. 3 shows a single-pole push-button switch, which type is also made double pole; as will be seen, the principle of the mechanism is simple, and the parts few in number.

These switches, known as the "New England," are made by the O. S. Platt Manufacturing Company, Bridgeport, Conn.

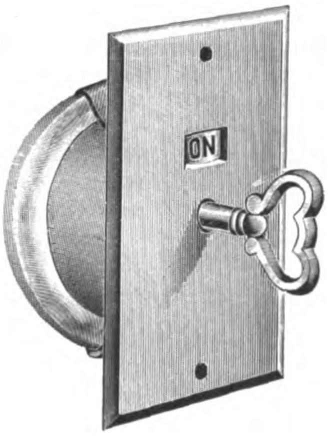

FIG. 2.—KEY SWITCH.

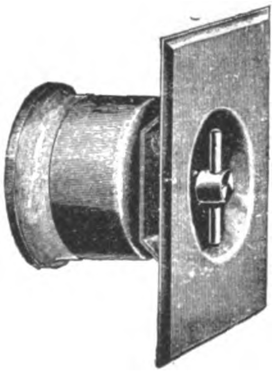

FIG. 3.—FLUSH SWITCH.

A NEW ARC-LIGHT CARBON.

Where steadiness of light is an object, and for use on constant-potential arc lamps, an expensive cored carbon is necessary. The grooved type of carbon herewith illustrated is claimed to give all of the good results of the much more costly cored carbons, and to possess the additional advantages of not only always holding the arc in one position, but, of exposing a maximum area of crater, the illumination from which is directed at the most desirable angle, and not downward as in the case of the central crater. In addition, the grooved carbon is claimed to prevent clinkering. Even with the best German carbons a clinker will occasionally build up on the lower pencil until it comes in contact with the upper one, when the light flickers or goes out. With the grooved

GROOVED ARC-LIGHT CARBON.

carbon, this clinker, when it appears, approaches the upper pencil where the groove has cut away the carbon, which, therefore, offers no point of contact; the feed of the lamp preventing an approach, under these conditions, sufficiently close for contact.

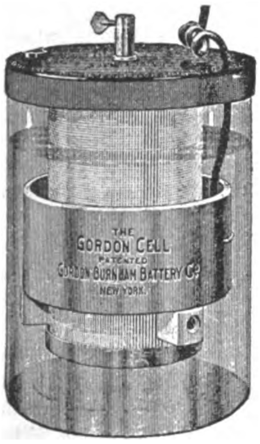

FIG. 1.—GORDON CELL.

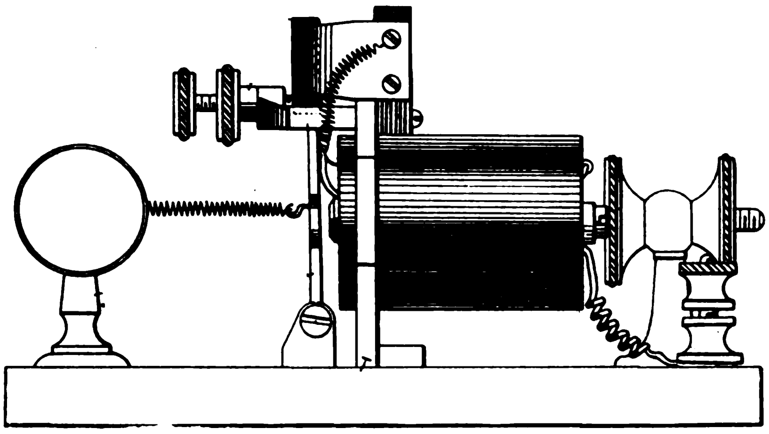

FIG. 2.—BANKS AUTOMATIC RESISTANCE INSERTER.

The carbon, as will be seen in the illustration, has a groove running laterally from end to end. In one style, used for general purposes, the groove is only sufficiently large to open the crater and hold the arc in position. The other is a "focusing" or larger groove, and is suitable for use in railway yards, shop windows, or wherever it is desired to throw the light in a definite direction.

The grooved carbon is used for the upper pencil, and in about two minutes after starting up, permanently adjusts its crater, all of the surface of which is effective in producing light. For general lighting, the carbons register axially; when a focused light is required, the groove is turned toward the objective point, and the lower carbon set slightly in front.

The new type of carbon described is made by the Open Arc Carbon Company, Downing Building, New York.

GORDON PRIMARY BATTERY, AND BANKS AUTOMATIC RESISTANCE INSERTER.

The old form of blue-stone gravity battery was defective in so many respects that its use was limited to the special conditions of telegraphic work, where a high internal resistance and low-rate current were not objectionable. The new form of alkaline cell herewith illustrated possesses none of these disadvantages of the old type, and is claimed to be superior to other primary cells in that it cannot be polarized under the most severe closed-circuit work, a constant current being maintained until the elements of the cell are exhausted. Its commercial E. M. F. is from .65 to .75 volt under working conditions, and it has been known to hold its voltage until an output of 375 ampere-hours or 250 watt-hours have been drawn from the elements contained in a 6 in. × 8 in. jar.

The negative element consists of a perforated tin cylinder filled with black oxide of copper, which is a powerful depolarizing agent. Three porcelain lugs or cleats are attached to the lower part of the tin cylinder, upon which rests a rolled-zinc cylinder 5½ ins. in diameter, 2½ ins. wide, and containing 1½ lbs. of chemically pure zinc amalgamated by a special process. The internal resistance of this cell is from .04 to .06 ohm.

The solution used is an alkaline technically known as electro-sodium, which will not freeze or be chilled at winter temperatures as low as 25 to 30 degs. below zero, Fahr.

These cells are largely used in the telegraph and other services of the Federal Government, by various large railroads telephone and telegraph companies, and in the fire and police telegraph departments of a large number of cities.

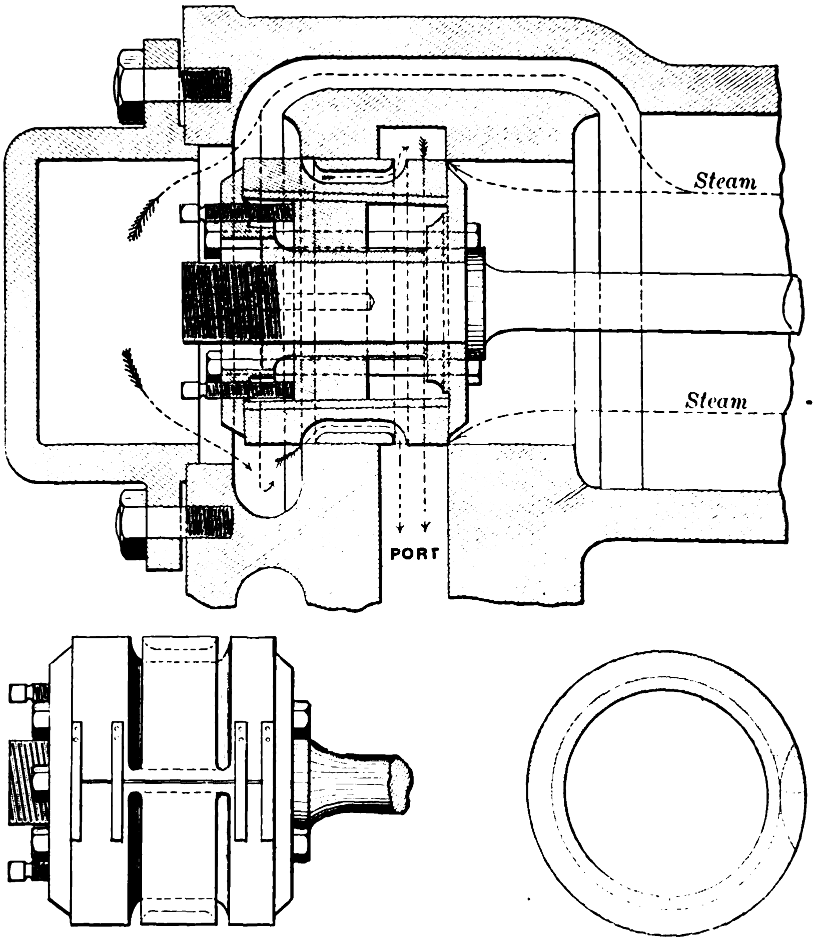
When used in block-signal work, on account of the low internal resistance of the cell, the current is apt to be excessive when a train of cars is on the block. In order to overcome this objection, Mr. Banks, the electrician of the Gordon-Burnham Electric Battery Company, has perfected a device which automatically keeps down the current discharge to an amount necessary to work the signal service. This device is illustrated in Fig. 2. There are two coils, one a primary and the other a secondary. The primary is of low resistance and the secondary coil, which is normally cut out of circuit, and only cut in when a train comes into the block, is of the same resistance as the relay used under normal conditions for operating the signal circuit.

When a train comes into the block, an excessive current starts to flow through the primary coil, which attracts an armature and throws into series with the batteries the resistance of the secondary circuit, which remains there until the train runs off the block, upon which the armature falls back into its former position and thus throws again into circuit the primary coil.

The primary cell and Banks automatic resistance inserter above described, are manufactured by the Gordon-Burnham Battery Company, 82 West Broadway, New York.

THE FITCHBURG VALVE.

The valve shown herewith, used on the Fitchburg engine, is notable in several respects. It is perfectly balanced and its construction is such that all wear is taken up, the makers guaranteeing the valve in this respect for twenty-five years. The details are excellently shown in Figs. 1 and 2, and it is only necessary to note that by removing the bonnets, which have ground joints,



FIGS. 1 AND 2.—FITCHBURG VALVE.

the valves are easily accessible. By slacking the bolts bearing on the head of the valve and tapped into the center plug, then tightening those tapped through the head and bearing against the taper plug, the latter is forced in and the valve expanded in diameter to any amount desired, from $\frac{1}{10000}$ in. up to $\frac{1}{16}$ in. The makers state that an hour's attention once a year will keep the valve steam-tight during the life of the engine.

The valve motion is shown in Fig. 3. The wrist-pin actuating the valve travels in the concentric arc of a cam, without moving it during more than half of its travel, then gradually starting the valve until its edge reaches the edge of the port; the form of the cam is such that the valve is then thrown open suddenly, remains open until cut off, and is then suddenly closed. The steam port is thus opened and closed swiftly, the valve only traveling as far as is necessary to fully open the port and then returning to its rest, when the valve at the opposite end opens and closes in its turn. The point of cut-off is automatically varied from nothing to two-thirds stroke with, the manufacturers claim, absolutely even speed.

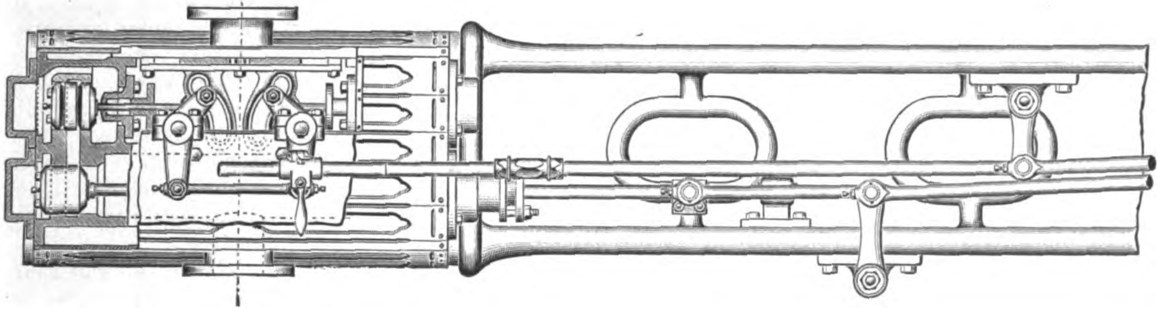


FIG. 3.—VALVE MOTION, FITCHBURG ENGINE.

The double-ported valve used and quickness of opening and closing of the valve with this gear, necessarily gives as clean an admission and cut-off as is obtained by the most efficient releasing valve-gear, with the advantage that the complications of the latter are avoided. With this valve motion a speed can be obtained ranging from 70 to 200 r. p. m. with perfect satisfaction, and with no noise, there being no dash-pots or clicking or catching of releasing gears.

IMPROVED ROBERTSON-THOMPSON INDICATOR.

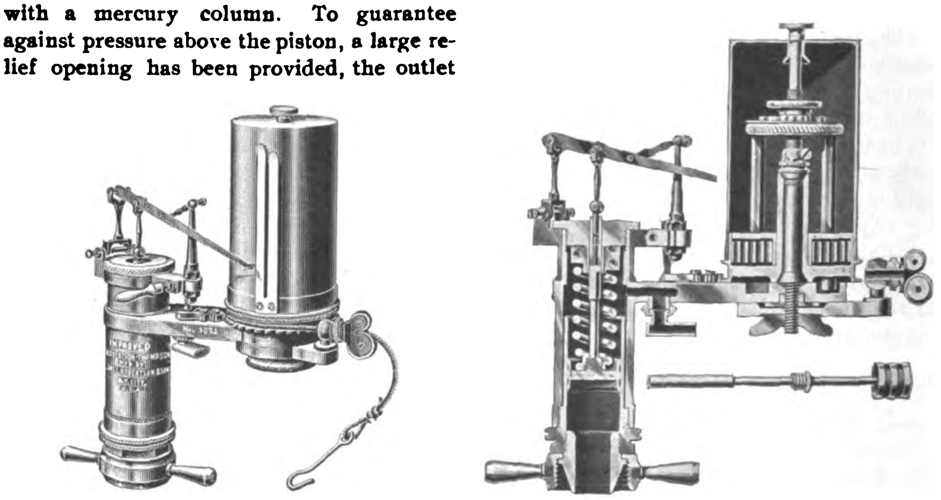
The improved Robertson-Thompson indicator, which has just been placed on the market, is unusually heavy, but as a result of most careful experiment this weight is so perfectly distributed that the best results may be attained at speeds far in excess of any met with in actual practice. One of the most serious errors in ordinary indicator work is caused by flexure of the arm which carries the drum, particularly when the cord is carried above or below the instrument. In this manner an error of 10 per cent. is easily possible, particularly if the instrument is being used with a high-pressure spring. For instance, with an 80 spring, it would require a movement of but $\frac{1}{80}$ in. to show an error of 1 lb. In many cases weakness at this point will account for the curious features often noticed at the junction of the admission and steam lines on the diagrams. The drum-carrying arm of the improved Robertson-Thompson indicator is so stiff that no error from this cause is possible.

The cylinder is steam-jacketed, and by its construction the possibility of the piston being cramped as a result of external strains is precluded. The area of this cylinder is exactly ½ in., and each spring is suitable for twice the pressure stamped on it; for instance, a 60 spring may be used for a pressure of 120 lbs. or less. The coupling is reamed to ¼-in. area, and with each instrument an extra ¼-in. piston is furnished, as shown in Fig. 2. With this piston each spring may be used for pressures four times as great as the number stamped thereon, so that with a 60 spring 240 lbs. may be safely indicated. This extra piston is of special value for hydraulic and gas-engine work. The pistons are made of steel, but phosphor-bronze will be substituted if preferred. The piston springs are standardized by the most approved testing apparatus, in connection with a mercury column. To guarantee against pressure above the piston, a large relief opening has been provided, the outlet being a neat swivel elbow, by means of which the "blow" may be discharged in any direction, at the will of the operator. Each instrument is provided with a detent or stop motion.

In Fig. 3 a new device is shown for adjusting the tension of the drum spring. By rotating the knurled head, *S*, to the right, the spring may be tightened as much as desired, and securely held by pawl, *P*; the ratchet wheel, *N*, is securely attached to the shaft by means of a left-hand thread. Thus the tendency of the drum spring is to tighten this ratchet nut more firmly. By pressing the thumb in to the recess in the spring winder, *S*, the pawl is released, when the tension may be diminished to any desired amount. This ratchet wheel has 16 teeth, which provide for the adjustment of the spring to a nicety. Drum springs are of the clock type, but spiral form will be furnished if preferred. Cone bearings are provided to take up all wear of the drum spindle. The parallel movement is made of tool steel, highly polished and richly blued. All bearings are wide and perfectly fitted.

All moving parts are worked down to the lightest weight consistent with durability. For comparison, it may be stated that the drum weight is but 1¼ oz., and the pencil lever 25 grs.

By special order the instrument is fitted with improved Victor reducing wheel, which comprises the usual cord-feeding device. The manufacturers are James L. Robertson & Sons, No. 204 Fulton Street, New York.



FIGS. 1 AND 2.—ROBERTSON-THOMPSON INDICATOR.

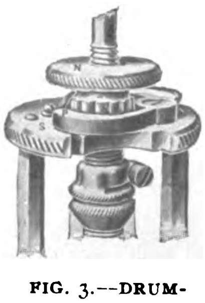


FIG. 3.—DRUM-SPRING ADJUSTING DEVICE.

AUTOMATIC WEIGHING MACHINES.

The accompanying illustrations show two classes of weighing machines made by the Pratt & Whitney Company, one being a gravity and the other a power machine. The former is applicable for weighing materials which spout freely, such as all kinds of grain, coffee, etc., while the latter is especially adopted for checking the weights of coal when received, and ascertaining the amount consumed daily in steam generation.

The machines are built upon the interlocking principle, which makes it impossible for both the supply valve and bucket closer or discharge valve to be open at the same time, thus preventing the material from going through the machine without being weighed and the weight registered. For example, if the supply valve in the receiving spout is open, letting the material into the bucket, it is impossible to open the bucket closer, and remove the material until the entire amount the machine is set to weigh has passed into the bucket. At this moment the supply valve closes automatically while the bucket closer unlocks, and the interlocking device connected with the latter passes behind the interlock on supply valve; the supply valve cannot, therefore, open until the bucket is closed, and *vice versa.*

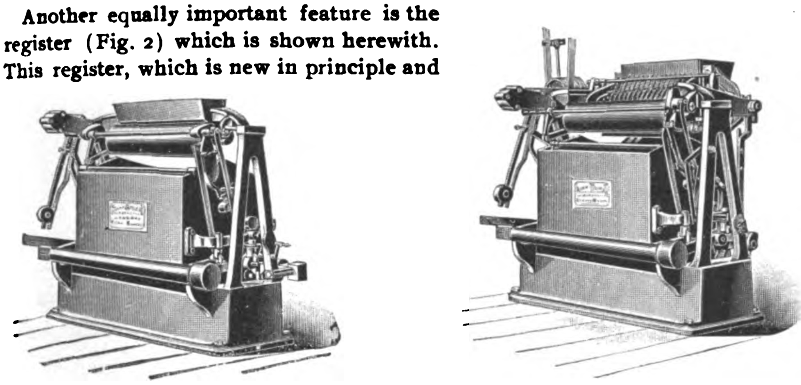

FIG. 1.—AUTOMATIC WEIGHING MACHINE.

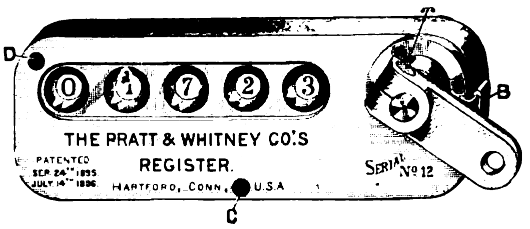

FIG. 2.—WEIGHT REGISTER.

Another equally important feature is the register (Fig. 2) which is shown herewith. This register, which is new in principle and design, is so connected with the bucket closer of the machine that it has a positive motion each way, and when the closer opens and closes, it registers one only, it not being possible to count more than one at a time with the two movements of the closer.

The machines are so constructed that in addition to the regular counter or register, an additional "stop-motion" register can be attached and set to weigh a given quantity or a specified number of drafts. When that number has passed through the machine, it will stop and remain in that conditon until the "stop-motion" register or counter is adjusted and the machine started off again, making it possible to weigh two or more different component parts of a fuel mixture.

The "power-feed" machine is practically the "gravity" scale with the addition of a feeder arrangement for delivering the material into the bucket. This feeder or supply apparatus, is an endless belt or conveyor, composed of a pair of drive chains and a series of overlapping slats, or bars, pivoted at one end to the chain links. On the upper side of the conveyor the bars lie flat to form a continuous surface, but on the lower or return side the bars swing down and so leave openings for the escape of any material that may have accumulated within the conveyor. The feeder belt is operated by belt-driven shafts and gearing having two speeds.

When a load has been discharged, the return movement of the bucket closer shifts the driving belt on to the high-speed pulley which then operates the conveyor, rapidly supplying material to the bucket, until a major part of a load has been received therein. Then the bucket partially descends and shifts the belt for slowly operating the feeder on to the slow-speed pulley for supplying the "drip" to complete the load. When the weighing mechanism is thus brought to a true poise, the feeder is instantly thrown out of action, and a valve brought into position to retain any material that may accidentally pass over the discharge end of the feeder belt after the poising has been accurately effected.

The machines described are manufactured, in sizes ranging from 2 lbs. each to 2000 lbs., by the Pratt & Whitney Company, Hartford, Conn.

MULTIPOLAR ELEVATOR MOTOR AND AUTOMATIC CONTROLLER.

The accompanying illustrations represent the class "E" reversible, multipolar "Keystone" elevator motors and automatic controllers. The field frame and poles of the former are of open-hearth steel, which combines the desirable features of high permeability, lightness and strength. The illustration shows the method of removing the field coils without taking out the armature, a very desirable feature in elevator work. The field is compound wound, all four poles having shunt coils, which are interchangeable. The end coils, which are longer, have series coils in addition to the shunt coils.

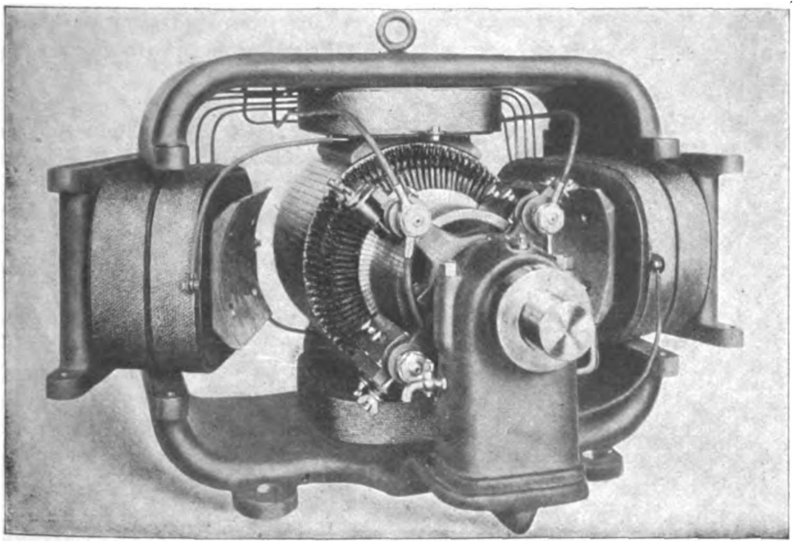

FIG. 1.—KEYSTONE ELEVATOR MOTOR.

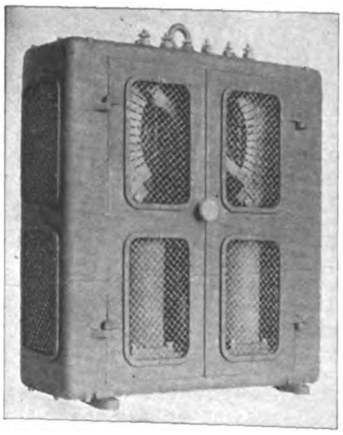

FIG. 2.—AUTOMATIC CONTROLLER.

The series coils are very much larger than in the ordinary compound-wound motor. The effect of these coils is to produce a very strong field and large starting torque immediately after the switch is closed for starting the motor, thus reducing the starting current. They are automatically cut out after the resistance in the automatic rheostat has been cut out and the motor has nearly attained its full speed. The shunt coils are of ample strength to operate the motor after attaining speed, and give a nearly constant speed for varying loads. In this manner are combined the advantages of a series motor for starting, and a shunt motor for operating after speed is attained.

The armature is Gramme-ring wound and of the iron-clad type with overhanging teeth, no binding wires being required. This permits of quick and easy repairs, and without removal of commutator if it is necessary to renew but a few coils. These motors are manufactured in sizes varying in capacity from 6 HP to 54 HP.

The automatic controllers are made in sizes to comform to the different sizes of motors. The principal features of these controllers are compactness, perfect ventilation, neatness of design, large number of contact plates and reliability under the most severe duty.

Among the large installations may be mentioned the American Lithograph Building, corner Ninteenth Street and Fourth Avenue, New York City, in which there are eight 30-HP motors in successful operation. The manufacturers, the Keystone Electric Company, Erie, Pa., have nearly 1000 motors in successful operation on elevators in different parts of the country.

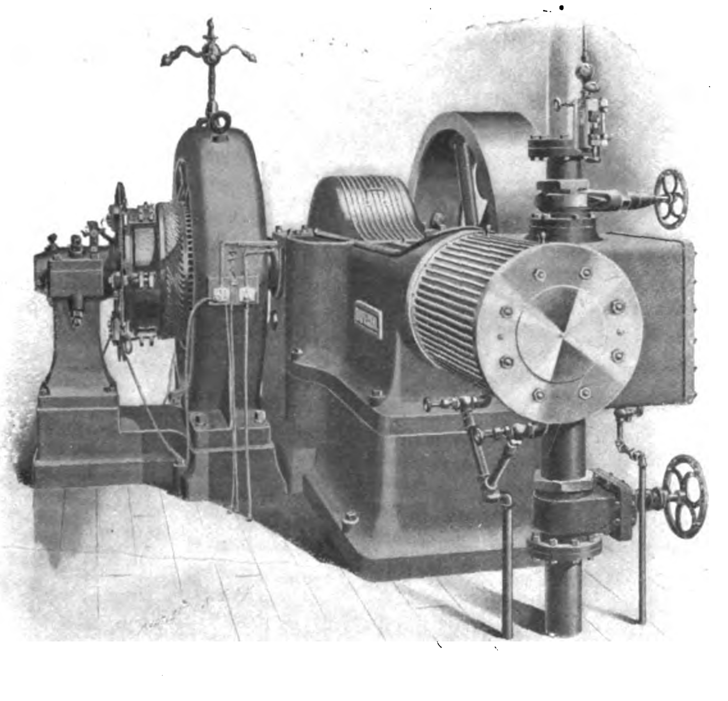
THE WESTON ENGINE.

The accompanying cut shows a 14 in. × 14 in. Imperial engine, which was exhibited at the recent Tennessee Centennial and awarded a silver medal. The engine is shown direct-connected to a 75-KW Triumph generator. The Imperial engine is of the center-crank automatic type, and is built for high and medium speeds. The engine is self-oiling; a partition plate prevents the oil in the crank case from coming into contact with the heated cylinder. The valve is double ported and balanced by means of a pressure plate, which is recessed with four openings to correspond with the ports of the cylinder. Between the pressure plate and steam-chest cover is a coil spring so placed as to allow the valve and plate to lift from the valve seat should the cylinder receive a charge of water.

The cross-head is of a new design and possesses the unusual features of fitting together in correct alignment and eliminating any possibility of the piston rod getting loose and backing out. It is made in two longitudinal sections, being divided on the line through the center and parallel with the face of the guides.

A governor of the Rites type is used, consisting of but a single moving piece swung on a single supporting arm, the eccentric even forming an integral part of the weight construction. In this type of governor, it will be remembered, the centrifugal element upon which the degree of refinement and regulation of all governors depends, is combined in the same piece with an inertia element relatively so great that instantaneous changes of load are provided for without waiting for centrifugal action. The most prominent feature, however, is the resistance which the exaggerated inertia offers to the disturbing action of gravity, a balancing weight being thus dispensed with and the whole governor reduced to a single piece.

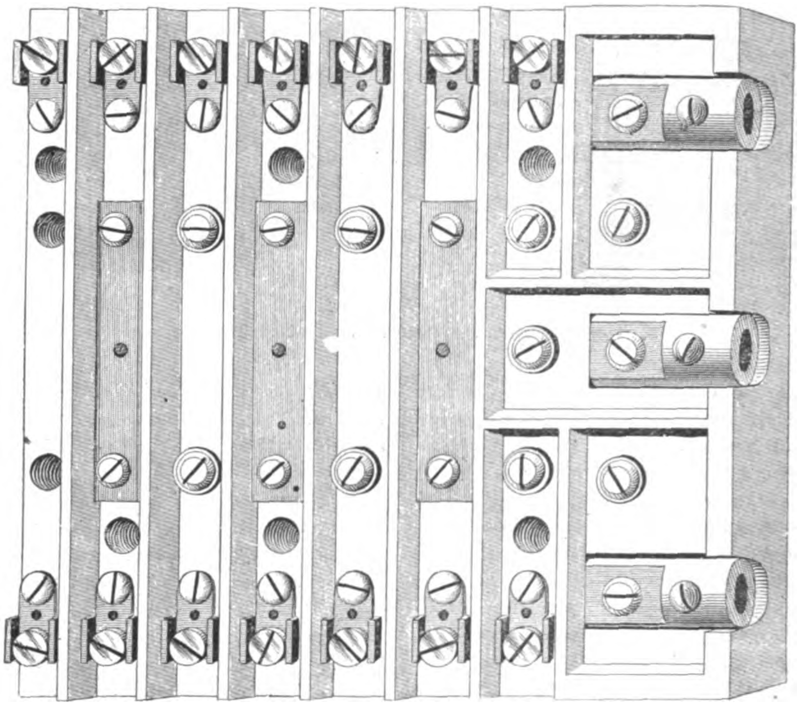
By means of this governor, remarkable simplicity and the most sensitive regulation are combined, a much greater uniformity of economy over the range of cut-off being thus available than was formerly possible. The Imperial engine is manufactured by the Weston Engine Company, Painted Post, N. Y.



IMPERIAL ENGINE AND TRIUMPH DYNAMO.

PORCELAIN-TABLET BOARDS.

The multiple-tablet form of switch-board has for the past several years come rapidly into use, and may now be considered to represent standard practice. A late type is illustrated herewith, designed for the three-wire system. The board is made of sectional pieces of porcelain and can be built for any number of circuits. The same type is also made for the usual two-wire circuit. The manufacturers are the Peru Electric Manufacturing Company, Peru, Ind.



PORCELAIN-TABLET BOARD.

BELT-DRIVEN RAILWAY GENERATORS.

So rapid has been the development of the railway generator directly connected to the driving engine, and so extensive its adaptation, that the railway public is apt to lose sight of the fact that the belt-driven generator is still greatly in demand. Many cases exist in which the conditions do not warrant the installation of direct-connected apparatus, and to these cases the belt-driven generator is more applicable.

Improvements in belt-driven generators have kept pace with those in all other classes of electrical apparatus, and the distinguishing features of excellence of the General Electric Company's direct-connected apparatus have been incorporated in its new line of belted machines. These are all six-pole generators, built in five sizes ranging from 110-KW, to 500 KW. That shown in the illustration is a 110-KW, six-pole, 500 revolution machine.

The magnet frame is of cast-steel heavily ribbed, making it both light and compact. Its magnetic efficiency is the highest obtainable. The bearings, which are built upon the ball-and-socket principle, are self-aligning and self-oiling The steel poles and pole pieces are cast in one piece and so bolted to the frame that they may easily be removed without disturbing either the armature or the frame.

The series winding of the field coils is of flat copper ribbon, the shunt winding of wire. Instead of winding the series coil on the field spool and covering it with the shunt winding, both windings are placed side by side on the pole, and being entirely independent, either may be removed without disturbing the other. It is no longer necessary with this new method to remove the shunt winding to reach the series winding.

The armature is of the barrel-wound type, such as is used in the General Electric direct-connected generators. This method of winding gives the smallest number of joints, and facilitates any necessary repairs, as few coils need to be removed to reach any particular one incapacitated for service. The cast-iron flange, bolted to the armature spider at each end of the core, forms a support as well as a cylindrical receptacle for the projecting ends of the coils. The coils are secured firmly in the slots of the core, and the cross connections are made on the barrel flange. The projecting ends of the coils in the flange are thoroughly insulated and held in place by steel bands. The flange extension also protects the windings from any oil that may be thrown from the bearings. The surface of the interior of the armature is perfectly smooth, offering no opportunity for the collection of oil or dust.

Ventilation is effected by the use of specially constructed vanes forming air ducts between the laminæ of the core. These convert the armature into a blower, and create a strong draft through the windings. The commutator leads are taken directly from the coil to the segment immediately beneath it. The construction of the commutator is similar to that of the direct-connected machines. It is ventilated by air drawn through the body and discharged through air ducts in the core. The small difference of potential between the segments secures the permanence of the insulation and freedom from sparking.

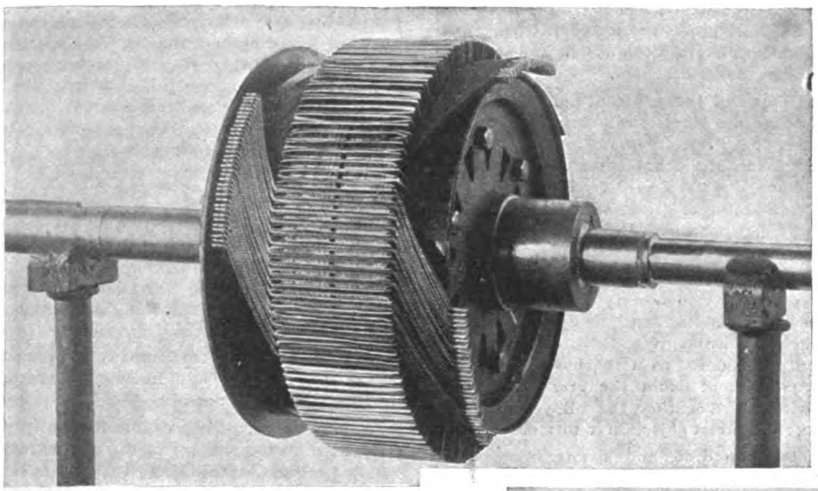


FIG. 1.—ARMATURE, PARTLY WOUND.

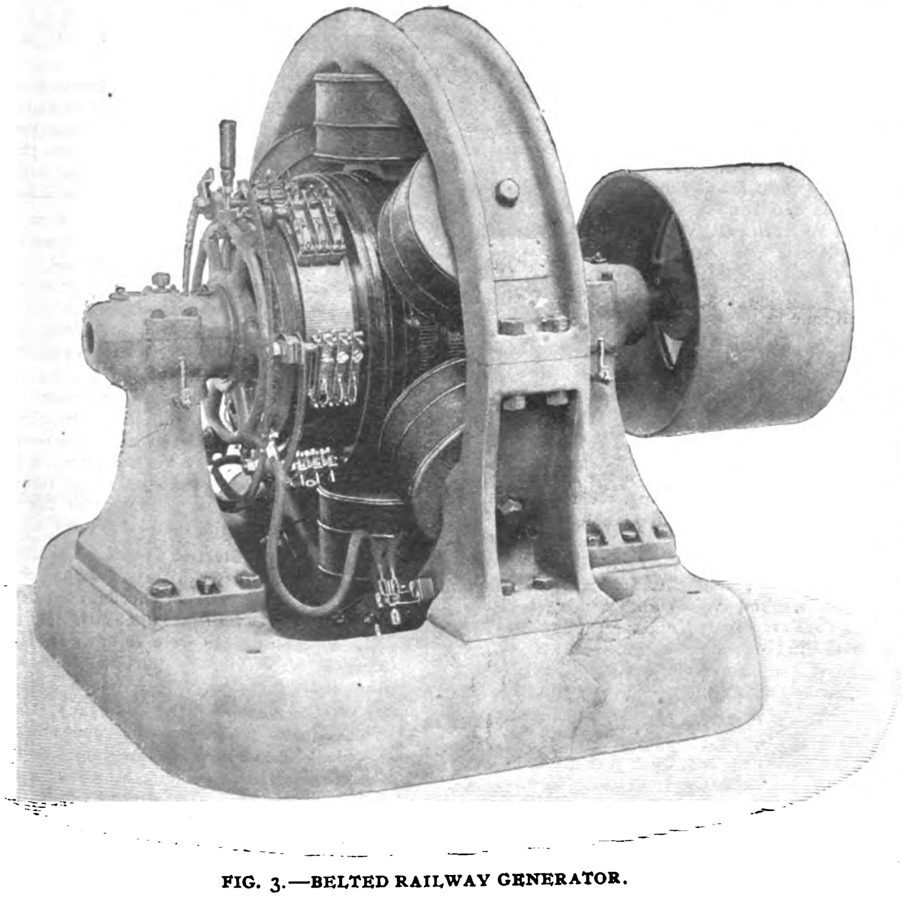

FIG. 3.—BELTED RAILWAY GENERATOR.

The strength of the magnetic field in these generators is so proportioned to the armature reaction that a constant brush lead and neutral point are ensured even with heavy overloads. These G. E. belt-driven generators have only been recently introduced, but up to Oct. 1 over fifty-five machines have been sold, aggregating considerably over 10,000 KW.

◆

NEW BOOKS.

PATENTED TELEPHONY. A Review of the Patents Pertaining to Telephones and Telephonic Apparatus. Chicago: American Electrical Engineering Association. 102 pages, illustrated. Price, $1.50.

To telephone manufacturers, owners of independent telephone exchanges, and all who wish to know the present situation with respect to telephone patents, this book will be invaluable. It is also a useful work technically, as all of the important details of switch-boards and other exchange apparatus are described and illustrated—in many cases for the first time outside of patent specifications and court records.

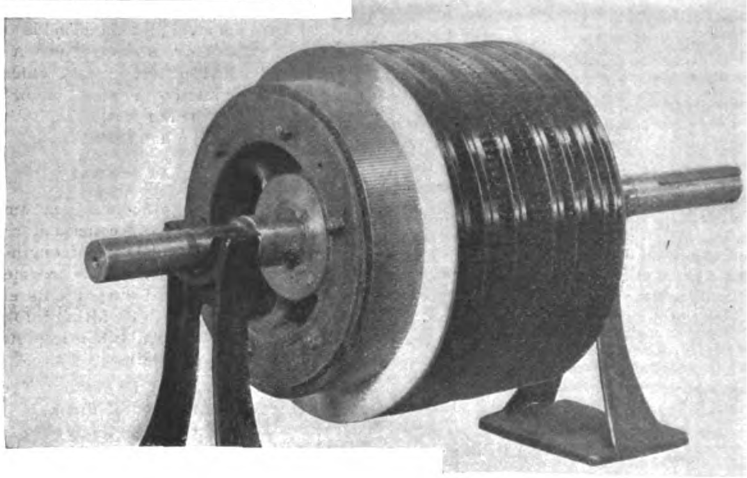

FIG. 2.—FINISHED ARMATURE.

THE MOTOR ENGINEER'S AND ELECTRICAL WORKER'S HANDBOOK. By Wm. Lintern. West Park, O: Wm. Lintern. 150 pages, illustrated. Price, 75 cents.

This is a book of instruction and reference in pocket-book form for the use of motormen and electric railway men generally. In the first four chapters the elementary principles of electricity and electrical machinery are briefly referred to. The following chapter and Chapter VIII, are reprints of instructions for operating generators and car apparatus, issued by the Westinghouse Company. The electric motor is briefly considered in Chapter VI, and the following chapter is on the measurement and tests of electric-railway motors. Chapter IX and XI contain detailed descriptions of motor-car apparatus and wiring. Chapter X contains definitions of electrical terms, and the final chapter consists of general electrical and mechanical information. The book will be found of assistance by motormen and others connected with street railway operation, who do not care to take up the systematic study of the subject, but desire to obtain some information concerning practical details.

THE THEORY OF ELECTRICITY AND MAGNETISM. Being Lectures on Mathematical Physics. By Arthur Gordon Webster, A. B. (Harvard), Ph. D. (Berol). New York: The Macmillan Company. 576 pages, 101 illustrations. Price, $3.50.

The object of this work is to present to the student an introduction to the mathematical theory of electricity as built up by Faraday, Maxwell, Hertz and Heaviside. The treatise is intended for students and others who have studied the calculus and vector analysis. A considerable portion of the work is purely mathematical, the writer aiming to bring out the geometrical or physical nature of the processes involved before coming to their electrical application. Though not so easily read as Mascart and Joubert, it does not present the difficulties encountered in Maxwell and in Heaviside, and has the advantage of including much of the work of the latter and that of Hertz.

◆

PERSONAL.

Mr. Seth C. Adams has been appointed by the Walker Company to look after its interests in central New York, and has opened an office and will have his headquarters at Utica, N. Y. With an uneqaled acquaintance within his territory among the electrical fraternity, Mr. Adams will be able to render a good account in his new appointment.

Mr. George R. Blodgett, counsel in charge of the patent business of the General Electric Company, was killed by a burglar in his home in Schenectady, early in the morning of Dec. 3. Notwithstanding the offer of a reward of $5000 by the General Electric Company, and most strenuous efforts on the part of the local and other detectives, no clue to the murderer has yet been discovered. Mr. Blodgett was born in Bucksport, Me., in 1862, and graduated from Yale in 1884. Soon afterwards he was appointed an examiner in the United States Patent Office at Washington. During his residence at the National Capital he studied law and was admitted to the bar. In 1888 Mr. Blodgett became one of the counsel of the Thomson-Houston Electric Company, and in 1893 his services were secured by the General Electric Company, and he removed his headquarters to Schenectady the following year. Mr. Blodgett attained a national reputation as a patent practicioner at a much earlier age than eminence usually comes to the lawyer, and, had his life been spared, he would undoubtedly in time have become an acknowledged head of that branch of the legal profession.

Mr. E. J. Wessels, who has been so strongly identified with the interests of the Standard Air-Brake Company since its formation, has resigned his position with that company as managing director, to take effect on Mar. 1. The retirement of Mr. Wessels from this field is a great loss, as it was through his ability, energy and persistence that the electric railway brake was advanced from a crude experimental stage to its present perfected form, with an automatic electrical control which makes the apparatus entirely independent of the motorman beyond the mere manual manipulation of a single handle. The activities of Mr. Wessels were not confined to this country, but extended to Europe and even to Australia, hundreds of air brake equipments having been introduced by him abroad. A potent factor in Mr. Wessels' work of bringing the electric railway brake to the front was his skill as a writer of advertisements, in which he has been unequaled in the entire electrical field, and referred to in high terms by *Printers' Ink*, the authority on advertisement writing in general. In whatever field Mr. Wessels' future labors may lie, he will undoubtedly be a great force.

◆

TRADE PUBLICATIONS.

Triplex Pumps. The Stilwell-Bierce & Smith-Vaile Company has in press a very complete catalogue devoted exclusively to triplex pumps, which will contain a large number of half-tone cuts of pumps of different styles, accompanied by much matter of technical interest.

Electrical Specialties. McLeod, Ward & Company, 27 Thames, Street, New York, in a recently issued catalogue illustrate and describe a number of their specialties, consisting of desk, portable, orchestra and electro-calcium lamps, safety wire holders and spark arresters.

Recording Instruments. Catalogue No. 2 of the Bristol Company, Waterbury, Conn., has for its subjects pressure, temperature and electrical recording instruments. All of the principal types are illustrated in detail, among others the Bristol recording vol meter, ammeter and wattmeter.

Walker Apparatus. A trade publication on luxurious hand-made paper with deckeled edges, is unusual even in these days of luxurious catalogues. The type "S" Walker solenoid blow-out controller furnishes the subject of the publication, which would in any event deserve especial mention from the beautiful design of the cover.

Steam Engines. In a recent catalogue the Fitchburg Steam Engine Company, Fitchburg, Mass., describes in detail the latest type of "Fitchburg" automatic variable cut-off steam engine, which embodies all the latest advances in the design of this class of engine. Those interested in the refinements of modern engine designs will find much in this pamphlet to instruct them.

Special Types of Incandescent Lamps. In a 42-page catalogue, the American Endoscopic Company, Providence, R. I., illustrates many forms of surgical, dental, miniature and other battery lamps, including telephone, bicycle, stereopticon and theatrical lamps. Many kinds of special series lamps for decorative and sign work are also illustrated, as well as different kinds of Röntgen ray tubes.

Electricity Direct from Heat. The Cox Thermo-Electric Company, 120 Liberty Street, New York, describes in a well illustrated pamphlet the Cox thermo-generator, and gives full directions for its operation. Considered as a thermo-pile, this apparatus is without doubt the greatest advance made during a half century, the alloyed junctions obviating the gravest objection to former types.

Fans. One hundred and twenty-four octavo pages are required to describe and illustrate the numerous types of steel-plate fans, made by the B. F. Sturtevant Company, Boston, Mass. A number of pages are devoted to electric fans, which are of large size and operated by a special motor forming a structural part of the fan case. The book is well printed and bound in a handsome cover of special design.

Steam Engines. The Weston Engine Company, Painted Post, N. Y., gives in a handsome and artistic catalogue, a well written and concise description of the Imperial engine. This type of engine, though but a few years on the market, has become a standard machine for electrical purposes, its admirable regulating qualities especially fitting it for this use. The governor, as well as all other important features, are illustrated in detail.

Engines and Multipolar Dynamos. The American Engine Company, Bound Brook, N. J., has issued two handsome catalogues, one having for its subject multipolar dynamos and electric motors, and the other American Ball engines. The latter has covers of particularly good artistic design, and both publications are profusely illustrated. The detail sketches of dynamo winding in the dynamo catalogue will be found of much interest by electricians.

The Victor Turbine. In a well illustrated and printed pamphlet of 150 octavo pages, the Stilwell-Bierce & Smith-Vaile Company, Dayton, O., describes in detail and in all of its forms, the Victor turbine, and incidentally gives sufficient information on hydraulic power construction to entitle the work a rank among technical treatises. The illustrations number not far from 200, those executed in half-tone being in quality much above the average seen in trade publications.

Indicators and Steam Gauges. A substantially cloth-bound octavo volume of 173 pages, issued by the Crosby Steam Gauge & Valve Company, 97 Olive Street, Boston, is an admirable example of a class of trade publications which also have a high value as technical treatises on the subjects considered. Steam, water, vacuum, recording and test gauges, and for every use imaginable, are illustrated by excellent cuts, accompanied by well written descriptions and, where necessary, by instructions for use. Safety and globe valves, feed-water regulators, lubricators, pump valves and many other steam fittings are represented, and last, but by no means least, the Crosby steam-engine indicator, which is described and illustrated in minute detail, with directions for handling.

The General Electric Press. The productions of the General Electric Press (Schenectady) at present rank with the very best work turned out by firms making a specialty of the finest typography, engraving and press work. Three recent pamphlets—two on incandescent lamps and the other on the operation of electric mining plants—are beautiful specimens of the printer's art. The cover designs are exceptionally handsome, a remarkably fine effect being produced by a skillful color combination of paper and inks. The general catalogue of incandescent lamps consists of 66 8 in. × 10½ in. pages, and forms by far the best practical treatise on the subject of incandescent lamps yet printed—the great amount of useful information contained in the pages justifying the use of the word treatise. A smaller pamphlet on the same subject is devoted to incandescent lamps for isolated plants, a considerable portion of the contents consisting also of useful information on the selection and use of lamps. The pamphlet on the "Operaton of Electric Mining Plants" consists principally of data on the cost of working, based upon actual figures obtained from companies operating electric mining plants. A fourth pamphlet recently issued from the same same press, is on incandescent lamps for railway service, which describes the manufacture, selection and use of lamps for that service.

◆

BUSINESS NEWS.

Removal. Goldmark & Wallace have removed from 29 Chambers Street to 121 Worth Street, New York.

The American Stoker Company has removed its offices from Dayton, O., to Rooms 72, 73 and 74, Garfield Building, New York.

The Murray Iron Works, Burlington, Ia., have completed the foundations for the new 100-HP boiler, which they are installing at their plant in West Burlington.

Mr. Charles Wirt, of Philadelphia, has recently been in Chicago renewing old acquaintance, and bringing to the attention of the Western trade the new Wirt rheostat.

The Gisholt Machine Company, Madison, Wis., has applied for an electric-light franchise. It is the intention of this company to extend its present system, as it already has a plant which furnishes its works with light.

Dissolution of Partnership. The partnership heretofore existing between W. W. Burnham and James L. Gethins, doing business at 181 Tremont Street, Boston, under the name of the Burnham-Gethins Company, was dissolved on Nov. 24, 1897, W. W. Burnham succeeding to the business.

Alternating-Current Fans. The Western Electric Company has been made exclusive agent for the Tuerk alternating-current ceiling fan in the territory west of Pittsburgh. It has also been made exclusive agent for the car heaters and office-heating devices manufactured by the Globe Heating Company.

Fan Motors. J. P. Williams, 39 Cortlandt Street, N. Y., who has just returned from an extended trip through the West and Northwest, reports that his sales have been increased 40 per cent. over those of last year. He, therefore, considers that the prospect is promising for a very properous fan-motor season.

Mr. William H. Taylor, of the Chandler-Taylor Company, Indianapolis, has just returned from a trip to Chicago and the Northwest. He states that the business outlook is extremely good, and his company is preparing for an unusually busy season. It is already running at full capacity, and expects to add an extra force soon.

The Diamond Electric Company, 1202 Fisher Building, Chicago and Peoria, Ill., report trade conditions in much better shape than at any time during the previous year. It feels very much elated over the prospects for a splendid winter trade, and is using every effort to promptly fill the many orders which are coming its way.

Gas Engines for Electric Plants. The Otto Gas Engine Works, Thirty-third and Walnut Streets, Philadelphia, Pa., report an excellent business, especially in engines for running electric-light plants Two 110-HP gas engines were recently installed at Sistersville, W. Va., for this purpose, and two 50-HP engines at Mannington, W. Va.

The Vilter Manufacturing Company, Milwaukee, Wis., during the past year has done an exceedingly large business in Corliss engines. A number of nice orders for engines, etc., for delivery in the early spring of 1898, are already recorded. Inquiries continue to come in, and the company considers that the outlook for a good season's business is very favorable.

Recording Instruments. The great extent to which recording instruments have entered into use is illustrated by the fact that the Bristol Company, of Waterbury, manufactures over 150 different varities of recorders for all commercial ranges of pressure, temperature and electrical current, voltage and power. Thousands of these instruments have been sold, and there is a constantly growing demand as their value is becoming better appreciated.

A New Telephone Company. The Kurtz National Telephone Company of the State of Indiana has been incorporated for $50,000, and the following officers elected: William H. Dye, president; J. V. Mitchell, secretary; John N. Cobb, treasurer; William J. Kurtz, vice-president and manager. This State company has a model plant in operation at Martinsville, Ind., and four towns connected up by toll lines, and is authorized to do business in every county in the state.

X-Ray Studio. Mr. Frank Martin, well known as an expert operator in the practical application of X-rays, is meeting with much success in his work. He was the first to make a business of applying X-rays, his studio at 110 East Twenty-sixth Street having been established in April, 1896, shortly after the first experiments with Prof. Röntgen's great discovery were made in this country. Mr. Martin also examines patients at their homes and acts as expert in legal cases.

Electrical Novelties. Devoted to the production of electrical novelties, the Ohio Electric Works, of Cleveland, are working night and day to meet the demand for their battery table lamp, necktie light, light, dollar motor and bicycle light. The head of the concern gives his personal supervision to every department, and the company has complete confidence in its ability to offer inducements which cannot fail to compel favorable consideration. The Ohio Electric Works desire agents everywhere to sell the four leading electric novelties above mentioned.

The Carbon Works of Julius Fuchs in Nuernberg is now controlled by Schiff, Jordan & Company, of Vienna, who inform us that Mr. Fuchs has manufactured the "Electra" carbons for a number of years, and will hereafter have charge of the manufacturing department of the Vienna Works, as well as of his Nuernberg plant. Mr. Fuchs has recently made great improvement in carbons for alternating current and for the enclosed-arc lamp. These carbons will be sold exclusively by Schiff, Jordan & Compnny, 232 Greenwich Street, New York.

Porcelain Fittings. The Peru Electric Manufacturing Company, of Peru, Ind., has recently patented and is placing upon the market, a multiple-tablet board for the three-wire system. This board is made of sectional pieces of porcelain and can be built for any number of circuits. A multiple-circuit board for two-wire system, somewhat similar to the above, is also manufactured. These boards, together with the same company's new line of branches and mains, and its new transformer fuse plug, are of general interest to electricians.

Mr. Hugo Reisinger, of No. 38 Beaver Street, sole agent of the celebrated "Electra" highest grade Nuernberg carbons, informs us that the outlook for the present season, is most promising. The large and numerous orders that have lately reached him, prove not only an increase in business, but that station managers are fully aware of the advantages gained by the use of the best carbons obtainable. The European factory Mr. Reisinger represents, has been enlarged recently, thus enabling him to fill orders for the largest quantities of carbons on short notice.

Enclosed-Arc Lamps. In an interview with Mr. F. E. Dolbier, manager of the arc lamp sales department of the General Incandescent Arc Light Company, Bowling Green Building, New York, he stated that the continued and increased success which they are meeting in the sale of their enclosed arc lamp is significant evidence of the satisfactory service obtained by the use of the same. He mentioned among others, that they had just closed a contract for the installation of the Bergmann enclosed arc lamp, in the new addition of Bloomingdale Bros., dry goods store in New York City.

Dry Batteries. Wm. Roche, 259 Greenwich Street, New York, has been making dry-battery cells for some of the well known supply dealers for many years, and in that time has produced several of the most popular dry cells now on the market. This experience Mr. Roche now proposes to use to his own advantage by establishing a business of his own, and has produced a new standard dry-battery cell of from 10 to 15 amperes capacity on short circuit, and from two to three years' life on ordinary open-circuit work. His aim will be to put out only the highest grade cells at a reasonable price.

Switches. In addition to its widely known New England switches, the O. S. Platt Manufacturing Company, of Bridgeport, Conn., has, within the past year, put upon the market, a single-pole and a double-pole push-button switch-knife switches that are thoroughly practical and reliable, meeting the 1897 rule of the National Board of Fire Underwriters' flush switches, 10- and 15-ampere sizes, with key or solid handle, and with or without indicator, showing the words "On" and "Off." The goods of this company are designed for service, utility and convenience, keeping in view the fact that low prices and the best goods are what the trade demands.

Fuel Economy. The Fuel Economizer Company, Matteawan, N. Y., has just completed erecting an economizer at the new station of the Edison Electric Illuminating Company, of Brooklyn. There are now in course of construction economizers for the new station of the United States Electric Lighting Company, Washington, D. C.; for the Brooklyn Heights Electric Railway Company; the Imperial Electric Light, Heat & Power Company, St. Louis, Mo.; the Merchants' Cotton Company, St. Henri, Montreal, Q e.; Lancaster Mills, Clinton, Mass.; Dutchess Hat Works, Tioronda, N. Y.; Chelsea Jute Mills, Brooklyn, N. Y., and S. Sanford & Sons, Amsterdam, N. Y.

Commutator Compound. Holm's Tesoline, made by the Boiler Expurgator Company, 115 Dearborn Street, Chicago, Ill., is rapidly becoming recognized as an indispensable article for the dynamo room. That its merits are not over-rated is evident from its adoption by concerns who only buy with discrimination, such as the Illinois Steel Company, Gates Iron Works, Illinois State Insane Asylum, Marshall Field & Company, the Woman's Temple, Chicago, and others too numerous to mention. The distributing agents for Holm's Tesoline are Bibber-White & Company, Boston, Mass., the Electric Appliance Company, Chicago, Ill., and the Southwick Oil & Grease Company, of San Francisco.

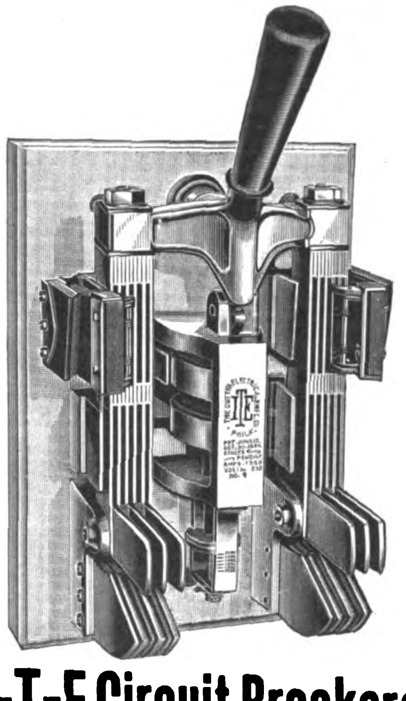
Water Power Governors. The Replogle Governer Works find the outlook for business in the line of water-wheel governors decidedly better than one year ago. There are more inquires, and manufacturing concerns that have had their water-power in use for years with little or no attempt at automatic regulation of speed, are beginning to see the desirability of putting their plants on a modern basis, and feel warranted at the business outlook to make the investment. The Replogle Governor Works call our attention to the interesting fact that in the illustration of thier governor in the article on "A Practical Application of Electric Heating," on page 463, of December issue, the hand wheel shows three different positions during the brief exposure of the photographic plate.

B. & O. Electric-Light Plant. In accordance with the policy of economy adopted by the receivers of the Baltimore & Ohio Railroad, an electric-lighting plant has been installed at Philadelphia for the purpose of lighting the passenger station, yards, freight stations, freight yards, docks, roundhouses, machine shops, etc. Twice as many lights are in service now as when the company purchased the current from local lighting companies, yet the expenses have been reduced one-half. The Philadelphia plant consists of one 150-HP boiler, two 50 G. E. arc-light generators, which are belted to a 125-HP standard Westinghouse engine. It took 20 miles of wire for the overhead construction, and a submarine cable is used in crossing the Schuylkill River.

Electrical Soldering Paste. The Highland electrical soldering paste is claimed by the Electric Appliance Company, Chicago, to be the only soldering flux to use where careful work is a requisite, and that careful comparative tests have shown that it gives the very best joint that can be made with the least possible amount of solder and without any corrosion whatever. It is now being used almost exclusively by telephone companies, with whom the foregoing points are particularly valuable. The electric-light companies are also coming to realize that it is very important that every joint made on their lines should be a good joint, and are now using the Highland paste very extensively.

THE PERFECT CLUTCH FOR T.-H. and Brush Lamps.

The Only Reliable Clutch
Guaranteed absolutely PERFECT in its action.
Used and endorsed by all the leading Central Stations throughout the country.
We also manufacture a superior line of
ARC CUT-OUTS and all
ARC LIGHTING SUPPLIES.
Our Goods are of the Highest Grade, our Prices are Low, and we can make Prompt Shipments.
THREE IMPORTANT THINGS TO CONSIDER WHEN BUYING.
The Philadelphia Elec. & Mfg. Co.,
OFFICE, No. 2011 MARKET STREET.
Factory, 2011 Market and 2010 Commerce Streets (formerly Jones Street).



I-T-E Circuit Breakers
are used exclusively in the American Lithographic Building, as described in the leading article in this issue.
The Cutter Electrical & Mfg. Co.,
PHILADELPHIA,
1112 Sansom Street.
NEW YORK OFFICE,
120 Liberty Street.

The Electric Appliance Company, Chicago, is sending out a small box at a nominal price, which gives an opportunity to test the paste and, besides, is a supply of paste which will last probably as long as one pound of soldering salt and do far better work.

The Weston Engine Company, is finding trade, so far as it is affected, far beyond expectations, in fact, being compelled to refuse orders for engines at the present time. Orders for something over 30 engines are booked, and arrangements are now being made for a large addition to its plant, to be erected as soon as weather will permit. A large night force of men is to be put on in order to take care of work in hand, in place of the small force at work at the present time. Only a few days ago telegraphic orders were received for two 125-HP engines, direct-connected type, to be used in lighting the municipal buildings in the City of Mexico. Three 175-HP engines, direct-connected type, are also being built for the new court house at Fort Wayne, Ind., and a number of other orders have been received for prominent buildings throughout the United States, and a large amount of possible work is in sight. The prospects for 1898 are very bright, and the Weston Company anticipates the best year in its history.

Gas Engines. The Lambert Gas Engine Company, of Anderson, Ind., reports business better than at any previous time in its history. Replying to an inquiry as to its present capacity, Mr. C. E. Hogle stated, "We started the year 1897 with the intention of building an engine a day. We have, however, more than doubled this output. The outlook for the coming year was never so bright, and it is our intention to increase our facilities in the immediate future, so that we may keep abreast of the demands made upon us." This company manufactures a specially designed engine for driving electrical apparatus, in which it guarantees a speed sufficiently uniform to develop current that will make light without any perceptible variation, direct belted without intermediate counter-shaft and balance wheels, or even a balance wheel on the armature of the dynamo. This company has recently issued a new catalogue of special importance to power users interested in gas engines.

Storage-Battery Contracts. The Electric Storage Battery Company, Drexel Building Philadelphia, has just closed a contract with the Chicago Edison Company for a storage-battery plant with a capacity of 7,436,800 watt-hours. This will be the largest battery installation ever made. The contract includes switch-board and all the auxiliary apparatus, and will be completed in March, 1898. This installation will be an object of great interest to the members of the National Electric Light Association at its next meeting which is to be held in Chicago in June. The Battery Company has also closed a very important contract with the Buffalo Railway Company. The battery is to be used in conjunction with power furnished by the Cataract Construction Company at Niagara, over its high-tension transmission lines to Buffalo. This is a most important development, and one which is being watched with intense interest all over the world. Both of the above batteries are the largest for their purpose that have ever been installed. The year's business done by the Electric Storage Battery Company shows a very remarkable increase over preceding years, and indications are that the coming year's business will far exceed the results of the present year.

The "Electra" Carbons. Mr Hugo Reisinger, No. 38 Beaver St., New York, desires us to make public the following notice concerning certain statements recently made in trade papers: "I wish to inform the trade that the word 'Electra' has been properly registered by me as my trade-mark and therefore, cannot be used by anybody else without infringing on my rights. The 'Electra' carbons are made, as heretofore, by the world renowned firm of C. Conradty, Nuernberg, who owns not only the oldest, but the most extensive carbon works in existence and whose carbons remain unequaled in quality and efficiency, having become the standard for electric lighting the world over. As to parties reported as makers of 'Electra' carbons, I wish to state that I have brought suit against them for having misused the trade-mark 'Electra' and that they have been enjoined by the Nuernberg courts from making any carbons stamped 'Electra' under penalty of 100 Mks. for each carbon. I shall guard the interest of buyers of my carbons as heretofore, and any information in regard to infringements on the registered trade-mark 'Electra' that will enable me to take legal proceedings, will oblige."

Fire Extinguisher for Electric Generating Stations. The Underwriters' Equipment Company, 2 Wall Street, New York, is soon to place on the market a new device for extinguishing fires which is

NATIONAL

Matte Smelter.

A PRACTICAL and simple method of matting sulphide ores. In localities where lead ores and fuels are scarce and almost unattainable, our pyritic, water-jacketed Matte Smelter has been recognized with highly satisfactory results, and has been thoroughly tested on various pyritic, sulphide and arsenide ores, in capacity of two to eighty tons per day. It is the most practical, cheapest and simplest method of gold and silver ore matting and concentrating that is known to-day.

It requires no extraordinary skill, no lead ores, no fluxing material, and no fuel of any kind for the smelter after it is started. The sulphur in the ore is its natural fuel only, and its cost has no comparison with any other process of concentrating.

We are prepared to furnish any size or capacity plant complete to substantial mining people, set it up and furnish our men to run it for them on easy payments. Prices and specifications furnished with references and testimonials on application.

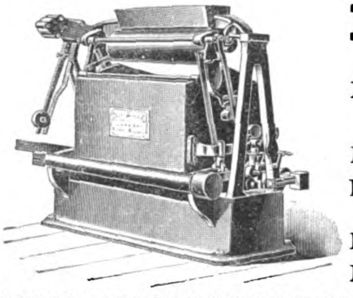
The National Ore & Reduction Co.

415 Locust Street,

ST. LOUIS, MO.

Manufacturers of Furnaces for

Nickel, Copper, Gold, Silver and Lead Ores.



HIGH CLASS MACHINE TOOLS

for Machine Shops and General Metal Finishing Use.

Machines, Fixtures, Small Tools and Gauges for the manufacture on the interchangeable plan of Guns, Sewing Machines, Typewriters, Cash Registers, Bicycle Parts, etc.

Brass Finishing Machinery.

Reliable Counting Registers, Standard Measuring and Testing Machines.

Drop Forging Machinery: United States Standard Threading Machines and appliances.

Milling Cutters, Combination Lathe Chucks.

AUTOMATIC WEIGHING MACHINES for accurately weighing coal and all material of a uniform size handled for storage and distribution.

Lathes, Planers, Shapers, Drilling and Milling Machines for Tool Room use.

Bar Iron Limit Gauges, useful to protect the buyer of bolt iron against the delivery of material of sizes unsuitable for use without changing dies for heading or threading and of excessive weight.

Brigg's Standard Pipe Thread Gauges, useful for testing pipe and fittings to insure their delivery in condition for connection without rethreading when ordered to said gauges.

EDDY DYNAMOS
EDDY MOTORS
CROWN BRUSHES

praticularly applicable to electrical plants, where the use of water for this purpose is apt to increase danger through establishing short circuits. It resembles, in appearance, the familiar portable chemical fire extinguisher. In fact, it is a chemical extinguisher itself, with an additional chamber, which acts as a reservoir for the carbonic acid gas generated by the combination of a saturated solution of bi-carbonate of soda with sulphuric acid. The dry gas is forced out through a suitable nozzle by its own pressure and directly applied to the flames, which are immediately extinguished. The design and construction of the gas extinguisher are remarkably simple, and its operation and control are equally simple. By an ingenious check valve used in mixing the two fluids, all danger from explosion is avoided. The apparatus has been practically tested, and found to work with satisfactory results. The gas, as it is ejected from the nozzle, is perfectly dry, and has no damaging effect on the material to which it may be applied.

Forty Years of Light. The firm of I. P. Frink, 551 Pearl Street, New York, has for forty consecutive years jealously guarded its reputation for fair dealing, and the superior quality and construction of its reflectors. Successful from the start, it kept far in the lead, keeping pace with this age of light, improving quality and construction, so that the 1897 could hardly be recognized as a distant relative of the 1857 reflector. During this time it has lighted over 20,000 churches, covering nearly every country in the world, and thousands of halls, theatres, armories, schools, hospitals, court-houses, stores and public buildings, receiving the first prize, medal and diploma at the World's Fair, Chicago, 1893. Although advertising "The Great Church Light" extensively, it does not confine its efforts to churches only, but has lighted a number of the finest private mansions in the principal cities of America, recently lighting a reception room in New York, in which over $100,000 was expended on the interior decorations, $4000 of which was for the Frink reflectors for lighting the room. The reflectors were heavily plated with gold. The new Corcoran Gallery of Art, Washington, D. C.; the Rhode Island School of Design, Providence, R. I.; and Brooklyn Institute of Arts and Sciences, and Hart Memorial Library, of Troy, N. Y., have recently been lighted by it, and it has now on hand good orders from Africa, China, England and France, and from churches in nearly every state in the Union, which goes to show the wide-spread popularity of the Frink reflector. During the holidays, it frequently receives orders by telegraph, giving size of room to be lighted, with no previous correspondence. These few straws clearly indicate the esteem in which the firm is held by the general public. Its facilities for turning out good work promptly are more perfect than ever before.

Recent Westinghouse Contracts. The factory of the Westinghouse Electric & Manufacturing Company, at East Pittsburgh, Pa., is at the present time very busy on a number of electrical machines all intended for Niagara Falls and other companies in the vicinity of the great electric power center. It will be remembered that about six months ago, the Cataract Coustruction Company contracted with the Westiughouse people for an enormous addition to the power station, consisting of five 5000-HP generators, of the same pattern as the three already installed. In addition to these five machines, which are now under way—in fact shipment has already commenced—the factory is also building exciters, representing a capacity of 675 HP. The switch-board with necessary appliances controlling the five 5000-HP generators is also being made now, and all of these machines will be applied to the Niagara power house as soon as required. The Niagara Falls Hydraulic Power & Manufacturing Company some time ago contracted with the Westinghouse Company for six 750-HP direct current generators, 300 volts, 250 r. p. m. These generators will be direct-connected to Leffell turbines, and they will be used for generating current, that will be supplied to the Aluminum factory of the Pittsburgh Reduction Company, at Niagara. The Westinghouse Company has also constructed two 300-HP, two-phase induction motors, contracted for by the Buffalo, Niagara Falls Electric Light & Power Company. These motors will be used for alternating-current generators, direct-current generators, arc machines, etc. The Niagara Electro Chemical Company has contracted for a large increase in its transformer station, located above the power house of the Niagara Falls Power Company,

consisting of three 235-HP, two-phase rotary transformers and one 175-KW rotary transformer supplying current for the reduction of metallic sodium from caustic soda. In addition to these transformers, the Westinghouse Company is also making for the same company, 800-HP in air-cooled oil converters, consisting of six 133-HP converters, 3000 alternations, which will supply current for the rotaries. The Acetylene Light & Power Company has contracted for two 1000-HP oil converters, water-cooled, of 3000 alternations, primary 2200 volts, secondary 100 volts. These converters will supply current for arc furnaces for the manufacture of calcium carbide. The Mathieson Alkali Company contracted with the Westinghouse Company some time ago for a number of rotary transformers, induction motors and oil converters, which were recently installed, and consist of eleven 165-HP rotary transformers, several small induction motors, twenty-two 82½-HP oil converters, four 33½-HP oil converters and two 13½-HP oil converters. These facts are the best evidence of the growing activity manifesting itself in the use of electrical apparatus at Niagara Falls, all of which has been occasioned by the erection of the large power station of the Cataract Construction Company, the generators for which were installed by the Westinghouse Company.

Vol. X. New York, February, 1898. No. 2.

BUTTE, MONTANA, ELECTRIC POWER TRANSMISSION PLANT.

THE MONTANA POWER COMPANY.

BY L. D. TANDY.

The Montana Power Company, which was organized Aug. 10, 1897, will have, when ready for practical operation, a plant that will rank among the finest in the United States, not only from an engineering but from a financial standpoint. The plant was projected, financed and built upon a different basis from any other of a similar character in the country, the entire proposed output having been contracted for before ground was broken. Thus the problematical feature as to the income to be derived from the en-

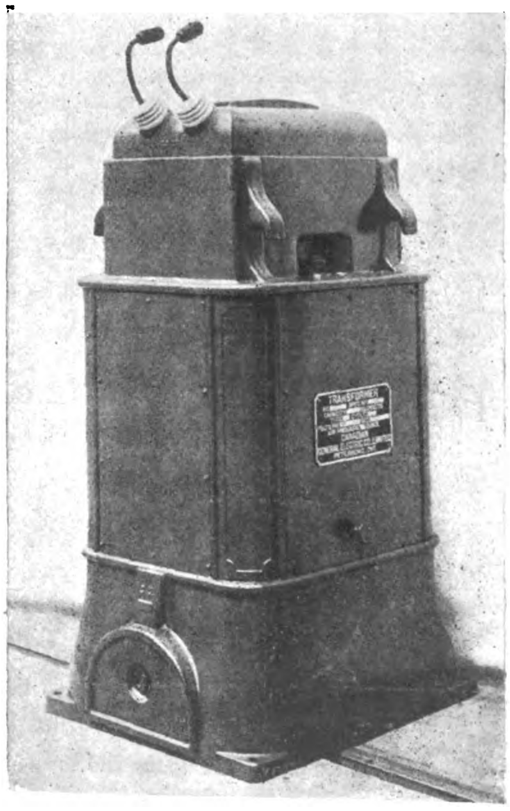

FIG. 4.—250 K. W. TRANSFORMER.

GENERATING MACHINERY AND TRANSFORMER.

terprise, was eliminated. The disposition of the power was made on a basis of five to ten year contracts, and at remarkably good prices for both the Power Company and the customers.

The coal used in the city of Butte is bituminous, from mines at Rock Springs, Wyo. Its high price ($3.60 per ton) and poor quality constitute one reason why its use for the generation of steam power is expensive. Another important factor in the high cost of steam power at Butte is the scarcity of water. The only way in which water can be obtained for condensing is from the city mains, and its cost, under such conditions, is, of course, prohibitive. It is consequently necessary to run all steam plants non-condensing, although the load factor of many of them is such as would make condensing a great source of economy.

The promoters of this company in drawing

FIG. 6.—TURBINE AND GOVERNOR.

up the preliminary plans, decided to employ only the best material and apparatus obtainable, without any of the embellishments, ornamental rather than useful, frequently included in projects of this character. The first step was to secure the best available engineering advice, and J. T. Fanning, of Minneapolis, Minn., and M. S. Parker, of Great Falls, Mont., were chosen. A careful investigation was then made of the various types and manufactures of apparatus suitable to work of this kind, with a view to the selection of the best hydraulic and electrical machinery that the present market affords.

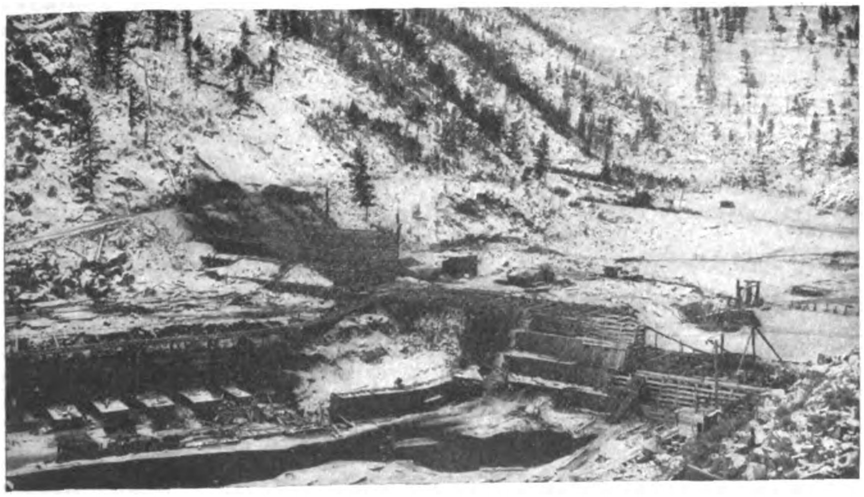

FIG. 7.—DAM, LOOKING DOWN STREAM.

Location.—The power station is located on the Big Hole River, 20.6 miles distant from the city of Butte, Mont. This distance is the total length of the transmission line, which is run in practically an air line from the power station to Butte.

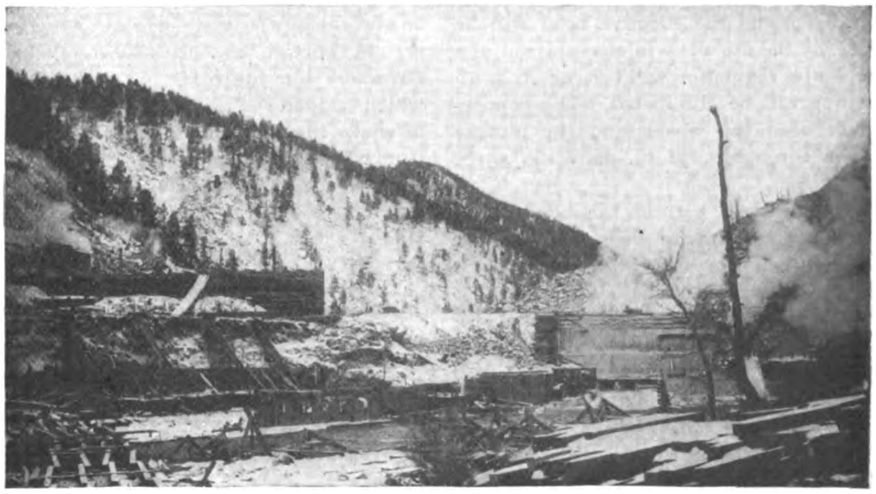

FIG. 8.—DAM, LOOKING UP STREAM.

Water Rights.—The water rights of the company are broad and cover three storage reservoirs above the main dam, as well as a location for an additional power station about 2 miles below the present one. Should it be found necessary, the capacity of the existing plant may be increased by building a second station on the latter site, utilizing the tail water of the present plant by carrying it through an open flume or pipe.

In California, where the laws for the protection of irrigation interests require that the normal flow of the stream be sustained, flood water only can be reserved, or stored. The storage of water in Montana, however, is not restrained by legislation, and when loads are light, water can be stored for use when heavy demands for power are made on the station. The lowest flow in the Big Hole River ever observed was 20,000 miner's inches, and that after a phenomenally dry season.

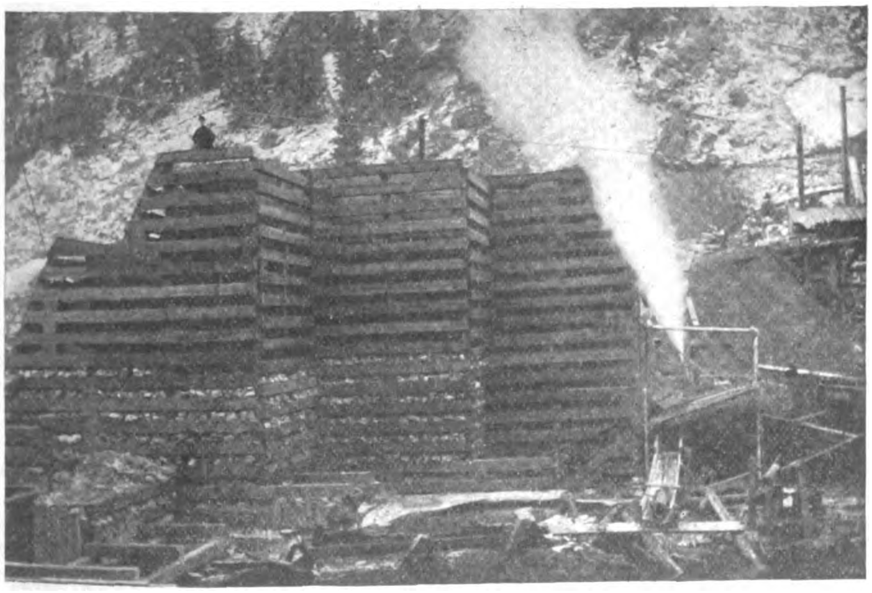

FIG. 9.—SHOWING CRIB CONSTRUCTION.

Dam.—The main dam (Figs. 7, 8 and 9) is a crib, the largest of its kind in the country, being 102 ft. wide at the base and 57 ft. high at the spillway. The total length at the crest is 450 ft., the spillway alone being 200 ft. wide. On the power station side, the dam will rise to a height of 12 ft. above the spillway. 10 in. × 12 in. Montana pine and fir timber in 12 and 16 ft. lengths, held together by 42 in. drift bolts, is used in the construction of the crib. (Fig. 9.) The foundations rest upon bed rock, and the crib is filled with concrete to a point 8 feet above the bed of the river, the remainder of the crib being filled with broken granite.

Two storage dams have been built, one 25 and one 28 miles up the river from the main dam, and a site has also been located for a third. These dams are 30 and 40 ft. high, respectively, and are built on the same general plans as the main dam.

The storage dams and the main dam will impound 2,100,000,000 cu. ft. of water. This will secure an ample reserve for heavy demands during exceedingly dry seasons.

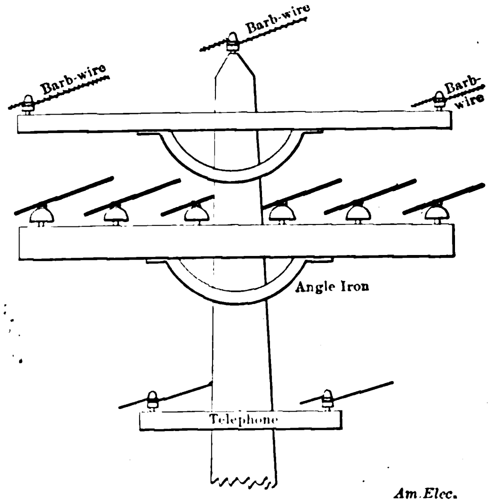

FIG. 10.—TRANSMISSION POLE.

Power Station.—The station, which is not yet completed, will be strictly fireproof and built of granite and concrete. The main

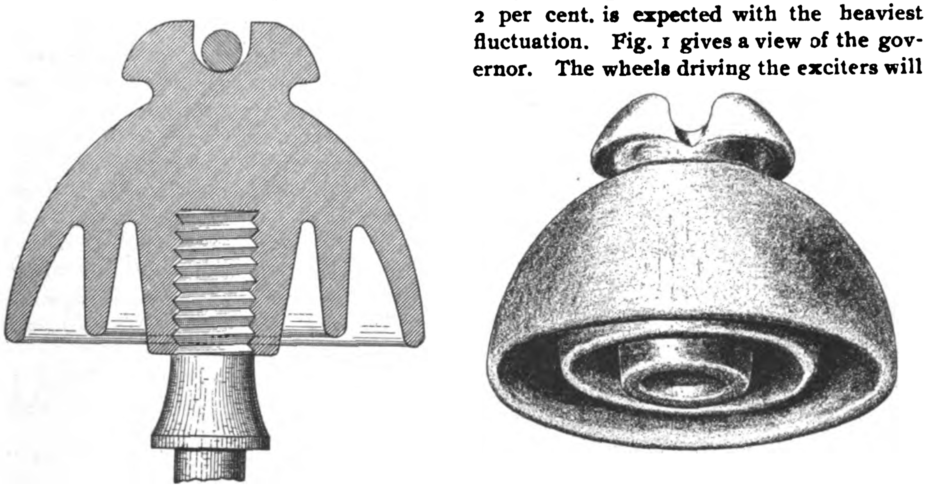

FIG. 11.—HIGH VOLTAGE INSULATORS.

building is located on the south side of the river, adjacent to the dam. Its ground dimensions are 125 × 78 ft., and the transformer room is 50 ft. × 30 ft. (Fig. 5.) The water will be supplied to the wheels from a forebay in the rear of the station. This forebay is 350 ft. long, 15 ft. wide and 23 ft. deep, and the effective head will be 60 ft. By the use of a forebay instead of a pipe, better regulation will be secured, as all ramming will be eliminated. The connection between the wheels and the forebay will be through a 72 in. penstock, 55 ft. long.

All foundations, both for the water wheels and generators, are on bed rock, and the space between them under the floors will be utilized as a cable tunnel. The roof will be of latticed steel girder, the contract for this and all the other iron work used having been placed with the Gillette, Herzog Company, of Minneapolis, Minn. Three traveling cranes will be installed, two of 16 tons capacity each, running the full length of the main building, and one of 5 tons capacity in the transformer section. These cranes will be furnished complete by the same company.

The building is exceptionally spacious, and is designed to receive five 1000 h. p. units, space being provided for an engine to be coupled to the fifth unit. Neither the fifth unit nor the engine, however, will be installed at present. This engine is designed for use only in times of excessively heavy loads, or when the water supply is abnormally low.

Water Wheels.—The James Leffel Company will furnish the water wheels for both the generators and exciters. There will be four 66 in. double turbines of the type shown in Fig. 3, directly coupled to the generators and developing 1200 h. p. at an effective head of 60 ft. while running at 180 r. p. m. These wheels are commonly known as the Niagara type and are of the same general design as those which have been installed for the Hydraulic Power & Manufacturing Company, of Niagara—the Cliff plant. Fig. 6 shows the details of the wheel and governor construction. The drawings from which the above cut was made have since been slightly changed, in that the intake will be from above the wheel where the air chamber is shown, instead of at the side. Two 36 in. single wheels will be *directly coupled* to the exciters.

Governors.—The Lombard water wheel governor will be used, one on each of the generator wheels. From the results obtained with this governor on the Leffel wheels at Niagara, a regulation somewhat better than 2 per cent. is expected with the heaviest fluctuation. Fig. 1 gives a view of the governor. The wheels driving the exciters will be governed by a simple mechanical governor. A special feature of the Lombard governors for this plant is that the water which actuates the primary cylinder is filtered, thereby eliminating any trouble from clogging of the cylinder or parts by sediment in the water. Otherwise they differ in only one important detail from the standard types of governors built by the same company, there being no pumping system connected with these governors, the circulating system being filled with water under flume pressure instead of oil under tank pressure.

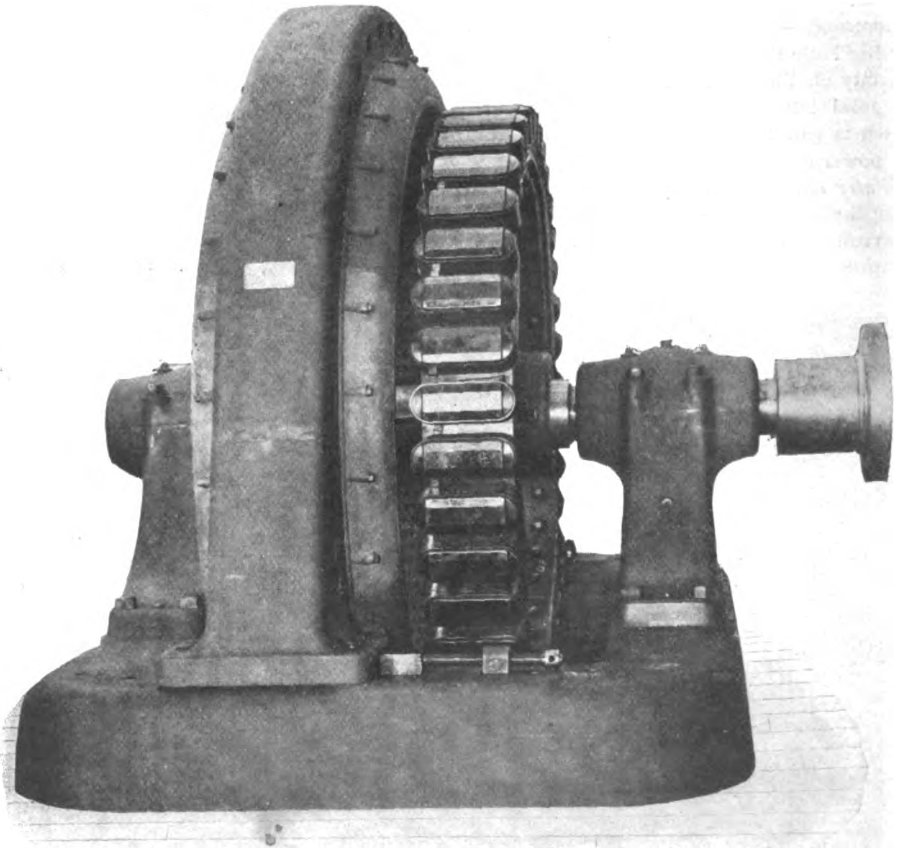

FIG. 12.—750-K THREE-PHASE GENERATOR, SHOWING ARMATURE WITHDRAWN.

In this particular plant the governor builders have specially designed the bed, ratio of gearing and connections in such a manner that the design is integral with the water wheels, of which the governors really become a part, as may be seen from the outline drawing, Fig. 6. These governors not only regulate the speed of the whole plant, but also start and stop the plant without manual effort. There are four units like the one shown in the illustrations.

Electric Equipment.—The entire electric equipment, both of the power company and of the companies utilizing the power, will be furnished by the General Electric Company, and will consist of four three-phase generators, of a capacity of 1000 h. p. each at their rated load. The generators are revolving field machines having forty poles, and a speed of 180 r. p. m., which gives a periodicity of sixty cycles. The current will be generated at a potential of 800 volts. The generators are practically the same in construction as other machines of the same company built to meet similar conditions, varying only in the number of poles and the speed. The revolving field will be 10 ft. in diameter over all and will weigh 23,500 lbs. A good idea of the general design of the generators can be had from Figs. 2 and 12. All the mechanical construction in these machines is based on a safety factor of twenty, ensuring absolute safety, even in case of a runaway at the full spouting velocity of the water.

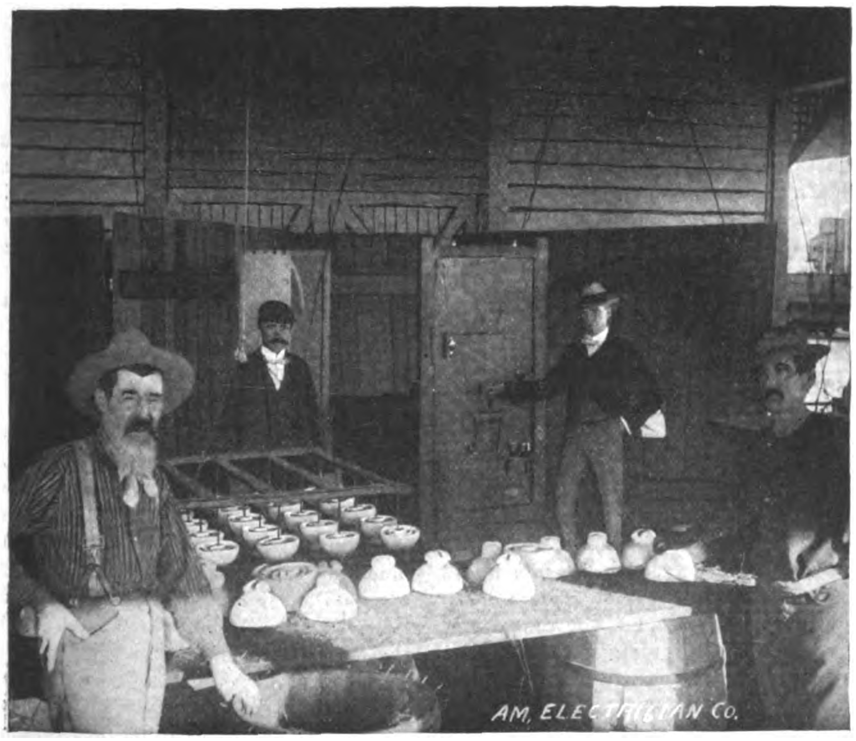
There will be two exciters of the multipolar type, having each a capacity of 100 k. w. at rated load, and one exciter can furnish sufficient current to excite the five 1000-h. p. generators. They will be entirely independent in their operation, being directly connected to individual water wheels running at 600 r. p.m., and will operate at a potential of 125 volts.

The step-up transformers will be of the air blast type, 12 in number and of 250 k. w. capacity each, and connected in delta. (Fig. 4). The current will be delivered to the low tension side at 800 volts and increased to 15,000 volts for transmission.

In the substation in Butte 2640 k. w. capacity in step-down transformers will be installed of the same design as those in the main station, but of units of various sizes best adapted to the several uses for which they are to be employed. The high tension side of these transformers is wound for 13,250 volts, and the low tension side for 2,200 volts.

Both the main station and substation will be provided with two electric blower sets for circulating the air through the transformers.

The switchboard will be made of blue Vermont marble and consist of 15 panels, divided as follows :



AM, ELECTRICIAN Co.

FIG. 13.—METHOD OF TESTING HIGH-VOLTAGE INSULATORS.

4 generator panels, 1 main station panel, 1 paralleling panel, 4 high tension transformer panels, 1 exciter panel, 2 line panels, and 2 low tension transformer panels.

The high tension portion of the main station switchboard will be located in the transformer building in a position where the attendant at the main switchboard can see it at all times.

The panels will be equipped with all of the latest improved instruments, and the station protected with General Electric lightning arresters. All generator and low tension transformer leads will be carried under the floor between the generator foundations, and will be accessible at all times for inspection, as there is ample room for a man to walk through the entire length.

Transmission Line.—The transmission line will be 20.6 miles long. The poles will be of Oregon fir varying in length from 33 ft. to 60 ft., with a minimum diameter of 12 ins. at the top, the average length being 40 ft. They are set 105 ft. apart or fifty poles to the mile, and have three cross arms, two 10 ft. 6 ins. in length, and one 3 ft. in length. The two upper or long cross arms are provided with a curved angle iron brace bolted to the pole and to the under side cf the cross arms. On the top of the pole and on the ends of the upper cross arm are glass pony insulators on which barbed wire is strung for lightning protection. Glass insulators are used for this purpose to prevent friction and consequent breaking, as is usually the case when the barbed wire is attached by staples. The upper arm is used exclusively for this barbed wire line.

The second or middle arm is provided with six pins to accommodate two three-wire circuits. The lower or short arm is for a private telephone line.

The insulators (Fig. 11) were furnished by the Imperial Porcelain Works, of Trenton, and are of the "Redlands" type. They have all been subjected to a test of 70,000 volts before and after glazing. The weight of each insulator is 5½ lbs., the diameter 6¾ ins., and the height 4⅞ ins. The surface distance from the tie wire to the pin is 13 ins.

A method for testing high voltage transmitters is shown in Fig. 13. The source of E. M. F. is a slot wound alternator. The insulators to be tested are partly immersed in water, one pole of the alternator being connected to the body of water. The other pole of the alternator is connected to a frame work in which are as many vertically downward projecting pins as there are insulators to be tested. The insultator pin hole is filled with water and the frame lowered until the pins in it are almost in contact with the water. Upon the circuit being closed, there is a spark across the gap between the water and the pin, and defective insulators are effected by the color of the spark. If the insulator is defective the spark is yellow and dull or bushy, and blue and sharp when the insulator is perfect.

The line will consist of six No. 1 B. & S. gage, soft drawn copper conductors. It is interesting to note that the copper from which the wire was drawn was mined at Butte and in the immediate vicinity of the station location, and is the first wire for transmission purposes drawn by the Waclark Company, of Elizabethport, N. J.

The transposition of the wires is accomplished between five pole spaces or 525 ft. The transposition is made in such a way that each leg of the circuits crosses each of the other two legs; and the circuits, as a unit, also cross each other. In making the transposition a third cross arm is used.

The two circuits can be used in multiple or independently, as desired, and each circuit is capable of carrying the full load if necessary. With the two circuits in parallel, the line loss is less than 7 per cent.

Cost.—In this interesting feature this plant shows a remarkably low figure. The entire cost, including the two storage dams and the step-down transformer equipment for the substation, will be $400,000.

In General.—Among the large contractors for power arethe Butte General Electric Company, the Butte Consolidated Street Railway Company, the Butte Reduction Works, the Colorado Smelting Company and the Montana Ore Purchasing Company.

The first named company has 27,000 incandescent lights connected, all to be operated from the Power company's circuits. In addition it will install a rotary converter to furnish current to its 550 volts direct current power circuits, and three 100 h. p. induction motors, each of which will be connected to a 125-light arc dynamo. The Butte Consolidated Street Railway Company has arranged for two rotary converters of similar size and capacity, for the supply of current to the city street railway system. The Butte Reduction Works will install one 215 h. p., 440 volt, revolving field synchronous motor, one 15 h. p. induction starting motor and two 150 h. p., 440 volt induction motors. The Colorado Smelting Company has contracted for two revolving field, synchronous motors, one of 300 h. p., 164 revolutions; and the other of 300 h. p., 450 revolutions, both on the 440 volt circuits; and three 15 h. p. induction starting motors. The Montana Ore Purchasing Company, will install one 300 h. p., revolving field, synchronous motor and two 100 h. p. induction motors.

LIQUID RHEOSTATS.

BY H. S. WEBB.

The object in view when the following tests were commenced, was to obtain some data from which the dimensions of a liquid rheostat for the dissipation as heat of a given amount of energy could be calculated, or at least estimated, when the maximum current and E. M. F. are known. These tests were rather hastily made and are far from being as complete as I should like to have them, and are published only to answer some inquiries for information on the subject.

In the first test, an ordinary Daniell jar (6¼ ins. in diameter by 8 ins. deep) with horizontal sheet-iron electrodes was filled with tap-water. It would not carry 4 amperes for over fifteen or twenty minutes, although the jar was full of water and the plates only ¾ in. apart. After that length of time it became too hot, causing great variation in the current on account of the large amount of gas liberated, much of which adhered to the under surface of the upper electrode. The difference of potential between the plates was 200 volts.

A run was made with 1 ampere and then with 2 amperes for one hour. In the latter case the voltage between the electrodes was about 71 volts, and the temperature rose to about 167° F.

From these tests it would be safe to allow a vessel with a cross section of 30.7 sq. ins. to carry from 2 to 2½ amperes when tap-water and horizontal electrodes are used.

In test No. 2, the same jar and electrodes were used as in the preceding test, but the tap-water was replaced by a saturated solution of salt water. Eleven amperes with a potential difference of 7 volts between the electrodes, which were 7¾ ins. apart, were passed through the solution for three hours and the temperature at the end of the run was 122° F., and was rising very slowly.

Although the current per square inch is much greater, the watts absorbed per cubic inch is much less in this case than when water was used. With the water carrying 2 amperes the watts absorbed would be over 10 per cubic inch, while for the saturated solution of salt when carrying 11 amperes, it would be only about .4 watt.

In test No. 3, use was made of a long, wooden rectangular trough (42 ins. × 6½ ins. × 8 ins.) with vertical, sheet-iron electrodes. The cross section of the liquid, which was a 10 per cent. solution of salt in water, was 44 sq. ins., and with 10 amperes passing through the solution for 1¾ hours the temperature rose to 95 degs. F., and was rising slowly at the end of the run.

The plates were 41¾ ins. apart, and at the end of the run the voltmeter across the terminals read 20. This gives a current density of nearly ¼ ampere per square inch and .11 watt per cubic inch. These values are too low to be considered maximum values, for this cross section of a 10 per cent. salt solution would probably carry 13 to 15 amperes safely.

It appears that as the amount of salt in the solution is increased from zero to saturation, the maximum current-carrying capacity is increased, but the watts absorbed per cubic inch are less.

A very small addition of salt to tap-water makes the solution a much better conductor than the water, and reduces greatly the safe maximum watts absorbed. In using glass vessels, such as Daniell jars, there is danger of cracking the jar if the temperature rises much above 165 to 175 degs. F.

In test No. 4, an ordinary whiskey barrel, filled up with tap-water, was used. Two horizontal circular iron plates ($\frac{3}{16}$ in. thick) were used for electrodes. The diameter of the inside of the barrel was approximately 19½ ins. With the two plates 26⅜ ins. apart a difference of potential of 486 volts gave a current of 2.6 amperes. With the plates ⅞ in. apart, 228 volts gave 35.5 amperes at the end of one hour when all the water in the barrel was very hot (175 degs. F.), and there was quite a good deal of gas given off. The current density in this case was about .12 ampere per square inch, and the watts absorbed 30.5 per cubic inch. If it were not for the large amount of water above both electrodes, it is doubtful if this current density could have been maintained.

In test No. 5 a rectangular box, in which was placed two vertical sheet-iron plates, was filled with tap-water. The distance between the plates was ⅝ in., and with a difference of potential of 414 at start and 397 at end of the run, a current of 35 amperes was kept flowing for 35 minutes. Cold tap-water was kept running in between the electrodes at the rate of 6.11 lbs. per minute (about $\frac{1}{10}$ cu. ft.), by means of a small rubber tube about ¼ in. inside diameter. This test is very interesting in comparison with the preceding. The current-carrying capacity, .3 ampere per square inch, was more than double, and the energy absorbed 183 watts per cubic inch, more than six times as great as in case where running water was not used.

The temperature in some places between the plates occasionally rose as high as 205 degs. F., and it was necessary in order to avoid too violent ebullition, to keep the inflowing stream of water directed along the water surface between the two plates. Less water would not have been sufficient, and, of course, by using more water, the temperature could have been kept lower, or with the same temperature the watts absorbed could have been increased.

When a large current density is used, there is considerable decomposition of the iron electrodes when either salt or pure water is used, and in the case of horizontal electrodes, the under surface of the top plate may become covered with bubbles of gas, making the resistance between the plates quite variable. For large current density, a horizontal top plate is not advisable, unless a large number of holes are drilled through it. A better form for the top electrode would be a hollow cylinder long enough to give sufficient surface. Washing soda is often a convenient substance to use instead of salt.

If, from experience, the size of a liquid rheostat for absorbing a given amount of energy cannot be estimated, the dimensions may be calculated approximately as follows: Suppose, for instance, it is desired to absorb 60 amperes at 40 volts difference of potential between the electrodes. Now, it is inconvenient to obtain a saturated solution of salt, and to use tap-water would require too large a cross-section—especially if a barrel or trough is to be used—in order to have the resistance with the plates at a safe distance apart, small enough to give 60 amperes with 40 volts.

Let us try a 10 per cent. solution of salt. Suppose the maximum current this will carry is ¼ ampere per square inch, which will give a cross-section of the solution of at least $60 \div \frac{1}{4} = 240$ sq. ins. Now, the specific resistance per inch cube (*i. e.*, the resistance between two opposite surfaces of a cube whose side measures 1 in.) of the 10 per cent. solution of salt used in test No. 3 was 2.12 ohms. The drop, CR, will be $2.12 \times \frac{1}{4} = .53$ volts per inch length of solution between electrodes. Hence, the electrodes will have to be $\frac{40}{.53} = 75$ ins. apart. This would require about three barrels connected in series. This was taken merely as an illustration, because its specific resistance was known when the current density was ¼ ampere per square inch. This solution, however, will carry safely ⅓ ampere per square inch, but I used the previous figure since I did not know its specific resistance for this current density, because its specific resistance will be lower for a larger current density on account of the higher temperature which it will have, for the resistance of a solution decreases as its temperature increases.

To reduce this length would require a solution of higher specific resistance, that is, a solution containing less than 10 per cent. of salt, and an increase in the cross-section, since the maximum carrying capacity also diminishes as the percentage of salt diminishes. Only approximate calculations are useful because variations in temperature, amount of salt actually in solution and the rate at which heat can be radiated, all combine to give results which may vary widely from those calculated.

As a matter of fact, it is seldom necessary or advisable to use a solution containing over 2 or 3 per cent. of salt. The best way to add salt to a liquid rheostat is to make a strong solution in a separate vessel and add as much of this solution as is needed. This avoids the annoying increase in conductivity of the solution which happens when the salt itself is added and is gradually dissolved.

Liquid rheostats are ever so much more satisfactory for alternating than for direct-current testing. The electrodes and solution are practically free from decomposition, and a given cross-section seems to be able to carry a larger alternating than direct-current—probably due partly to the absence of the scum on the surface which hinders the radiation of heat.

ARMATURE WINDINGS.

ARMATURE CONNECTIONS AND DIAGRAMS—I.

BY PROF. ARTHUR L. RICE.

In a properly designed armature, the circuits must be in electrical balance, the armature must be in mechanical balance and the conductors must be connected so that their E. M. Fs. are in series throughout any one circuit. To fulfill these conditions, there must be the same number of conductors in each path through the armature, the connections must be such that at all times the pressure in each path is the same, the winding must have mechanical symmetry and the conductors must be so connected that in none of them is the current opposed to the E. M. F.

Without going deeply into the relations of magnetic field, current and motion, it may be helpful to glance at Fig. 1 and note that the lines of magnetic force flow from the north pole to the south; that when a conductor moves through the field it tends to bend the lines with it as if they were elastic cords; that the lines tend to curl up around the conductor and set up an E. M. F. in it; and that, if the direction of curling of the lines around the wire is such as would force a right-hand screw ahead, the E. M. F. tends to produce current flow in the direction of motion of the screw. Also, it will be convenient to remember that, with right-hand rotation (which will be used throughout these articles), the current in a conductor under a north pole should flow towards the back, and under a south pole towards the front of the machine.

The simplest form of armature is the Gramme ring. In this type only the conductors on the outside of the core are active, *i. e.*, produce any E. M. F. The current must flow from front to back in all active conductors under a north pole, so that the front end of one conductor must be joined to the back end of the one next it; in like manner the front end of each active conductor under a south pole must be joined to the back end of the adjacent one so that current may always flow forward in the active conductors under a south pole. The conductors on the inside of the core are to make these connections. (See Fig. 2.) The continuous winding thus formed may be spread over the entire surface of a smooth core, or, more commonly, placed in the slots of a toothed core.

There may be any number of conductors connected together before a lead is taken to the commutator, the only condition being that there shall be the same number of conductors joined in between each two commutator bars. The leads are usually brought out straight to the commutator bars. The lead from the inside conductor on one coil must be joined to the same commuator bar as that from the outside conductor on the adjacent coil, in order that the series connection of conductors may not be broken.

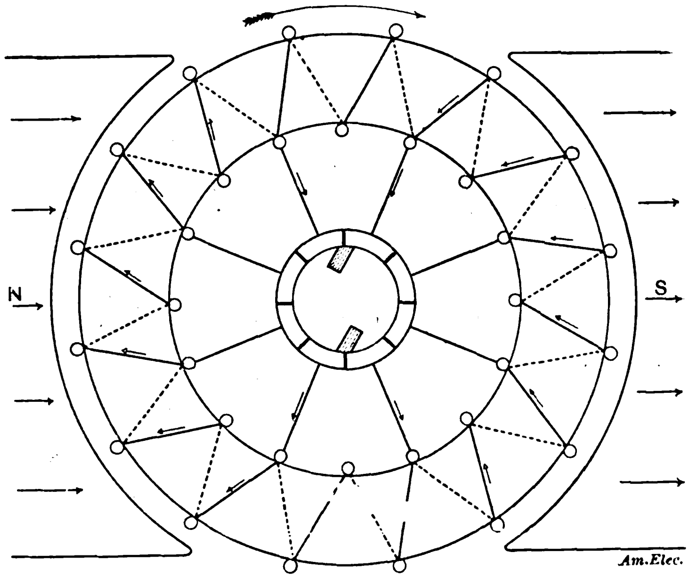


FIG. 3.—GRAMME RING WINDING.

The method of winding and connecting is too obvious to need comment. At the top and bottom of the armature, in a two-pole machine, there will be a point where the currents will meet and tend to flow against each other; these are the points to which the brushes should be connected, *i. e.* they should be placed in the commutator bars which are connected to those points (see Fig. 3). There will be as many commutator bars as coils.

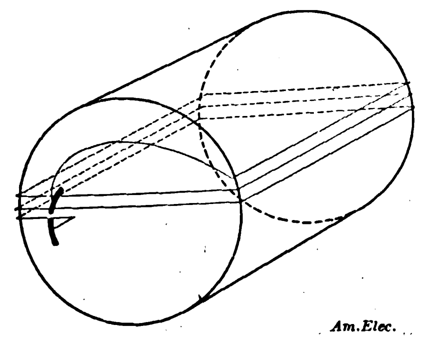

FIG. 4.—DRUM WINDING.

This is the simplest form of armature to wind and connect, but there is a large proportion of inactive wire on account of the inside connections. To lessen the dead wire, the drum winding is used. In that form, the conductors on the outside of the armature are connected by wires running across the end on a chord of a circle. Take the case of a two-pole armature having twelve coils; each coil is really two conductors, so that there will be twenty-four conductors, as in Fig. 5. The front end of each conductor must be joined to a commutator bar and the back end of each conductor to the back end of another conductor. In order that the conductors may be in series, the back end of a conductor under a north pole must be joined to the back end of a conductor under a south pole; and to get a symmetrical winding, conductors as nearly opposite as possible should be joined. There are to be as many commutator bars as coils, since an end from each of two coils is joined to a commutator bar; also, since there are to be two paths through the armature, there must be an even number of coils, so that there may be the same number in each path or circuit. Number the conductors and commutator bars as shown.

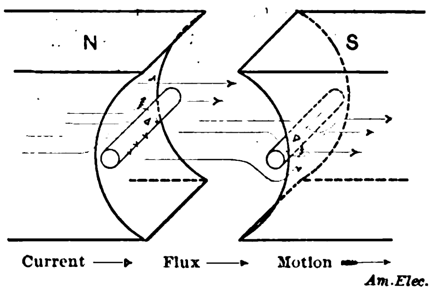

FIG I.—GENERATION OF E. M. F.

Suppose that the commutator is set so that the bars come opposite the odd-numbered conductors; the natural connection is from conductor 1 to commutator bar 1, thus giving a straight lead. Conductor 1 must be connected on the back end, to a conductor that is not over a commutator bar, in order to get symmetrical winding; it may connect to either 12 or 14; suppose it be connected to 12. The front end of 12 must be connected to some commutator bar; it is desirable to keep the end connections as short as possible, yet the connection must be to a conductor under the north pole, and, for the sake of symmetry, nearly opposite. The connection is therefore carried to commutator bar 2; as conductor 1 has been connected to bar 1 directly underneath, each odd-numbered conductor must be connected to the bar under it; hence bar 2 is connected to conductor 3. In joining conductor 1 to 12, the advance was eleven conductors; therefore, from 3 the advance must be eleven, or to conductor 14; from 12 the connection was to 3, or a retreat of nine, hence from 14 the retreat is nine or to 5 through bar 3; the number of conductors advance on the back is called "back pitch;" that of retreat on the front, "front pitch."

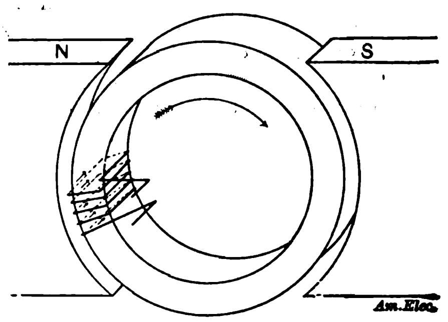

FIG. 2.—GRAMME RING WINDING.

This form of winding, alternately advancing and retreating, is called "lap winding" because the coils lap over one another. (Note that the back connections have been drawn in dotted lines, and the front connections in full lines.) The rest of the connection follows the same rule, and may be tabulated thus:

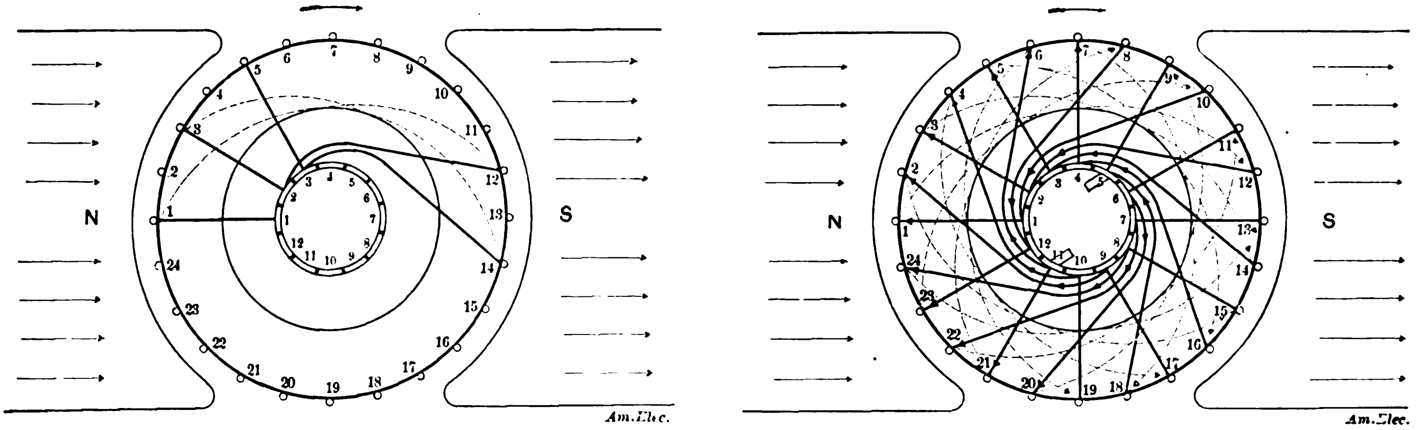
Bar 1	to conductor 1,	back, to 12,	front
" 2	" " 3,	" " 14,	"
" 3	" " 5,	" " 16,	"
" 4	" " 7,	" " 18,	"
" 5	" " 9,	" " 20,	"
" 6	" " 11,	" " 22,	"
" 7	" " 13,	" " 24,	"
" 8	" " 15,	" " 2,	"
" 9	" " 17,	" " 4,	"
" 10	" " 19,	" " 6,	"
" 11	" " 21,	" " 8,	"
" 12	" " 23,	" " 10,	"
" 1			

and the starting point has been reached, all the conductors and bars having been connected. From a table like the above, called a winding table, it may be determined, without the labor of drawing a complete connection diagram, whether or not an armature is to connect properly with a given number of conductors and pitch.

The completed diagram is shown in Fig. 6. It is desirable to test the winding and see if it fulfills the necessary conditions. First, where are the brushes to be placed to collect current?

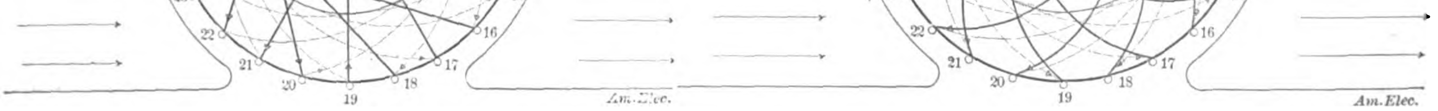
Bear in mind that, with right-hand rotation, as shown by the arrow, the E. M. F. under a north pole tends to set up current from front to back of the machine, *i. e.*, away from the observer; hence under a north pole the current should flow away from a conductor in the back (dotted) connection, and towards it in the front (full) connection, and *vice versa* under a south pole.

Starting with conductor 1, current should flow away on the back connection to 12, from 12 to 3 through bar 2, and so the current may be traced successively through conductors 14, 5, 16, 7 and 18, the current being, so far, in unison with the E. M. F. If the course be continued, it must pass through 9; but in 9 the E. M. F. tends to send current towards the front, and the next conductor, 20, tends to send current towards 9; current should, therefore, flow into bar 5 from both directions, and a brush should be placed on that bar to carry current from the armature to the outside circuit.



FIGS. 5 AND 6.—LAP WINDING.

Returning to conductor 1, and going in the opposite direction, current comes to 1 from 10, 23, 8, 21, successively in unison with the generated E. M. F.; if the course be followed further, in 6 the E. M. F. is found tending to set up current towards the back end, *i. e.*, away from bar 11, so that current must flow into the armature from bar 11 and the other brush should be placed on that bar. Continuing from 6, the current would flow through conductors 19, 4, 17, 2, 15, 24, 13, 22, 11, 20 and 9 to the other brush already placed on bar 5, and will always flow in the same direction as the E. M. F.



FIGS. 7 AND 8.—LAP WINDING.

The winding has, therefore, the current always in the same direction as the E. M. F.; moreover there are twelve conductors in each path from brush to brush, and diametrically opposite conductors are in different circuits so that, for symmetrical flux distribution, the E. M. Fs. of the two circuits will be the same. Since the diagram has geometric symmetry, the winding will be in mechanical balance and the conditions stated at the outset are fulfilled.

In the actual winding of a machine, it is probable that, instead of two conductors to a coil, there would be several; those lying at 1 would be connected in series with those lying at 12 by end connections front and back (See Fig. 4), and the ends of the coil brought out and connected as before, the same being done for the other coils. In the process of winding, coil 1-12 should be put on first, then 24-13; next 7-18, and afterwards 6-19; next 3-14, and after that 2-15 and so on; this ensures easier winding, better shaped heads and more even resistance than would be gotten by beginning with one coil and winding in succession around the armature.

If, after connecting conductor 1 to conductor 12, the front lead had been carried from 12 eleven conductors ahead, to bar 12, and thus joined to conductor 23, and all the other front leads from even-numbered conductors had been changed correspondingly, the result would have been a "wave" winding, so called because the connection always advances like a wave traveling around the armature; the front and back pitch would both be 11. The winding table would be as follows:

Bar	1	to conductor	1,	back to	12,	front.
"	12	" "	23,	" "	10,	"
"	11	" "	21,	" "	8.	"
"	10	" "	19,	" "	6,	"
"	9	" "	17,	" "	4,	"
"	8	" "	15,	" "	2,	"
"	7	" "	13,	" "	24,	"
"	6	" "	11,	" "	22,	"
"	5	" "	9,	" "	20.	"
"	4	" "	7,	" "	18,	"
"	3	" "	5,	" "	16,	"
"	2	" "	3.	" "	14,	"
"	1					

The diagram of connections would be as shown in Fig. 7. The winding of the coils would be the same as before, the difference being in the connections to the commutator.

In the case of a two-pole machine, there is little preference between the lap and wave forms of winding, the former giving somewhat shorter end connections. In the case of a lap winding, the only condition is that the number of coils shall be the same as the number of commutator bars, and the number of bars must be even to allow of equal division between the brushes. The pitch, front and back, must be so chosen that an odd-numbered conductor will be connected to an even-numbered one, and *vice versa*, alternating in passing around the circuit.

The connection to the commutator used above (Fig. 6) gives the position of the brushes about half way between the poles. If desired, the front leads from 1 and 10 may be carried to a bar about half way between the conductors, say, to bar 3, thus equalizing the length of the leads. If the same change be made in all the connections, the position of the brushes would be advanced, approximately, 90 degs., and the armature would be as in Fig. 8. The brushes may thus be made to come in any position desired to accomodate the mechanical design of the machine, or to give the appearance of a small brush lead.

The same process of winding and connecting would be followed for an armature having a large number of coils and commutator bars, but the diagram would, of course, be more intricate and the winding table longer.

LIBRARY

DESIGNING DYNAMOS AND MOTORS.

SMALL MOTORS.

BY CECIL P. POOLE

The calculation of the magnetic and electric details of dynamos and motors naturally begins at the armature, and for best results all the characteristics of the armature should be determined before any work is done upon the field-magnet data. The controlling factors in armature design are the iron and copper losses, and these must be assumed roughly and experimental calculations made in order to obtain a foundation for definite proportions.

For example, suppose it is desired to design a $\frac{1}{8}$ HP bipolar motor with a toothed armature to work on a 110-volt circuit. So small a machine would be given a series field winding because of the expensiveness of winding both field and armature for 110 volts. Allowing one-half of the total energy for consumption in the field and armature, the counter E. M. F. will be 55 volts. The current will therefore be $\frac{746}{16} \div 55 = 0.85$ amperes approximately, but some allowance must be made for the friction loss, so 1 ampere may as well be assumed for the current. This will make it a 110-watt machine. Anyone familiar in the remotest degree with the general run of sizes will know that the armature will be somewhere near 1½ or 2 ins. in diameter. Taking the larger size, the first step will be to determine the size of the slots. In so small a machine eight coils will be enough, so that there will be eight slots. About one-half of the outer circumference should be iron, and as the circumference is 6.28 ins. the sum of the angular width of the teeth will be about 3 ins.; for convenience assume 3.08 ins. for the teeth, leaving for the sum of the slot widths 3.2 ins., or .4 in. each. It is safe to make the slots square, or as near so as will make the winding fit comfortably; so for the present the slots are .4 in. × .4 in.

A.—The size of the wire comes next. The output being 1 ampere, each wire will carry ½ ampere, so that No. 24 or No. 25 wire will be about right for the usual depth of armature winding. No. 24 measures 28 mils over insulation; the slot insulation should be at least 0.025 in. thick, taking up 0.05 in. of the width and leaving 0.35 for wire; 12 No. 24 wires, side by side, measure 0.339 in. over all, so that the slots would have to be $0.339 + 0.5 = 0.389$ in. wide, to be exact, but the insulation will spread enough to let the width remain 0.4 in. The depth of the slot deducting the insulation on the "floor" (0.025 in.) is 0.375 and this will accommodate 13 layers of No. 24 wire, so that there will be $156 \times 8 = 1248$ wires all around the armature.

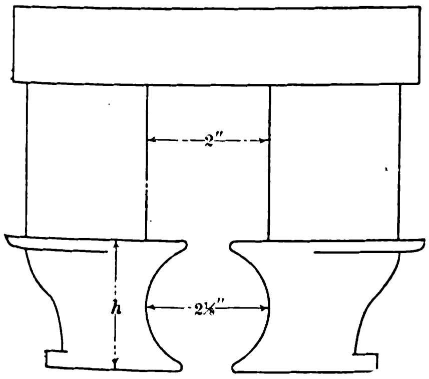


FIG. 1.—ARMATURE DISC.

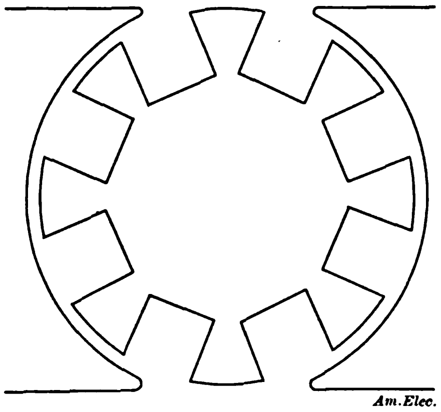
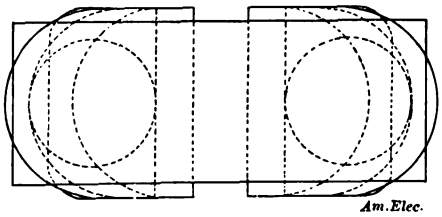
B.—Allowing an armature speed of 300 r. p. m., the total number of magnetic lines passing through the armature must be, to generate 55 volts,

$$\frac{55 \times 10^8}{1248 - \frac{300}{60}} = 89{,}743.$$

As the lines will pass through less than half of the teeth, three teeth will have to carry them, and the density of the flux in the teeth will determine the length of the armature.



Am. Elec.



Am. Elec.

FIG. 2.—FIELD FRAME.

The width of one tooth averages practically $\frac{(1.6\,\pi) - (8 \times 0.4)}{8} = 0.228$ in., and three teeth give 0.68 in. angular breadth of iron pathway. The teeth should be saturated magnetically, and as an experimental figure, a density of 90,000 lines may be assumed. As the total flux required is 89,743 lines, only 1 sq. in. of aggregate cross-section in the three teeth will be needed; the angular width being 0.68 in., the axial width will need to be 1.5 ins., so that the armature may be made 1½ ins. long, provided the iron loss is not excessive.

The so-called hysteresis loss in the teeth will be approximately 9 watts per cubic inch, or a trifle over $\frac{7}{10}$ watt for all six teeth (three on each side). The density in the body of the armature is $\frac{89{,}743 \text{ lines}}{1.8 \text{ sq. in.}} =$ 49,860, which is low for sheet iron. The iron loss would not exceed 6¼ watts, making less than 7 watts for the entire core, or 6.36 per cent. of the output, which is reasonable.

The armature dimensions, then, may remain as first assumed: Length, 6.36 ins., diameter, 2 ins.; 8 slots, .4 in. wide and 0.4 in. deep, containing coils of No. 1½ wire 13 layers deep and 12 turns wide in each slot. (As each slot will carry one-half of each of two coils, each individual coil will contain 78 turns.)

C.—The armature being 1½ ins. long, the pole-pieces will be 1½ ins. long, and the height, *h*, should be not less than the diameter of the armature—2 ins.—with the corners rounded away until, with a bore of 2⅛ ins., each polar arc embraces about three-fourths of one side of the armature. The area of the field cores will depend, of course, upon the density employed; an average grade of wrought-iron shows a curve, the "knee" of which extends from about 75,000 to 85,000 lines per square inch, and the middle of the knee is a good point at which to work small magnets. Assume temporarily a density of 77,400 lines (12,000 gausses).

Besides the total flux of 77,000 lines figured for the armature, the magnet will have to supply from 35 to 50 per cent. more lines which are lost by leakage; in so small a machine the leakage may be arbitrarily assumed to be 40 per cent.; if it be more the speed will be slightly higher and if less it will be lower. With 40 per cent. leakage the total flux generated will be $77{,}000 \times 1.4 = 107{,}800$ lines; if the density be 77,400 lines the sectional area of the limbs will be

$$\frac{107{,}800}{77{,}400} = 1.4 \text{ ins. roughly}$$

—say 1⅜ ins. in diameter for round cores, which will give an area of 1.48 ins. The density in the yoke should be as low as possible to lessen the leakage at the corners.

The width of the yoke must be at least 1⅞ ins. in order to cover the ends of the cores, and it should be wide enough to "back up" the coils; 2 ins. across will not be excessive. If cast-iron be used the density should be not over 30,000 lines; if wrought-iron, about 60,000 to 65,000 lines. The flux through the yoke is usually from 5 to 15 per cent. less than that through the cores, owing to the leakage at each end of each coil; the maximum flux being 107,800, that in the yoke will be about 97,000. A cast-iron yoke must have, therefore, a cross-section of $\frac{97{,}000 \text{ lines}}{30{,}000 \text{ density}} =$ 3.233 ins., and the thickness will be $1\frac{3}{16}$ ins., 2 ins. having been taken as the width. A wrought-iron yoke, at 65,000 density, would have a cross-section of $\frac{97{,}000}{65{,}000} = 1.49 +$ ins. (say 1½) or a thickness of ¾ in. (If cast-iron be used the field cores should be let into the yoke with a taper fit instead of being simply "butted" to it).

D.—The length of the cores depends largely upon the C^2R loss in the field coils, as with constant potential at the terminals and a fixed size of wire and depth of winding, the exciting power of a coil is the same for any length within reasonable limits, the only effect of lengthening a coil being to reduce the heat loss. The length of the cores

TABLE OF AMPERE-TURNS PER INCH OF LENGTH FOR VARIOUS MATERIALS AT DIFFERENT DENSITIES.

Lines per sq. cm.	Lines per sq. in.	Cast Iron	Cast Steel	Wr'ght Iron	Sheet Iron

15000	96,750	......	60	58	50.0

may be temporarily assumed as two to three times their diameter, say 3 ins.

E.—**In computing ampere-turns, the writer figures in ampere-turns per inch of length instead of working out a permeability or reluctance of the circuit, having prepared from a number of magnetic tests the accompanying table giving the ampere-turns per inch required by wrought-iron, sheet-iron. cast-steel and cast-iron at various densities,**

The densities, etc., in the various parts of the circuit are summed up as follows:

	Total Density.	Length of Path.	Amp. turns.
Armature body	49,860	1.6 ins.	8
Armature teeth	89,740	0.8 in.	26
Air-gap	$\frac{77.000}{5 \text{ ins.}} = 15.400$	⅛ "	603
Pole-pieces (cast	$\frac{97.000}{5 \text{ ins.}} = 19,400$	3 ins.	21
Field-cores	$\frac{107,800}{1.48} = 72,838$	6 "	98
Yoke (wrought)	$\frac{90\,000}{1.25} = 72,000$	3¾ "	57
Total ampere-turns			813

As the current at full load is to be 1 ampere, the ampere-turns and total convolutions of wire are identical—813; the winding being in two coils 814 will be a more convenient number. In the case of a small series motor on a constant potential circuit both the voltage and current are regarded as constant in calculations, full load only being considered.

The counter E. M. F. of the armature being put at 55 volts, the losses must be deducted from the remaining 55 volts so far unaccounted for. The iron loss was shown to be a trifle under 6.95 watts, so 6.95 volts (the current being 1 ampere) are absorbed here; the resistance of the armature, hot, will be 3.3 ohms, which takes up 3.3 volts more, and 0.25 will certainly be lost in connections. This leaves available 44½ volts (or 44½ watts). It is not advisable to dissipate much more thon ⅓ watt per sq. in. of coil surface, and as the two coils will have from 25 to 30 sq. ins. of surface, 10 watts will be about the limit for the C^2R loss. This means 10 volts drop in the windings. Assuming a depth of $\frac{3}{16}$ in. for the wire on the core, the average length of each turn will be 4.9 ins., with armature winding, and as there are 814 turns the total length will be 3988½ ins. on the cores, and 3990 ins. or 332½ ft. including connections.

If 332½ ft. must have a resistance of 10 ohms, 1000 ft. will have 30 ohms. The nearest *larger* size (which should always be taken) is No. 24 B. & S. gauge, having a resistance of 0.257 ohms per 1000 ft. at 75 degs. F.; this will rise to about 30 ohms hot. Allowing for insulating heads, each coil will be 98 turns in length, so that there need be only 4⅙ layers of wire to give the required number of turns total. This will reduce the depth of winding to scant ⅛ in., and the mean length of each turn to 4.7 ins. The revised total length will therefore be $\frac{4.7 \times 814}{12} =$ 320+ ft. and the resistance 9.6 ohms, leaving 34.9 ohms for the extraneous resistance.

It is obvious that by making the magnets longer the energy expended in the outside resistance could be applied to them and a higher efficiency obtained; it is also obvious that the armature might be made longer and the fields larger so as to obtain a greater number of lines of force and consequently a higher counter E. M. F., thus eliminating the outside resistance. The gain in efficiency, however, does not justify the extra first cost in so small a machine; in fact, it is rather too efficient as it is, the electrical losses being only one-half of the total applied energy.

It is easy to see that the lower the voltage, within the ordinary limits, the more efficient a machine of any size may be made for a given ratio of cost to output, or the lower the cost for a given output and efficiency. In the case of the particular motor here described, if the impressed E. M. F. were 75 volts no extraneous resistance would be required and the electrical efficiency would be about 66 per cent. instead of 50.

FUSES vs. CIRCUIT BREAKERS.

SOME FACTS AS TO FUSES AND CIRCUIT-BREAKERS.

BY JOSEPH SACHS.

It is to be regretted that a discussion regarding the relative merits of technical apparatus cannot be freely carried on without some of the participants therein indulging in uncalled-for personalities. The writer has attempted to show in previous articles, appearing in this journal, the relative advantages of a possible protective device which is practically unknown to the commercial electrical public, and an electromagnetic mechanism which has had ample advertising and usage to create a most thorough familiarity with its characteristics.

One of the writers who takes upon himself the defense of circuit-breakers says that "Personally, while I have no interest whatever in circuit-breakers at this writing, I took up the cudgel owing to the speciousness of the arguments advanced. In looking for the animus of the attacks I am informed that both writers are financially interested in cartridge fuses." If I am correctly informed, the writer of the above has a decided interest in circuit-breakers at this writing.

Mr. Harrington, quoting a statement that "a properly designed fuse will open the circuit as quickly on heavy overloads as a circuit-breaker," says that if this assumption is granted as correct, "then such engineers as Dr. Cary T. Hutchinson, C. O. Mailloux, Gano S. Dunn, etc., must be mistaken." In reply to this misleading comment, it is merely necessary to say that this discussion refers to the enclosed fuse, and not the open fuse which the above gentlemen have condemned, in common with the writer and all other advocates of the enclosed fuse. Their engineering ability is undisputed, but being as yet quite unfamiliar with the improved types of fusible cut-out, their decision to use circuit-breakers for certain classes of electrical protection could scarcely be otherwise, considering that the other available protection has been the common type of open-air fuse. Yet so thoroughly do these gentlemen believe in protection that they almost invariably guard against any unfaithfulness on the part of the circuit-breaker by using, in conjunction with it, an open-air fusible cut-out.

Now as to the statement, "A properly designed fuse will open the circuit as quickly on heavy overload as a circuit-breaker" of which it is said that both Mr. Cutler and the writer are very positive. Mr. Cutler makes this statement in his last article. What reason has Mr. Harrington to differ therefrom? Has he ever compared the relative action of circuit-breakers and such fuses as are mentioned as "properly designed" fuses in this discussion? It may be most emphatically stated that a properly designed fuse is not an open-air fuse of any arbitrary length, placed in any contact block, and run at about 50 per cent. below its actual carrying capacity, with an overload factor of perhaps 25 per cent. above. Let Mr. Harrington try an improved fuse which will act at about 10 to 15 per cent. overload current in a short-time interval, and compare it with a circuit-breaker having the same carrying capacity. Probably he will then find his differences not quite so emphatic.

Another luminous argument advanced by the same writer is that "no two manufacturers would produce a similar type of fuse, and the same unfortunate diversity of conditions, sizes, shapes, alloy, length, position, method of enclosure, kind of contacts, character of current and age; thus the fuses placed upon the market would soon assume the proportions that now bewilder the layman upon investigating the fuse question."

Notwithstanding the fact that this objection always accompanies fuses, none are expected to think of the many different forms of circuit-breakers, their different sizes, shapes, methods of operation, etc. Who has ever suggested the use of the electromagnetic trip arrangement used in the circuit-breaker of one make, applied to the switching and circuit-controlling mechanism of another? When we buy such a device we usually expect both of these essential elements to be adapted to one another.

Fuse cut-outs must be considered in exactly the same light. The fuse and its receptacle or contact block are one complete device, in which each element has its own special function. It is no more essential that the fuses of one manufacture should be used in blocks of another, than it is that magnetic operating mechanisms adapted to one form of switch device should be applied to another. The variety of magnetic circuit-breakers on the market at the present time, and still developing, promises to be quite as bewildering to the layman as any present aggregation of fusible-cut-out protective appliances.

Another point may be made as to "character of current and age." Has Mr. Harrington ever designed a direct-current circuit-breaker which would work at the same rating on alternating current? Has he ever found that age has a peculiar affinity for the releasing mechanism of an automatic electromagnetic circuit-breaker? There are few who have used circuit-breakers in all sizes who will not bear witness to that peculiar sticking disability which old age brings on, and which is most decidedly an infirmity in the wrong direction. Such infirmities may exist in fuses. In some they are of the same nature as those of the circuit-breaker. It is, however, but just that the writer should here assert that this infirmity, if at all a characteristic of the fuse mentioned in a previous article, is in the opposite direction. It will by no means permit excesses due to sticking.

Mr. L. W. Downes in his article takes exception to a number of my previous statements. He should, however, have credited the writer with a fair knowledge of the essential elements for fuse calibration. No mention of the fact that "a fuse calibrated in this way at 60 degs. would not by any means carry the same current at 80, 90 or 100 degs." was made, because it was assumed that the necessity of such "a fixed standard for the surrounding temperature" was well understood.

By including a time factor for, say, the smallest percentage of operating current, and perhaps also giving the current, which will operate almost instantly, say, in one second, readily enables the user to understand the exact working of the devices at various intermediate points of overload, and to better plan his protecting devices.

Mr. Downes accuses the writer of "failing to realize that an enclosed fuse constructed as described is quite worthless as a protective device, except in cases of short circuit, without the chamber; for the reason that its maximum carrying capacity changes with the length of time the fuse is in circuit, gradually becoming less as the mass of surrounding material becomes heated, with a proportional change in its blowing time, for any given overload factor."

Such a realization is scarcely essential in order to produce a fuse of the type mentioned, which will give as good results as those described by Mr. Downes. It is unnecessary to give at this moment the exact methods adopted to produce this result, but it may be positively stated that it has been accomplished and without an air chamber such as Mr. Downes uses. A full description of these methods will shortly appear. It may be well to realize for the present, that this difference in time of action between cold and hot points is almost entirely a question of the heat capacity of the environment. This being the case, Mr. Downes will perhaps appreciate that by a suitable proportioning of the latter, the difference in time between the hot and cold operation can be minimized. It may also be said that the idea that "the calibration of such fuses to their maximum carrying capacity at a given temperature is, however, a very tedious process, requiring the most careful attention for many hours, as with large sizes it requires from eight to ten hours for the mass to reach its maximum temperature," is also erroneous and depends upon the same consideration.

Quoting again, Mr. Downes claims that the writer stated in regard to fuses of his design "that they can be built to blow on 10 per cent. or even less above its continuous running point." * * * "In the assumption that it is impossible to construct air-suspended fuses, with a short-time interval, is another error, and it is possible to secure almost any desired time factor by a suitable adjustment of the various parts."

It is not intended to credit the fuse with any peculiarly remarkable performance in the above without considering time. When, however, both time and overload are considered, a fuse which will operate at, say, 10 per cent. overload current in a *very* small time interval, is certainly notable. Owing to a peculiar action in the fuse described, this time interval with a minimum acting overload, can be made very small, and, it is fully believed, attain results unattainable with an air-suspended fuse.

By no means is it intended to propose the general utilization of a fuse operating at 10 per cent. overload in one second. The one-second operating point mentioned is in no way connected, or intended to be connected, with the 10 per cent. overload. The statement will be found to read, "whose one-second operating point leaves a certain factor of safety in the apparatus to be protected." The fuse therefore would operate in one second at a current which would leave a large factor of safety for the *same time interval* in the apparatus to be protected, but this current may be far above the 10 per cent. point.

As it is expected that the writer will shortly be able to go into details of this new form of thermo-electric protecting device, it is deemed advisable to simply refute and not advance new features and characteristics. It may be said that in the development of this appliance many peculiar features were found which, when combined, produce a protecting device with the advantages of both the ideal fuse and the present forms of circuit-breaker.

THE ENCLOSED FUSE.

BY D. J. CARTWRIGHT.

In discussing this question, I am not influenced by any prejudice against my competitors in the field. My object is simply to state the main features of various protective devices as they appear to me after careful study.

Which is the more reliable, a mechanical device with its many springs and its liability to get out of adjustment, or a thermal device containing no springs, no poor contacts, no friction, and which can be installed by any man of ordinary intelligence? A mechanical device for opening the circuit with a given current in amperes in a given time has been long sought; fuses and circuit-breakers have been designed for this purpose and there are devices that will do it.

There are various circumstances to be considered in selecting a proper cut-out. A motor in starting will require a greater number of amperes than could be maintained indefinitely without danger to the insulation of the machine. The insulation is likely to be destroyed also by the quick breaking of the circuit. For these reasons, it is desirable that the cut-out, whether an electro-mechanical or a thermal device, should have a time limit. In a central station where men are in constant attendance, a mechanical device may be more economical and serve to protect a machine from dangerous overload. But, away from the station, a device not liable to get out of order should be used; one, in fact, requiring no attention and which can be installed in any convenient location.

When a fuse melts, it must be removed and another put in its place. To do this requires some little time and exposes the operator to more or less danger if *naked* fuses are used; this danger is entirely eliminated by using enclosed fuses.

When a circuit-breaker in a station operates, all that becomes necessary is to close the circuit. If it is used on a power system, a sufficient time must elapse to allow for the cutting out of all the motors which are supplied by the machine. The use of a mechanical circuit-breaker is not a saving of time—in fact, it saves only the cost of a fuse.

The defects of naked fuses are well known, but a few words will not, however, be out of place.

The carrying capacity of a naked fuse is affected by a draught of air, by its position, either horizontal or vertical, by the substance it may be in contact with, by its length, by the composition of the fuse-wire, and many other reasons which increase or decrease the melting point of the fuse.

On a short circuit of 220 volts or greater, with an open fuse in any form of cut-out now in common use, either the cover, the side, or the terminals are destroyed, or partially so, and in many cases a new cut-out must be put in. It is important that the fuse may be handled with impunity even when in the circuit.

I have designed a new enclosed safety fuse constructed and operated in a novel way and producing, I believe, the most desirable results in a better and more efficient manner than any other device of its class. It can be provided with means for preventing the ferules on the ends of the fuse case making contact with the circuit.

In this device, the fuse is so constructed that the wire melts within the central section and the heated air and gases formed thereby, in forcing themselves to the outer or end sections, blow out the arc. This fuse can be used on any pressure less than 2200 volts. It will not maintain an arc between its terminals when short-circuited on the mains of a 2200-volt, 120-KW alternating dynamo.

The cut-out consists of two parts: the base and tube. The base is made of slate, and the tube of fibre tightly closed. Fig. 1 represents the cut-out complete, Fig. 2 shows the fuse with the central part of the case cut away to show the fuse-wire in the central air-space and also the filling at each end; and Fig. 3 represents a 50-ampere fuse cut open after it had been short-circuited on a 500-volt circuit of 450-KW capacity, and it opened the circuit without noise or flash. This fuse would have carried 50 amperes of current indefinitely. It would have melted on a current increase of 25 per cent. in less than three minutes.

In testing, a fuse that carried 60 amperes of current for three hours was allowed to cool for 15 minutes; the current was then increased to 75 amperes, and the fuse operated in 2 minutes 48 seconds, an increase of

25 per cent. over the carrying capacity of the fuse.

This fuse has a definite length, cannot come in contact with any foreign substance, can be operated in a room filled with inflammable gas, and it will open the circuit in in a predetermined time on a given current in amperes.

Owing to the peculiar construction of this enclosed safety fuse, a tube or case 3 ins. long will open the circuit where other devices require more than twice that length operated under the same conditions and with a fuse of the same carrying capacity.

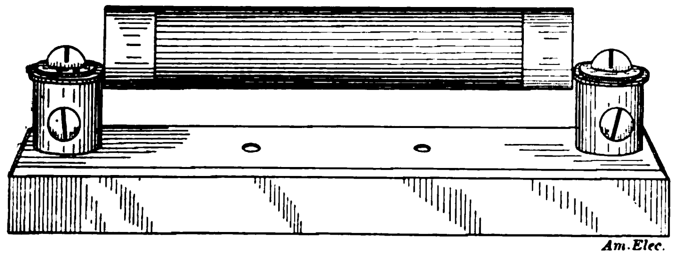

FIG. I.—CUT-OUT COMPLETE.

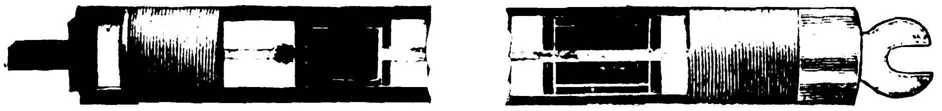
It has, in fact, broken a short circuit of 220 volts and 375 amperes within a space of ¾ in., leaving the other parts of the fuse-wire whole, and it accomplished this result without any explosion or destructive arc.

A fuse of this type and of 50 amperes capacity has been short-circuited on a 2200-volt alternator within 10 ft. of the dynamo without any extra resistance or shunt in the circuit, and opened the circuit without maintaining an arc between the terminals which were 6½ ins. apart.



FIGS. 2 AND 3.—CUT-OUT BEFORE AND AFTER BLOWING.

In a test made at the Boston Electric Light Company's station before the representatives of the wire department of the City of Boston, and the Factory Mutual Insurance Company, several sizes of fuses were tested on 2140 volts, 500 volts, 104 volts, and all of the fuses operated in a quiet and satisfactory manner.

It has been claimed by a manufacturer of fuses of the enclosed type that the arc is extinguished by the carbonic acid gas generated when the fuse melts. This is an error, as Faraday in his book, ' Experimental Researches in Electricity," says that "In carbonic acid gas there seems to be a facility to occasion spark discharge." This is also proved by the enclosed-arc lamp, in which the arc is maintained within a globe filled with carbonic acid gas.

The growth of the enclosed fuse is quite interesting. A careful search of records of the Patent Office shows that the first patent for an enclosed fuse was issued to T. A. Edison, Oct. 14, 1890.

This device shows a naked fuse-wire within a tube closed at each end, flanges or *disks* on the *outside* of the tube located near the terminals, the fuse, however, being in contact with the case at one or more points within the tube—a device which could not have a constant melting point.

The second patent was issued by D. J. Cartwright, Dec. 2, 1890. This device shows a fuse-wire enclosed within a case closed at each end, with removable partitions located *within* the tube through or around which the fuse-wire passes; a *definite air-space surrounding the fuse*, the case being divided into sections of different lengths and provided with a means for preventing the maintenance of the arc formed between the terminals.

The third patent was issued to G. F. Curtiss, March 31, 1891. This appears to be the same device patented by Mr. Edison, except that the ends of the tube are *open*.

The fourth patent was issued to H. V. Hayes, Sept. 1, 1891. This device shows a fuse enclosed within a *ventilated tube* and a device for indicating the rupture of the fuse when operated on a short circuit, and is now used for the protection of telephone circuits and instruments.

The fifth patent was issued to O. T. Blathy, Aug. 16, 1892. This device shows a fuse-wire enclosed within a case closed at each end, ventilated sides, fixed partitions located within the tube through which the fuse-wire passes, and a *definite air-space surrounding the fuse wire.* In another form he shows an open fuse with movable *disks* at each end.

The sixth patent was issued to J. Sachs, July 3, 1894. This device shows a fuse surrounded by a chemical salt that combines with the metal when heated so that the circuit is opened. Is its carrying capacity lessened when subject to an overload?

The seventh patent was issued to A. H. McCullock, Dec. 3, 1895. This device shows *a fuse loosely surrounded by asbestos* throughout its entire length, the ends re-enforced by the fuse being bent back and twisted around itself in such a manner as to make its central portion of less carrying capacity than the ends, and the whole being placed within a case.

The eighth patent was issued to L. W. Downes, June 2, 1896. This device appears to be a combination of McCullock's fuse, which is surrounded by loose asbestos, with the disks of Edison and Blathy, the perforated ends of Curtiss and the confined body of air of Cartwright and Blathy.

The ninth patent was issued to L. W Downes, Oct. 13, 1896. This device appears to be the same as the patent of June 2, 1896, except that the disks of Edison and Blathy are omitted and a finely divided refractory material in a loose condition is used instead of asbestos, and the definite air-space of Blathy and Cartwright is perforated by many holes.

The tenth patent was issued to W. E. Harrington, April 27, 1897. This device appears to be the fuse of McCullock with the asbestos removed from the central portion, and the center of the fuse in the open air; the ends of the fuse are constructed as shown in Curtiss' patent.

The eleventh patent was issued to D. J. Cartwright, Sept. 28, 1897. This device is an improvement on the device patented Dec. 2, 1890, and appears to be the same except that the ends of the fuse are surrounded by a foreign substance for the purpose of conducting away from that part of the fuse-wire the heat generated by the current passing through the fuse-wire at that point and to absorb the gases produced when the fuse-wire has become broken.

One great advantage of this device is that it may be provided with a means for indicating a break of the fuse wire caused by a short circuit or overload.

The Hunter Alternating-Current Patents.

To the Editor of American Electrician:

I am just in receipt of a copy of your paper of January, and notice on page 24 thereof an article criticising my recent patents of Dec. 21, 1897, which cover broadly the alternating system. Your article, like a great many others which attempt to perform the function of judge and jury on legal questions, walks into many errors, and while no doubt desiring to be just, is led to make many misrepresentations and do a great deal of injustice.

The statements in the first paragraph are not correct, for while my broad patent 596,041 covers the entire art, the second patent 596,042, assigned to the General Electric Company, is sufficiently broad to cover all of the apparatus employing transformers for reducing potential now in use or likely to be used. The first patent mentioned dominates the second and is not owned by the General Electric Company.

You say the other two patents cover "step-up" and "step-down" systems, but in this you are in error, for my patents which cover that special construction and method are 460,071 of Sept. 22, 1891, and 581,684 of Apr. 27, 1897. These patents are issued to the General Electric Company.

Your reference to the work of Faraday, Berliner, Rossetti, Gaulard & Gibbs, and others, is misleading, but will not deceive those who understand the true situation. You may rest assured that these broad patents were not granted to me without the strongest opposition on the part of the Patent Office on the account of the broadness of their scope, but the justness of my position was acceded to, and the Patent Office, which knows more about my work than the writers of articles (who have never known me and do not know anything of my work), is, I think, the better judge of what is due me.

Your reference to me as being widely known as a "paper patent inventor" is one of the idiotic *noms de plume* given to me by those who hate me because I stand in their way in original research. Who originated such a name I do not know and do not care, but in any event it was used in ignorance and only shows the prejudice of the parties using it. No doubt the party would be found to have no acquaintance with me and none whatever with my work. I have seen so much of this that it has no more effect upon me than pouring water on a duck's back.

There is a great deal relating to the alternating system which the public knows nothing about, but will in due time possibly be more enlightened, but they may rest assured that there is more invention in the matters covered by these patents than they would like to believe.

The last paragraph of your article referring to my patents on electric traction, is also another case of an attempt to deprive an inventor of his dues before the public. To this part of your article I would make the following statement: In railway work I have defeated the following parties in numerous interferences (probably fifty or sixty), namely, Van Depoele, Sprague, Knight, Erhart, Wightman, Mansfield, Field, Brill, Bentley, Short, Priest and others. As a matter of fact, the modern car as it is built and used to-day, with every appliance connected with it, from the trolley to the series-multiple controller and trucks, *was built, constructed and operated by me before any one else.* My railway patents are broader in scope than those of any one else, and are justly granted to me. The suits under my broad patents when controlled by the Thomson-Houston Electric Company brought the Edison Company and the Sprague Company to terms and aided largely in the formation of the General Elecric Company. The reason why litigation, has not been largely carried on under my patents is due to the fact that as litigation was started under the Van Depoele patents, common sense dictated that the company owning both sets of patents should confine its litigation to one set until it was necessary to bring in the other set. I object to the insinuations which your article contains, because they are unfair and unjust, and are based upon a misunderstanding and a lack of accurate knowledge upon the real situation, which no one knows better than I.

In conclusion, let me assure you that I am not dead yet and that if I retain my health, my detractors will yet have full opportunity to change their opinions and views, probably to their discomfort, for time usually rights all things.

Philadelphia. R. M. HUNTER.

Electrical Journals.

To the Editor of American Electrician:

Since reading in the January issue of the AMERICAN ELECTRICIAN, that you had been unable to obtain any information concerning the *Telegraphic Journal*, the immediate predecessor of the *Journal of the Telegraph*, I have made a search of contemporary telegraphic literature, and have found the full history of that short-lived publication. It made its first appearance on March 7, 1867, and continued as a weekly until November of the same year, when it was succeeded by the *Journal of the Telegraph*, the first issue of which appeared, as stated in your list, on Dec. 2, 1867, under the editorship of James D. Reid. *The Telegrapher* was the first really successful paper in the United States devoted to the interests of the electric telegraph. It began publication on Sept. 26, 1864, and flourished for thirteen years, first as a monthly, then as a semi-monthly and finally as a weekly as the official organ of the "National Telegraphic Union." The late Franklin L. Pope was at one time its editor. It was in opposition to *The Telegrapher*, which was an independent organ in the days of rival telegraph companies, that the *Telegraphic Journal* was started in 1867, evidently but not openly in the interests of the Western Union Telegraph Company. Eight months later, with a slightly changed name it became the official organ of that company, and has so continued for more than thirty years.

New York. EDWARD CALDWELL.

JACQUES CELL DISCUSSION.

The Jacques Cell.

To the Editor of American Electrician:

In Mr. Reed's last letter he states that I have referred to no facts in support of my contention that the oxygen forced into the Jacques cell takes part in the electro-chemical reaction. I have repeatedly stated that the current is greatly increased by the introduction of oxygen. In my own experiments it, in fact, becomes *at once* about three times as great, when oxygen is introduced. When the gas flows slowly, 15 or 20 bubbles per minute, the needle of the ammeter swings from 1 to 3 amperes with every bubble. This last fact, I think, I have not before mentioned. I have also stated that more oxygen is *absorbed* by the cell when the circuit is closed than when it is open. This I demonstrated by adjusting the flow to give 60 bubbles per minute with circuit open. When circuit was closed this was reduced at once to 40. The change in rate was very marked, was perfectly evident without counting, and occurred every time the circuit was opened or closed. These are facts which seem, to others than Mr. Reed, to have a bearing upon the question at issue.

Mr. Reed says my analogies are not analogies, and makes some surprising statements in relation to the action of a couple in dilute acid. Surprising because they are contrary to all accepted beliefs. He says that agitation of a copper electrode in a zinc-copper cell, or the flow of an inert gas over it, mechanically removing the bubbles of hydrogen, will have the same effect as introducing oxygen.

These are the facts. If a zinc-copper couple be put on closed circuit through a small resistance for a few minutes it will gradually recover its E. M. F. on opening the circuit by shaking or even if left to itself. But if an inert gas be run through a closed cell so as to displace all oxygen and then the circuit be closed for intervals of an hour or so, it will take a longer and longer time after each interval for the recovery, until, in my experiments, after ten or twelve intervals of an hour each, the cell only recovered very slightly after standing open for an hour. It was violently agitated. Hydrogen gas was run rapidly through it. Nitrogen was substituted for the hydrogen. None of these had any sensible effect, although my instruments would have given a marked indication for a variation of $\frac{1}{10000}$ volt. Oxygen was then substituted for the nitrogen. The index at once shot off the scale, and as soon as a balance could be obtained, which required not more than fifteen seconds, the cell was found to have completely recovered, its E. M. F. having increased in that interval from .58 to 1.04 volts, while in the previous hour with all the shaking and treatment with inert gases, it had risen only from .52 to .58.

After the E. M. F. is restored by running oxygen through it, the cell must be left on closed circuit for several hours, the air at the same time being displaced from it by an inert gas, before it will again be in a condition not to recover its E. M. F. on opening the circuit.

Again, the circuit was closed through a resistance less than the internal resistance of the cell. The potential difference between its terminals was measured and found to be .214 volt. Hydrogen was then run through the cell slowly, rapidly, stopped, started again, without apparent effect, except that when the gas flowed very rapidly the E. M. F. was $\frac{2}{1000}$ or $\frac{3}{1000}$ *less.* Oxygen was then substituted and the potential difference at once increased, reaching .348 volt when the flow was quite rapid. This meant an increase of E. M. F. due to the oxygen flowing through the cell, from .52 to .827 volt, with a corresponding increase in the current.

The results attained were entirely similar when a zinc-carbon cell was used except that carbon gives a somewhat higher E. M. F. than copper.

I may say that, in my experiments, the liquid was a $\frac{1}{10}$ solution of pure H_2SO_4 in distilled water, and that the two electrodes were in separate porous cups set in a bottle and surrounded by a considerable volume of the electrolyte. The copper electrode was a tube through which the gases were introduced. I have recently verified these results, but they are in entire accord with the views I have derived from the literature of the subject within the last ten or twenty years.

They effectually dispose of Mr. Reed's statement that shaking the electrode, or running an inert gas through the cell, will have the same effect as oxygen. They demonstrate that oxygen gas conveyed into a cell *does* act as a depolarizer, does act to increase the current, while an inert gas does not. Oxygen gas conveyed into the Jacques cell increases the current three to one. The ammeter in circuit with the Jacques cell indicates the instant that the flow is started or cut-off. Where is the lack of analogy?

Mr. Reed says that when a platinum plate is used, the oxygen combines with it. This is not an accepted fact. The view generally held is that oxygen is condensed upon the surface, not absorbed into the plate even.

I repeat here what I have already said many times. For the oxygen to take part in the development of electrical energy in the Jacques or any other galvanic cell, it is only necessary that it *come into electrical contact with the cathode.* This it may do by entering into combination, by going into solution, by being condensed upon the surface of the electrode, by being absorbed by the electrode. In fact some of my experiments seem to indicate that merely damp oxygen in the gaseous form may so act.

It is absolutely certain that in the Jacques cell it does come into electrical contact, otherwise the current would not instantly respond to the flow of oxygen, and the absorption of oxygen would not at once vary with the opening and closing of the circuit.

Mr. Reed asks me to explain the "fact" that two iron electrodes, one hot and the other cold, maintain an E. M. F. of 1.2 volts "indefinitely, so long as the temperature is maintained." Will they?

The German experimenters, to whose work I have already referred in these letters, showed that the E. M. F. depends upon the oxidation going in at the surface of the electrolyte and that it is *not* maintained indefinitely. I expect before long to have some results of my own to present, bearing upon this matter. **Wm. A. Anthony.**

On the Theory of the Jacques Cell.

To the Editor of American Electrician:

You have asked my opinion concerning the views advanced in a number of articles in the columns of the AMERICAN ELECTRICIAN, on the theory of the so-called thermo-electric cell constructed by Archereau and Jacques.

This cell consists, as is well known, of a vessel of iron, in which hydrate of sodium is kept in a state of fusion at a temperature of 400 to 500 degs, C., and in which a rod of carbon is dipped. As soon as the iron vessel and the carbon are connected by a conductor, and atmospheric air is forced through the fused hydrate, an electric current is set up, and this will continue, according to the connections made, as long as the air is forced through the hydrate, but stops when the supply of air ceases.

The chemical process which takes place in this cell is the following: The carbon is oxidized to carbonic acid, which combines with the sodium hydrate, while the iron does not seem to be acted upon. The question is now, What is the source of the electric energy in the cell? Some are of the opinion that the battery should be considered as thermo-electrical, and consequently that the energy is produced by the heat added to it; while others maintain that the source of the electric current is the energy which is set free by the chemical process, and that the battery, consequently, should be classed with ordinary galvanic batteries.

Unfortunately, as far as known, no measurements have been made regarding the consumption of carbon and oxygen in the cell compared to the electric energy produced; such measurements would have served to decide the question immediately. Nevertheless, I am inclined to express it as my opinion, that the source of the electric current should be looked for in the heat set free by the chemical process.

The different materials in reaction are carbon, hydrate of sodium and oxygen, and the products are carbonate of soda and water. The total amount of energy, W, which is set free by the process is, as it will be remembered, independent of the manner in which the process is carried out, and can be expressed by the formula

$$C + 2\,NaOH + O_2 = Na_2\,CO_3 + H_2O + W.$$

According to my measurements,[1] the heat of formation of $2\,NaOH$ from its elements is 203740 calories, and for H_2O we have 68360c. Further, the reaction Na_2, O, CO_2 produces[2] 175,680c. As the heat of combustion of artificial graphite (retort carbon) according to the measurements of Favre[3] is 93,140c for 12 grammes of carbon, the heat of formation for Na_2CO_3 will be 268,820c, and we will, according to the formula, have

$$W = 268,820\,c + 68,360\,c - 203,740\,c = 133.440\,c.$$

These figures are, of course, not correct except at a temperature of about 18° $C.$, but the differences at a higher temperature will partly balance each other, and the value of W will therefore be correct to a sufficient approximation.

In order, now, to determine how much of the total energy can be changed into electrical energy, it is necessary to examine more closely into the process of oxidation of the carbon. There are three possibilities: 1°. The oxygen may combine direct with the carbon. 2°. The oxygen may form oxide of iron, which is again reduced by the electric current. 3°. The oxygen may be occluded by the iron or by the hydrate of sodium before the reaction of the carbon takes place.

1°. To my knowledge no decided instances are known where heat, produced by direct combination of two elements, is changed into an electric current. It is required, in order to transform energy produced by a chemical process into electric energy, that the two agents between which the chemical process takes place, should be separated by two other bodies, of which one should be a direct and the other an electrolytic conductor[4].

2°. If the oxygen is first united with the iron in chemical combination, the whole energy will be heat and no electric energy will be produced. And as the heat liberated by the oxidation of iron is 68,280 c. for each atom of oxygen, the heat produced by the oxidation of the carbon and the reaction of the carbonic acid on the hydrate of sodium will hardly compensate for the heat required for the separation of oxide of iron, and there is consequently no chemical energy left which could be transformed into electrical energy.

3°. It is, therefore, reasonable to believe that the oxygen which is brought into the cell, is to a certain degree occluded by the iron (direct, or supported by the hydrate of soda), in a manner similar to that in which oxygen and hydrogen are occluded by the platinum plates in the Grove (gas) cell, before they act as a factor in the production of electric energy. By such occlusion heat is produced, and this should be deducted from the total heat produced by the chemical reaction, in order to find out how much of this heat can be transformed into electric energy. According to measurements[5] by W. Ramsay, L. Maud and J. Shields, the heat of occlusion by platinum of 1 atom of oxygen (16 grammes) is 17,600 c. If it should be the same for iron, which has many qualities in common with platinum—and it seems to me reasonable to suppose that it will be near it—we will, if the heat of the occlusion is x, have as the whole energy, which can be transformed into electricity

$$W' = W - 2\,x = 133.440\,c - 35,200\,c$$
$$W' = 98,240\,c$$

or for 1 atom of oxygen absorbed there are 49,120 calories.

In the Daniell cell the energy which is transformed into electric energy is 50,130c for each atom of oxygen or zinc[6]. If the E. M. F. of this element is 1.090 volts, 46,000 c will correspond to 1 volt, and consequently we will, if all these 49,120 c are transformed into electric energy, find the E. M. F. of the Jacques cell to be

$$E = \frac{49120}{46000} = 1.07 \text{ volts.}$$

Should the heat of occlusion of the oxygen be less than 17,600 c, E will be larger; and should it be zero, E would be 1.45 volts. Between these two numbers, and most probable nearer the lowest, will the E. M. F. of the Jacques cell lay. This corresponds well with what J. H. Hellurg, Jr.,[7] has found, 1.11 volt; if the heat of occlusion of oxygen in iron should be 15,660 c, it being 17,600c for platinum, E would be exactly 1.1 volt.

In view of the above, I am of the opinion that the process in the Jacques cell is as follows: The oxygen introduced into the cell is occluded by the iron, and the whole apparatus has thus the same character as the galvanic cell; the electric current produced will, as usual, decompose the water in the hydrate of sodium, the oxygen will go to the carbon, the hydrogen to the iron, where it will combine with the occluded oxygen, and the result of this reaction will give an E. M. F. very near to 1.1 volt.

I am not inclined to think that this apparatus, which is difficult to work and expensive to keep in active condition, will be of practical value as a producer of electricity.

Julius Thomsen.

Copenhagen, Denmark.

Kilowatts and Microwatts.

A western newspaper prints a glowing account of the achievement of a local "Wizard" who has built an "electromotive machine weighing less than 50 lbs. that has a power of 100,000,000 microwatts"—that is about an eighth of a horse power. The local wizard apparently could see no harm in carrying out to its logical consequences an occasional commercial custom of expressing in watts, capacities whose proper expression is in kilowatts.

NORTHWESTERN ELECTRICAL ASSOCIATION

One of the most interesting conventions ever held by the Northwestern Electrical Association convened at the Hotel Pfister, Milwaukee, Wis., January 19th, being the sixth annual meeting of this association. In point of numbers, this meeting was the largest ever held, nearly 175 delegates being present. The supply men were well represented, the Chicago delegation alone comprising nearly 60 members.

The report of Secretary Mercien showed the association to be in a very flourishing condition, and over 50 new members were added to the rolls at this meeting.

Of the papers read, those by Mr. Alex. Dow, Prof. R. B. Owens and Mr. W. H. Edgar excited particular interest, that of Mr. Dow leading to a prolonged discussion.

Among the reports of committees was one by Mr. Pliny Norcross on "Legislation." Mr. Norcross stated that at Madison, during the session of the Legislature in 1897, some of the interests fearing adverse legislation were strongly represented. The gas interest and water companies were very strongly represented. Street railway companies, insufficiently so and the central station interests exhibited still less strength than the last named. Mr. Norcross stated that his committee was handicapped by lack of knowledge as to the views of the electric lighting companies of the State on questions that came up, and regrets the lack of organization of the electric lighting interests. As it was, his committee succeeded in defeating or amending certain bills that were thought to be antagonistic, and Mr. Norcross hoped that the association at this meeting would outline some clear plan for future guidance.

In his presidential address, Mr. H. C. Higgins spoke highly of the value of associations and frequent conventions to the members and attendants. He stated that it is gratifying to know that the hard times have been bridged over, and that we are now on the eve of better times. No company represented in the association had gone into the hands of a receiver within the past year except one, and that only temporarily, while there has been no state legislation enacted particularly offensive to the electric lighting business. Mr. Higgins considers that the greatest danger to the electric lighting business is from inventive genius, which he believes may any day destroy their investments.

The street railway business, he thinks, has suffered more during the past two years than any other legitimate business, notwithstanding that the expense of operation and cost of apparatus and material has been very much reduced. He, however, looks forward to the future of this business with much hope. As the result of a considerable experience, he advises that not less than a 60-pound steel T rail be used, with good ties, not less than 6 inches wide, laid with two feet between centres, still closer being better. In bonding, not less than No. 0 bond should be used and nothing less than No. 0 trolley wire. Nothing larger than 16 to 20 feet cars should be bought for general use, and no mistake can be made in buying the latest types of generators and equipment. Extra lines should not be laid out in order to establish a park, unless the latter is on the edge of a body of water and the road in a town of not less than 30,000 people. No animals should be purchased for the park, and vaudeville or other shows should not be run unless the situation is such that transportation would cost but little. Street railway parks should be well enclosed, and no one admitted without paying car fare each way, no matter whether they come by carriage or bicycle. Mr. Higgins does not believe that any town of less than 25,000 people will support an electric railway and give a decent return to its investors, although two towns aggregating a little less than that population, and being some distance apart, might support a good paying property. Mr. Higgins considers that the electric railway business is also menaced by inventive genius, which may at any moment render electric railway investments valueless.

The following officers were elected for the ensuing year:

President, F. A. Copeland, La Crosse, Wis.; Vice-Presidents, James R. Dee, Houghton, Mich. and P. H. Korst, Racine, Wis.; Secy. and Treas., Thomas R. Mercien, Milwaukee, Wis.; Directors, E. L. Debell, Sheboygan, Wis.; George L. Thayer, Belle Plain, Ia.; and S. B. Livermore, Winona, Minn.

THE PRACTICE OF THEORY.

Mr. John C. McMynn read a paper having for its object to show the close relations existing between the theoretical man and the practical engineer. He said that he firmly believes, after mature observation, that the educated engineer who can master practice as well as theory, is the one who will rise above his competitors in the future. By "educated," however, is meant not necessarily a college graduate, but also the man who can master the laws of mechanics and can conquer mathematics by his own exertion. As a good example of the application of theory, a recent invention is referred to which consists in pumping water into a closed tank at an elevation above the water level of a boiler, from which tank the water flows into the boiler by gravity; the head against which the pump has to work may therefore only be 20 feet, instead of perhaps a 200 ft. head; thus entailing a saving of about 85 per cent of the steam formerly used by the boiler pump.

THE PRESENT EFFICIENCY OF INCANDESCENT LAMPS.

In a paper with the above title, Mr. John E. Randall gave a sketch of the incandescent lamp art to date and concludes that at present the best efficiency for central stations lies somewhere between 3 and 3¾ watts per c. p. The present incandescent lamp owes its good qualities, he said, to the use of cellulose filament.

Referring to the vacuum of lamps, Mr. Randall considers that after a vacuum of one part in ten thousand is reached, the loss of heat through convection is negligable, and that the degree of exhaustion ordinarily found in the incandescent lamp is better than need be, so far as this loss is concerned. A high degree of exhaustion is not the main object to be obtained, an unchanging vacuum being the essential point with respect to the maintenance of the highest brilliancy. If a lamp is properly made and exhausted in the first place, absolutely no leak can be detected after usage. In some cases where used for at least twelve years, in rheostats where the current at times brought them to full brilliancy, the vacuum of lamps has been found as good as when first made.

In purity, density, surface polish and uniformity, which are the features that determine quality and maintain efficiency, the cellulose filament, properly made, far exceeds any other kind. A graphitic coating on an amorphous carbon body in a vacuum is, so far as known, the best combination for fulfilling these conditions. The use of cellulose has also made the 220 volt lamp a commercial possibility. Recent lamps, he said, are approaching the ideal lamp which, when its work is done, breaks and thus announces its own smashing point.

The results of tests on three classes of lamps—110 volt cellulose, 110 volt untreated bamboo and 50 volt treated bamboo—are given, the initial watts per candle power being 3.2 for each. At the end of 600 hours the candle power of the first mentioned lamp was 14.96 and the watts 3.54; of the second mentioned lamp, 9.9 and 4.75; and of the third lamp 14 and 3.67.

The writer stated that one of the largest alternating stations in the country has, by substituting the highly efficient cellulose lamp for the low economy silk and bamboo lamps, and by improving its regulation, been able not only to reduce the price of service to its customers, but to increase its lamp capacity over 25 per cent. There is one condition which must be fulfilled in order that incandescent lighting may be more profitable—the voltage at the lamps must be kept everlastingly and unceasingly steady. There has been some improvement in this respect but much is yet necessary and desirable.

PHYSICAL AND CHEMICAL PROPERTIES OF VOLATILE OILS IN BOILERS.

Mr. W. H. Edgar spoke on the ill effects of using volatile hydro-carbon oils in boilers, and gave a clear and concise theory of the proper methods of preventing incrustation. Referring to the use of kerosene pumped into the steam boiler with the object of converting the incrustation into such form as to readily wash out, or preventing its formation, he says that its effect is purely mechanical, there being no chemical reaction whatever. The kerosene penetrates the scale and softens it by running between the scale and the iron, and when the boilers are shut down, loosens it and thus renders its removal more easy. A disadvantage from the use of kerosene is that if it distills over, it forms a series of oxidizing hydro carbons, which will intensify pitting and grooving, eat through flanges, and destroy thread connections; it passes, besides, into the cylinder, dilutes the lubricating cylinder oil, blackens the piston rods, has a deleterious oxidizing effect on the piston rings and on metallic packing, if this latter be used. In addition, that part of the oil which goes through the scale and reaches a surface at high temperature, is carbonized, which results in the carbonization of the iron and the appearance of a blistered spot.

In answer to a question, Mr. Edgar stated that the corrosion from condensed water is purely an oxidation with the aid of hydrogen, ferric hydrate being formed, which may subsequently be converted into an oxide. Speaking of vegetable compounds, he said that sugars and tannins (but not tannic acid), may be used, the latter taking care of the carbonates of lime and magnesia. Sugar introduced in the steam boiler will convert the sulphates into saccharates, the latter breaking up into oxalates, tartrates and carbonates, and, in the presence of tannin extracts, into the tannate of lime, so that but a small proportion of sugar is necessary in the general mixture to handle a water containing both the sulphates and the carbonates, the components to be proportioned according to the impurities found by analysis in a given water. It is well to also mix in a little slippery elm, poke root or powdered willow hard wood pulp, so as to get a little soluble starch to keep the sugars and the tannins from being too stable.

In conclusion, Mr. Edgar stated that under no circumstances should kerosene oil or caustic soda be used in boilers. A surface blow-off contrivance is good if intelligently used. Finally, he advises the steam user to have the water analyzed and then go to the wholesale druggist to have the tannin and sugars mixed in proper proportions, and the boilers should be dosed regularly.

TOPICS OF INTEREST TO CENTRAL STATION MEN.

Lieut. F. B. Badt delivered an address on the above mentioned subject. Taking up the old question of alternating vs. direct currents. Mr. Badt thinks it is now the universal opinion of engineers and such managers of central stations as have had an experience in the matter, that where the conditions are favorable to the direct current system, it has many advantages over the alternating system; but that in certain cases an alternating current system must be installed where long distances ate involved. The 220-volt direct current system was referred to in high terms. It is much more easily managed by the three-wire system, costs less to install and less to maintain. To-day good 220-volt incandescent lamps can be procured, and also an enclosed arc lamp burning singly across a 220-volt circuit. As 220-volt direct current motors have many advantages over a 110-volt motor, the 220-volt system is a good one in all respects for small central stations where distances of, say, less than ¾ of a mile radius from the station are made. The 220-volt arc lamp uses 2½ amperes with 160 volts at the arc, to produce a nominal candle power of 2,000, the arc being ¾ of an inch long.

Where there is an elevator service the 220-volt system has a great advantage in that great fluctuations of the power circuit will not be noticeable in the arc, which will practically not be affected by a variation in the power circuit of, say, 50 volts. Lieut. Badt considers that it will not be very long before we will have an enclosed arc of 500 volts for use on 500-volt railway circuits. It is suggested that, owing to the diversity in the diameters of the opening in the gas cap of enclosed arc lamps, which may lead to considerable trouble to those who buy carbons indiscriminately, this diameter should be standardized, and he suggests that it would be desirable for the Association to use its influence to that end.

Lieut. Badt considers that the single phase alternating current system will eventually be regarded superior to polyphase systems, owing to its simplicity, and he thinks that it will not be long before there will be any number of different makes of single phase motors on the market. The use of large transformers serving a number of customers is advocated, it being recommended to use one transformer, if possible, for a block, the block to be wired on the 220-volt system for 220-volt lamps and motors. The steam engine was referred to, Lieut. Badt saying that in the best type the efficiency is only 13 per cent, there being thus 87 per cent left for improvement; and this efficiency is compared to that of the dynamo where manufacturers guarantee as high as 95 or 96 per cent. The Diesel gas engine was spoken of in very high terms, Lieut. Badt believing that it will be the heat engine of the future.

ELECTRICITY IN MUNICIPAL ENGINEERING.

Prof. R. B. Owens presented a paper with the above title, the object of which, he stated, was to emphasize the economy which can often be effected by generating at one point all the power required by a municipality and distributing it for whatever purpose by electrical means. In small towns where a supply of water is obtained from driven wells, power pumps may be used, obtaining power through a counter shaft from an engine of economical design, one or more dynamos being attached to the same counter shaft. If both dynamos and pumps are driven by clutch pulleys, it is possible by shutting down pumps as the dynamos are started, and varying the number in operation as the lighting load varies, to keep an almost exact constant load on the engine. In larger towns, where it is not unusual to find half a dozen pumping stations from a half to a mile or more apart, triplex power pumps, operated by constant torque speed motors, may be substituted, the current for such motors to come from a central power plant equipped with economical machinery and suitably located; this arrangement, it was estimated, would give in a certain town that has been under consideration, a saving of more than 50 per cent in the total cost of operation. A suitable reservoir should always be supplied so as to allow the engine or engines to operate at a constant load, and also to supply extra water for fire purposes whenever required.

Prof. Owens considers that no system of sewerage is complete which does not abstract the solid matter and sterilize the liquid portion before turning it into water ways. In the disinfection of sewage it would seem that electrical methods must supersede chemical ones in the future. In the electrical system the disinfection is obtained by passing a large current of electricity at low voltage through sea or salt water, prior to or after being mixed with the sewage, which results in the disinfection of the latter. An important point in this connection is that the electrical system implies a high efficiency of operation, for the reason that a current would be used at a practically uniform rate, thus fitting in very perfectly with the economic operation of a pumping plant, and the requirements of a plant to burn and utilize town refuse.

The calorific value of town refuse, which is about one-fifth that of coal, should be utilized, and as it requires to be burned at a very regular rate during the 24 hours, electrical energy generated therefrom will be suitable for use in pumping and for the electrical purification of sewage, the demands of power for these purposes being practically constant.

Referring to a thermal storage in connection with lighting plants, a scheme is proposed in which, instead of using separate thermal storage tanks, by carefully lagging the entire boiler setting and providing removable non-inductive covers for the fire and ashpit tools, the boilers themselves may be converted into heat reservoirs.

When one boiler or battery is put out of service, the steam generated by the remaining fire on the grate and by the heat absorbed by the setting will, when it exceeds by a certain amount the pressure in the main steam pipe, pass into the latter through a reducing valve. When the boiler is to be put in operation again, it has a pressure equal, or perhaps greater than that of the service, in the latter case immediately aiding by its volume of stored energy, to supply the demand for steam. By providing an arrangement for starting fires with oil when necessary, the standing-by boilers in a battery can be put into full operation at the rate of perhaps one a minute.

Prof. Owens referred to the fact that in Great Britain, ashbin refuse is burned in destructors in more than 50 towns, in many cases the heat therefrom being utilized in the generation of steam. In most cases a combined plant can be designed to burn and utilize the ash bin refuse in the pumping of water from a series of scattered wells, and supply current for street lighting and sewage disinfection, the arrangement being such that all the machinery will be loaded very nearly to full capacity 24 hours a day.

MUNICIPAL SOCIALISM.

Mr. Fred DeLand, in a paper with the above title, dealt with the subject of municipal ownership, taking its operation in the City of Des Moines, Ia., and several other cities as examples. In the first mentioned city an attempt to start a municipal plant was prevented, temporarily at least, by an injunction, whereupon the Mayor, upon the expiration of the lighting contract, refused to pay more than $75 per year per lamp. $126 having previously been paid. Mr. DeLand shows that even under the figures given as to the cost of lighting from the proposed municipal plant, the cost would be $76. The last official report of the cost of street lighting in Detroit was $89.42 per lamp. In Allegheny City, Pa., the cost of operating arc lamps from a municipal plant is $74.32 and the official in charge of the plant stated that a fair price for commercial companies, under the conditions of that city, would be $80 per year with coal at $1.00 per ton; $90. with coal at $2.00 per ton; and $100 with coal at $3.00 per ton. Topeka, Kan., paid during the first six years of municipal ownership, when machinery, circuits and lamps were in good condition, $93 per year for each arc lamp used in street lighting, not taking into consideration the extra investment necessary to replace old machinery, the risk that attends all enterprises of like character, loss of water rates, taxes, etc. The average cost for Detroit, Topeka and Allegheny City is therfore $85 per lamp under municipal operation, and in view of the statement of the mangement of the plant in the latter place, that where good steaming coal costs $1.00 per ton, $80 is a fair price for commercial companies to charge for street lights of 2,000 c. p., burning all night and every night, Mr. De Land considers that the action of the Mayor of Des Moines in only allowing $75 per light is simply a political stroke to gain the applause of unthinking voters.

In the discussion on Mr. DeLand's paper, it was stated that in an official report of the Mayor of Des Moines, the cost of lighting in Topeka was given at only $40 per year, whereas a proper analysis shows the actual cost at $93 per lamp, without taking into account depreciation.

Mr. Doherty stated that some time ago a total depreciation on electric plant was figured at 8.3 per cent, based upon information obtained from competent authority. He stated that even on a depreciation of 5 per cent the cost of lighting from the Detroit plant amounts to $105 per year per lamp.

Prof. Jackson expressed the opinion that in a plant put up in the best manner, in a town of from 20,000 to 100,000 inhabitants, the depreciation is not less than 7½ per cent per year, and he doubts if there are many plants that have a right to write off less than 10 or 15 per cent. He added that these figures did not take into consideration changes in market value; that is, the market value of material is assumed the same at the end of a given period, as when the plant was constructed.

Mr. Thayer gave some data concerning the cost of lighting in some towns where he had made investigations. At Vinton, Ia., he found that the cost of a 32 c. p. lamp on a street is about $13 per year, the plant being a municipal one. At Lisbon, the cost of arc lights from a municipal plant is over $100 per year. Mr. Pierce stated that the City of Negaunee has been assured, when considering the subject of a municipal plant, that 35 arc lamps and 1,000 incandescent lamps could be run on less than a ton of coal per day. He said that the plant had now been running less than four months and had already burned the year's supply of coal, based on the above estimate. He added that the estimate for putting in the plant was $10,000, that the bid of the successful company was $9,904, but the extras, etc., have brought the price close to $18,000, and the plant is not yet finished. A 16 c. p. light is furnished for 13 cents a month from this plant. Mr. Trott related an experience which the citizens of Holland, Mich., have had with their plant. The initial investment has been exceeded many times, the prices of the lights have been raised 50 per cent and the plant is still running behind.

Mr. Bean stated that he had been informed by a lawyer of Grand Ledge, Mich., that they were running from their municipal plant 2,000 c. p. lamps at a cost of one cent a night, but upon investigation he found that the lamps cost $10 per month. The chairman of the board of works, however, informed him that they had been charging $5 per month for arc lights, but were going to cut that price to $2.50!

ELECTRIC LIGHTING FOR PROFIT.

Mr. Alex. Dow, in a paper with the above title, maintained that the proper policy of electric light management under the conditions of the present time, is to sell electric energy to every accessible user in any shape that the user requires, and at the lowest price that will pay a reasonable profit on the capital invested. The evil effects of the former policy of operating under "systems" was referred to, one of the results being that unduly high prices had to be charged for the product sold to customers, which led to the growth of municipal plants.

As to what is reasonable profit, Mr. Dow believes that after operating expenses are paid and any deterioration of the investment shown by a carefully made inventory has been made good, a dividend such as is paid by a good manufacturing business is reasonable for electric lighting. The amount of this dividend will depend upon circumstances, as in other lines of business. A well established station, with no ruinous competition to meet, and not threatened by municipal interference, nor obliged to continually risk money in extensions of uncertain character, may pay a dividend but little in excess of the current rate of interest paid by savings banks. On the other hand, the station in which all these conditions are reversed, is entitled to a greater return.

Unfairness of municipal lighting advocates is pointed out. A man who thinks it no harm that he should draw from the capital invested in his own business 10 or 15 or 20 per cent, in addition to a fair salary for management and any loss that is shown by annual inventory, and who thinks it entirely proper that he should build up a business worth much more than its normal capital by turning into it a large surplus, may nevertheless denounce a private electric lighting company which pays a good deal less than 10 per cent, which he refuses to assist in protecting from unlimited competition, though demanding that it does business for a rate of profit accepted only on the safest class of investment bonds.

The method of analysis of station costs, introduced by Mr. Arthur Wright, by means of which to arrive at a rational system of rate making, is highly spoken of; but Mr. Dow considers that as American conditions usually differ from those existing at Brighton, it is seldom possible to apply the short method of estimating standing and running cost which Mr. Wright finds convenient, and an analysis in detail must be made.

The method used by Mr. Dow involves a consideration of what the condition of the situation would be if one were obliged to be ready to do the same business now being done and during the same time, but with no customers taking current. The rule is to ask whether any item of expense will continue or would cease under the conditions described. If it would continue, it is a standing charge; if it would cease, it is a running charge. It is clear that taxes, insurance and interest are also standing charges. Account should also be taken of a customer's load factor. Mr. Dow says that by using Mr. Wright's Niagara paper as a text book, others will find, as he did, that the labor is well paid for by the results which will follow carrying out its indications. His anaylsis showed that he could afford to sell current to a large class of users at 4½ cents per unit, while at a rate already established of 14.4 cents, another large class was unprofitable. He states that he is now taking all the 4½ cents business he can find, and letting other people hunt for the 14.4 cents kind.

Mr. Dow recommends working up a motor load, as there is in nearly every village some demand for power, and even if the rates are very low, they will pay the additional cost of running the station during the day time, and also carry some proportion of the standing charges.

The only way to do residence lighting at a profit is to do all the lighting, or nearly all, that there is in a given residence district, and for this reason the rate must be placed so that every posible customer can afford it. Mr. Dow has tried the experiment of low residence rates, and in each instance with success. He adds that the load factor of residence lighting is much better than the average load factor of many stations. Mr. Dow says that to design a new station on any other than a general distribution system, furnishing incandescent and arc lights and electric power from the same dynamos and the same mains, is almost criminal.

A proposition that a lighting station should furnish street railway current should be dealt with as involving a new investment, always the cost of a dynamo and switchboard, and usually the cost of an engine. Furnishing street railway current appears to be equivalent to the sale of steam to a special engine and the furnishing of attendants to additional engines and dynamos; and it should be considered as a business proposition on that basis and not in the same manner as a demand for current from the electric lighting plant.

If a street lighting contract can be taken without investment in special machinery, it may be done at a very narrow margin of profit; but when an investment is required in special machinery and the building of special lines, such a contract is usually undesirable business. This follows from the reason that city contracts are usually short, and there is no security as to their renewal. A good educational work would be to make clear to the people that the price for a year's street lighting depends upon whether the street lighting plant would be employed next year or would be standing idle, as a company might have some chance to make close bids for a long contract without feeling that it was engaged in a risky speculation.

Among special sources of revenue mentioned is the employment of a lighting plant in work not usually considered as part of the lighting business, such as involved in an arrangement with a manufacturer whereby machinery required by the plant during evening hours will be used by the manufacturer in the day time, and the sale of exhaust steam for heating purposes. An arrangement can be made in some places for the joint use of water power.

As to the question: How can business be held when once obtained?, Mr. Dow states that the whole law and gospel consists in getting customers to believe that they receive good value for their money, and to convince them you must yourself know in your own mind that you really are giving good value. To this end it is essential that the central station manager shall know what each block of lighting costs, and he should use every opportunity to keep his customers satisfied, though this latter requirement may mean that a man has to idle at times around the station waiting for trouble calls. Mr. Dow summed up his paper as follows:

(1) The electric lighting business should pay a reasonable profit, approximately the same rate as any manufacturing business which has similar risks. This profit should be paid after the expenses of operation, maintenance, and depreciation shown by annual inventory have been provided for. (2) Rates for electric supply should be so adjusted that each unit sold will pay its share of operating and standing charges, and in addition thereto a uniform proportion towards profit. No business should be done at a loss and no business should pay more towards profit than its proper share. (3) Every class of business that can be profitably done should be obtained. Business that improves the load factor should be taken if it can be obtained at any price greater than its share of operating and standing charges, because the improvement of the load factor reduces the amount of standing charges to be borne by existing load. (4) Business once obtained should be kept by careful study of, and prompt attention to the requirements of each customer. It is not possible in the present stage of electric development for an American electricity supply company to limit its interest in the supply to its delivery to the customer's premises. It must do much work in order to secure that the customer uses the supply to the best advantage. It is not sufficient that a customer should be well served; he must also be well pleased. (5) There is need of educational work to be done among electric light men, among municipal authorities and municipal theorists, and among our own customers. It is our interest that this educational work should be done, and as it does not appear to be the duty of any other person to do the work, we will have to do it ourselves.

In a discussion of Mr. Dow's paper a question having been asked concerning the installation of a power circuit in connection with a combined alternating and direct current plant, Mr. Dow said that a person who had such a plant is unfortunate, and that a selling agent or consulting engineer who would recommend such a plant is almost criminal.

In establishing a new plant or reorganizing an old one, Mr. Dow said that the monocyclic system is a good one, and very satisfactory for the general class of country towns and attendants; he considers it a mistake, however, to put in 2,200 volts if a little more copper will let one out with 1,100 volts. The 220-volt system is also excellent for the above conditions, and will answer for most of the small towns.

◆

HORSE POWER OF WATER-WHEELS AND TURBINES.

BY PROF. OLIN H. LANDRETH.

The accompanying diagram is for the graphical determination of the HP of any given waterfall, being a simple form for the graphical reading off of the HP from the formula, $HP = \frac{HQDE}{550}$, in which H is the effective head on the wheel in feet; Q, is the quantity of water flowing in cubic feet per second; D, is weight of water per cubic foot, and E, is the percentage of efficiency of the wheel.

For $D = 62.4$ lbs. per cubic foot, $HP = 0.1134\ HQE$.

The inclined lines radiating from the zero at the lower left corner are of three different kinds: Those running to the upper edge of the diagram represent the quantity of water; those running to the right side of the diagram represent the different percentages of efficiency, except the one line which crosses the margin between 85 per cent. and 90 per cent., which is a conversion line to transform the resulting value of the HP into such linear values as to permit them to be represented by the graduations along the base of the diagram. This line is drawn at an angle with the vertical lines, whose tangent $t = \frac{1}{2}(0.1134)\,75 \cdot \frac{v}{h}$ where v and h are the numerical values of the vertical scale of head and the horizontal scale of quantity; the ½ being introduced in this side to make the HP units along the case of the diagram one-half the value of the quantity units along the top of the diagram.

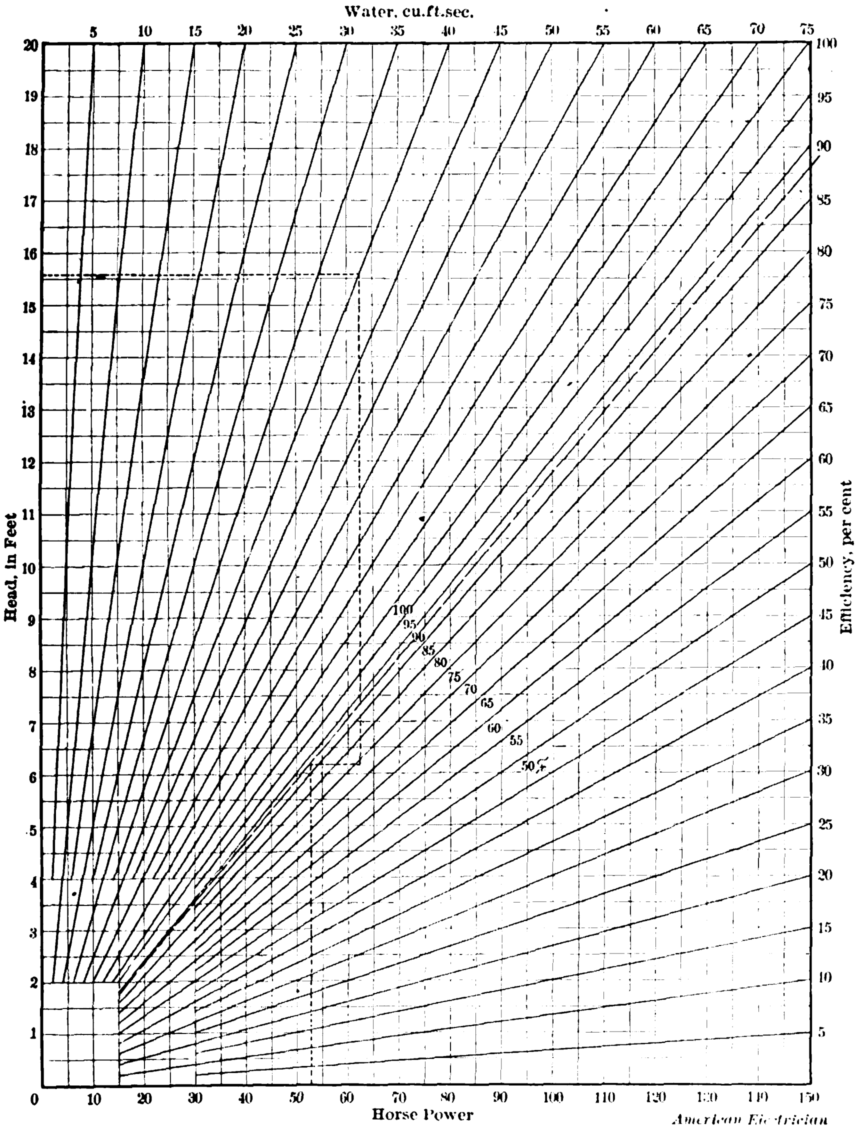

DIAGRAM FOR DETERMINATION OF HORSE POWER OF WHEELS AND TURBINES.

To use the diagram, start with the value of the head on the left margin, pass horizontally to the radiating line representing the given quantity, thence pass vertically down to the proper efficiency line, then pass horizontally to the inclined conversion line, thence vertically down to the HP line along the base of the diagram, where the proper value may be read off. With heads or quantities in excess of the maximum value of the diagram, the scale may be assumed changed to ten times that graduated, and the resulting HP read off to a scale either ten or one hundred times that graduated, according to whether one or both the argument scales have been amplified. One or two other arrangements of the lines indicating respectively the heads, quantity and efficiency have been used, but the one here given is offered where compactness is the prime requisite.

As an example, with a head of 15.6 ft., a quantity of 40 cu. ft. per second, and an efficiency of 75 per cent., the HP is 53.2.

* * *

NOTES.

Electrolysis from Electric Railway Currents.—Electric railway superintendents will find much to interest them in a United States Senate document, dated October 29, 1897, and containing reports, accompanied by a number of maps, on electrolysis from electric railway currents in the District of Columbia.

Lightning.—Professor Trowbridge, of Harvard University, in recent experiments has found that the length of electrical discharges between widely separated points varies directly with the E. M. F. Discharges 4 ft. long were produced by means of an E. M. F. of 1,200,000 volts, and Professor Trowbridge has made the calculation that for the discharge of a flash of lightning 1 mile long, at least 1,000,000,000 volts would be required. The apparatus with which the experiments were performed consists of 10,000 Planté storage cells and a glass-plate condenser of sixty leaves.

Columbia University Lectures. In co-operation with The American Museum of Natural History, and under the auspices of Columbia University, a series of lectures will be given at the Museum, Central Park (77th Street and 8th Avenue), Saturday evenings, at 8 o'clock. The lectures for February will be on electrical engineering, as follows: Feb. 5, Mechanical Sources of Energy, by Prof. Frederick R. Hutton; Feb. 12, Generation of Electrical Energy, by Prof. Francis B. Crocker; Feb. 19, Transmission of Electrical Energy, by Dr. A. E. Kennelly; Feb. 26, Utilization of Electrical Energy, by Prof. William A. Anthony. The lectures will be illustrated by slides and experiments. Tickets of admission are required, which can be procured, without charge, by application to the Secretary of Columbia University.

Electrical Engineering at Union College.—A course of electrical engineering which was started in the fall of 1895 at Union College, Schenectady, N. Y., is at present complete in its several branches. An arrangement has been effected between the college authorities and the General Electric Company by which students in the junior and senior classes are admitted to the company's works at regular scheduled times under the direction of their instructor, with the privilege and opportunity of studying and inspecting the plant and operations, and of being regularly instructed therein by their instructor. This work is systematically arranged and given simultaneously with the corresponding class and laboratory work, to which it forms an important and valuable adjunct. Prof. Olin H. Landreth is in charge of the electrical engineering course.

The Milliampere.—In medicine the milliampere appears to occupy a place of unique importance, for Dr. W. D. Hedley, in the London *Electrical Review*, says that the history of electro-therapeutics since 1878 "is largely the history of the milliampere"! It appears that one medical authority lays claim to the invention of this unit of such surpassing medical importance, and the *New York Medical Journal* (January, 1889) ascribed its discovery to—of all men in the world—a late gynæcologist, Sir Spencer Wells. It appears, however, that Mr. W. H. Preece in 1877 suggested the adoption of the milliweber (ampere was substituted for weber by the Paris Electrical Congress of 1881) as a convenient unit for measuring weak currents, which suggestion bore immediate fruit.

Cost of Arc Lighting.—In a recent report, Mr. Horatio Foster gives the cost of arc lighting from a number of municipal plants, the figures being based upon data obtained from official reports issued by the respective municipalities. Mr. Foster finds that of New York State plants, the cost of arc lighting at Jamestown is 2.15 cents per lamp hour; at Batavia, 2.23 cents, and at Dunkirk, 2.51 cents. The lamps in the two last mentioned towns are of 1200 c. p. and of 2000 c. p. at Jamestown. The following data is given for the cost of lighting per lamp-hour from Massachusetts municipal plants: Peabody, 2.2 cents; Marblehead, 2.39 cents; Danvers, 3.29 cents; Middleboro, 4 cents; Braintree, 4.55 cents; Reading, 5.53 cents; Wakely, 7.52 cents —all of the lamps being of 1200 c. p. Mr. Foster considers that for average depreciation, 7½ per cent is a safe figure. He states that a fair cost for an arc light plant is from $200 to $250 per lamp installed.

A University Department of Instruction by Correspondence.—West Virginia University, of Morgantown, W. Va., is now ready to begin the work of giving instruction at a distance from the University, by correspondence, to be carried on by a series of printed instruction and question sheets. The course in electrical engineering is in charge of Profs. Hodges, Aldrich and Jones, and comprises the branches of electricity and magnetism, electrodynamic machinery, electrical wiring and distribution, electric street railway systems and working, electric coal mining, electric lighting systems, telephone systems, electric power transmission, electric light plants and central station working. Hereafter, the University will be in continuous session, and correspondence students may spend the summer quarter in resident study at Morgantown.

Economy of Electric Power.—The Metropolitan Street Railway Company, of Kansas City, Mo., which operates some 120 miles of surface, cable, electric and horse railway, and 16 miles of electric elevated road, has during the past several years been making extensive improvements of its properties, particularly in the way of introducing electric power. Recently the electrical equipment has been extended by the addition of another Walker generator of 2400 amperes and 550 volts, there now being four stations equipped electrically out of a total of eleven. A careful account has been kept of the cost of generating power in one of the electric power stations; including the items of labor, repairs, oil and waste, fuel, water and miscellaneous, and covering a period of four months, the average cost per KW-hour was found to be .48 cent. The cable machinery in one power house is operated by a motor at a large saving, the cost being $366.23 per month as against $1,025.25 when operating with a steam plant.

Electric Switching.—The use of electricity for switching purposes has been adopted by the Hoboken Shore Road, which provides connecting facilities between the railroad companies entering Hoboken, and the numerous warehouses and docks which line the west side of the North River from Hoboken to the Weehawken. The new plan was put in regular operation Jan. 4, a 540-HP General Electric locomotive being used, which resembles in appearance the electric locomotives now handling the entire freight traffic of the B. & O. R. R., through the Belt Line tunnel at Baltimore. The overhead trolley is used, the wire being No. 00 in size, current being obtained from the Hudson Electric Light Company. The dimensions of the Hoboken locomotive are: Length over all, 29 ft.; width, 8 ft.; height over trolley stand, 13 ft.; wheel base, 5 ft., 6 ins.; truck centers, 12 ft., 9 ins.; weight, 57,000 lbs. A motor is mounted on each of the axles of two four-wheel trucks.

A Small Accident with Large Consequences.—The daily papers reported several weeks ago a serious break down in the power house of the Chicago Metropolitan Railway, it being stated that two armatures were burnt out, shafts broken, a fly-wheel burst, etc., in consequence of excessive current due to too many trains starting up at once. We find that, as usual, the reporter depended upon his imagination instead of going to the trouble of ascertaining the real facts of the case. It appears that one of the engines of the power house had been dismantled in order to make some repairs, which threw a heavy load on the other generating machinery. The governor belt of a small engine operating the condenser slipped, and in racing its fly-wheel—about 4 ft. in diameter—burst, but without doing any damage of consequence. Owing to the main engine having then to run non-condensing, the traffic of the road had to be lightened until the condenser engine was repaired.

The Corliss Steam Engine.—In an article in the London *Electrical Review* on the progress of the steam engine during the past twenty-five years, Mr. J. S. Raworth says that many inventors had tried to improve on the steam engine of Watt, but it was left to George H. Corliss to do it. During the past twenty-five years the record of progress in mill engines is simply, he says, a history of the Corliss engine. He adds that if ever Lancashire should desire to spend some infinitesimal fraction of 1 per cent. of its wealth in honoring those who have contributed to its success, it ought to raise a statue to the memory of G. H. Corliss. "It should be made of white marble, and standing in front of the Town Hall, Manchester, bear this inscription: 'When your boilers are equal to my engines, you will save the cost of this statue in gold'" Has any statue been erected to the memory of Corliss in the land of his birth?

Municipal Electrical Inspection.—At the recent annual meeting of the Underwriters National Electric Association, a resolution was adopted, addressed to the Executive Committee of the National Board of Fire Underwriters, asking the Board to consider the advisability of encouraging the establishment of municipal electrical departments in the various cities and towns throughout the country, for the regulation and control of electrical fire hazard. At the same meeting the action of certain municipal electrical departments in drawing up sets of electrical inspection rules at variance with the National Electric Code was condemned. In other words, the association in one breath welcomed the establishment of municipal electrical departments, and in another condemned some of said departments for instituting special sets of rules—and without special requirements there would be no cause for the existence of such departments, since the underwriters' inspection service assures sufficient protection to the public from fire hazard. It is directly against the interest of electrical contractors to have such departments instituted, on account of the arbitrary interference which will undoubtedly result, and there seems to be no public reason for their existence.

Candle Power of Search Lights.—As usually expressed, the candle power of a search light is obtained by equating the total flux of light from the area of the crater exposed to the reflector, with the total flux from the opening of the search light. That is, by multiplying the area of the search light opening by the candle power of the ray, and equating it to the product of the area of exposed crater and a hypothetical candle power, which latter is the unknown quantity in the equation and, when found, is the commercial rating of the search light. For instance, suppose the beam has a diameter of 20 ins. and a candle power of 2000, and that the diameter of a circle equivalent to the area of the crater is .5 in. The total flux from the search-light opening is $\frac{\pi}{4} \times 400 \times 2000$; and from the crater $\frac{\pi}{4} \times .25 \times x$, where x is the hypothetical candle power expressing the rating of the search light. This reduces to $2000\ (400 \div .25) = x$, or in this case the rating of the search light would be 3,200,000 CP. Thus, in order to find the candle power of a search light, 1°, the area of exposed crater is estimated, and the diameter found of the circle which corresponds to this area; 2°, the candle power of the ray, is measured by the ordinary photometer, usually at a distance of several thousand feet from the search light, the mean of measurements at the axis and near the periphery being taken. The diameter of the ray being known, its ratio to the equivalant crater diameter is squared and multiplied by the photometer candle power. This method of expressing the candle power of a search light is unsatisfactory, giving as it does absurd figures for the candle powers. The factor of practical importance is the amount of illumination furnished by the ray, which is the product of its cross-sectional area by its photometer mean candle power, the latter (leaving aside absorption and assuming perfect parallelism of component rays) being the same at all distances from the search light. Rational systems of light units have been proposed that would numerically express a rating in accordance with the latter statement. Such a system would also obviate many of the other absurdities inherent in the present system of dealing only with intensity of light and not with the more direct factor of illumination. The man who defined a 2000-CP arc light as one which, when placed at the intersection of two streets, would send 500 CP up and down each street, was scarcely less logical than, in some respects, the system which misled him.

Rapid Telegraphy.—Dr. Crehore and Lieut. G. O. Squier in a paper read before the Franklin Institute, Jan. 19, described some tests of their synchronograph on the telegraph lines of the British Government, in which a Wheatstone receiver was operated by the alternating current in transmitting telegraphic signals. The longest loop tried was 1097 miles—from London to Glasgow, Aberdeen, Edinburgh, and return to London by a different pole line; the loop contained some iron wire and also 48 miles of underground cable. It was discovered that the synchronograph could operate the Wheatstone receiver approximately three times as fast as the Wheatstone transmitter on any line. The authors conclude that the results of their experiment show that the use of an alternating E. M. F. which does not rise suddenly and fall off so abrubtly as is the case with that of most transmitters, but which rises gradually from zero to a maximum and falls again to zero as gradually, is the best kind of transmitting current for use on actual lines with distributed capacities.

Photographing by Light.—The sensational newspaper press recently devoted columns to an announcement that Tesla had taken photographs by means of light from vacuum tubes, in proof of which a reproduction of a vacuum-light photograph of his hand was printed. Had the announcement been that he had been *unable* to take photographs by light from vacuum tubes, there would have been some occasion for sensational comment. That the vacuum-tube light is one of the oldest known electrical phenomena, does not appear to be generally recognized. Discovered by Hawksbee in 1709, it figures prominently in the electrical literature of the last century. For almost a half-century vacuum tubes have, under the name of Geissler tubes, formed part of the equipment of college laboratories. In fact, at any time since Daguerre's discovery, photography by means of the vacuum-light has been possible. It is even quite probable that photographs have frequently been taken by means of this source of artificial light, and with no inkling that a wonder was being wrought.

Electrical Exhibition.—The applications for space in Madison Square for the Electrical Exhibition to be held there next May, are flowing in so rapidly that we learn every available foot will very soon be exhausted. The position of consulting engineer of the exhibition has been accepted, on the invitation of the management, by Prof. F. B. Crocker, who, as is well known, is President of the American Institute of Electrical Engineers, Professor of Electrical Engineering at Columbia University, and senior member of the Crocker-Wheeler Electric Company. A committee has been organized to take charge of exhibition matters other than commercial, among whose members are Prof. Morris Loeb, of the University of New York; Prof. W. E. Geyer, of Stevens Institute of Technology; Prof. Chas. A. Doremus, of the College of the City of New York; Mr. Herbert L. Webb, of New York Telephone Company; Lieut. G. O. Squier, U. S. A., and Dr. Park Benjamin. The New York Electrical Society, which is the oldest body of its kind in the United States, has lent the aid of its name and prestige to the exhibition, in view of the very worthy object for which it has been organized. An advisory committee has been appointed by the Society, composed of its present officers and past presidents, and consisting of Prof. M. I. Pupin, Prof. F. B. Crocker, Prof. Willard Case, Dr. C. E. Emery, and Messrs. Dunn, Sinclair, Osterberg, Geyer, Riker, Coho, Kerr, Small, Pendleton, Wetzler, Mailloux, Francis W. Jones and J. W. Lieb, Jr.

Important Electric Railway Decision.—The Circuit Court of the United States for the Southern District of New York has sustained the validity of a patent granted August 25, 1885, to Frank J. Sprague, on the suspension of electric railway motors. The patent in question is on the method of suspending the field magnet by journaling it on the axis of the driving wheels at one end, suspending it from a spring on the truck or the car body at the other, and carrying the armature shaft upon its pole pieces parallel to the shaft of the driving wheels, the two shafts being connected by gearing. One of the claims of the patent is for a spring support at both ends of the motor. The decision states that "If Sprague's patent was for merely handling and centering one end of a motor of a carriage upon the axles of the driving wheels, and suspending the other by a spring from the body of the vehicle or the truck, it would be shown from that case [one involved in a previous decision] to be wholly lacking in novelty, and void. He was not a pioneer here, and could have a valid patent for only what was new in his method of making the power of the electrical current turn the driving wheels. No one had before, however, hung a field magnet at one end upon the axle of the driving wheels, and at the other upon a spring from the body of the car, or the truck, and an armature axle upon the pole pieces of the magnet, parallel with, and geared to, the axle of the driving wheels for driving a car by a current of electricity." This latter combination, the opinion states, simplified greatly the required structures, improved their results, and came into immediate use, and the court therefore believes that the invention of the combination seems to well support these claims of the patent. An order of the court was subsequently issued suspending action under the decision for a month, in order to permit the defendants to appeal the case, should they so desire.

New Method of Preventing Sparking.—Mr. J. Fischer-Hinnen writes a short but interesting article in the *Elektrotechnische Zeitschrift* of Dec. 30th, describing an ingenious method of preventing sparking at the brushes of direct current generators, which seems to be a modification of the now well-known Swinburne device with its auxiliary poles. As described, it is applicable only to the consequent pole type of machine, such as the "Manchester," old "United States," etc., and is in principle briefly as follows: The neutralization of the reaction being but indirectly related to the prevention of sparking, he omits it altogether from the consideration of the question and confines his attention solely to the production of induced poles in the line drawn through the neutral or non-sparking position, the poles having the same polarity as that of those which the armature is advancing in the course of its movement. Like Swinburne, he uses auxiliary pole pieces in the neutral zone, cast integral with or bolted to the field magnet core, but, unlike him, places no windings on these poles. In the consequent pole type of generator he describes, these are, of course, placed midway of the legs on which the spools are wound. In the first place, the number of ampere-turns per auxiliary pole is determined as in the case of the Swinburne winding, and extra turns to make up this number are then added to the field spool above the auxiliary pole piece and omitted below, the reverse being the case for the opposite leg. The total energizing force thus remains the same as in the case of the ordinary machine, but the poles are produced as in the Swinburne generator. The author describes a recent test on a generator of a nominal output of 400 amperes built in this way, where a load of 1200 amperes was taken without brush movement, and he claims that it was impossible to tell by the closest scrutiny of the brushes whether the whole 300 per cent of load was off or on. Particular advantage is claimed for this construction in the case of variable speed motors, as the speed may be varied through the "widest limits" by simple field commutation without sparking, thus giving a control without loss of energy.

Early Days of the Electric Railway.—In his presidential address before the recent Northwestern Electrical Association, Mr. H. C. Higgins gave the following amusing account of the electric railway craze of some years ago: "We all went into the electric street railway business with the greatest hopes of financial success. It was a very attractive business. The man who was running a horse car or a mule car line would go to a town where they were running the new electric street railway, he would see the beautiful cars, with every seat occupied by a passenger, gliding over the track without any apparent effort and at a more rapid rate than he had ever hoped to accomplish on his line, a uniformed conductor on one end, a uniformed motorman on the other, with everything bright and shiny. It was a beautiful sight to him, and frequently he did not go home until he first visited the office of Mr. John I. Beggs or Mr. B. E. Sunny, whose bright smiling countenances were only a continuation of the bright things he had just seen, and got prices from each of these gentlemen for electrically equipping his road at once. He went home, immediately consulted his board of directors, explained what he had seen and some of the things he had felt, and that night sent a night message accepting the proposition of one of the two contestants before mentioned. The next day he had a meeting of the council called, his franchise was changed from horse to electric, and he could not get his stuff quick enough in his mad desire to be the manager of an electric street railway, such as he had just seen. We all thought in those days that about all that was necessary was to secure a favorable franchise, and the electrical companies would do the rest, but I know of no writing that so fittingly applies to the result as a verse in one of Moore's poems which reads:

I saw from the beach when the morning was shining
A bark o'er the waters ride gracefully on,
And I saw from that beach when the eve was declining,
The bark was still there but the waters were gone.

LIBRARY

The nickels which we had expected to have supported our enterprise had, like the waters, gone and left our bark, the street railway, stranded."

Oliver Blackburn Shallenberger.—The death of O. B. Shallenberger, which occurred at Colorado Springs, Col., Jan. 24, removed one of the most brilliant of the band of electrical pioneers whose achievements have given the distinctive name of the "Electrical Age" to the latter part of the nineteenth century. Dying in the early prime of manhood—he was but thirty-seven years of age—and while engaged on one of the most comprehensive schemes of high voltage power transmission yet put under execution, his loss to the electrical profession and industry is a severe blow. Mr. Shallenberger was one of the first to enter the electrical field thoroughly equipped to scientifically cope with the problems which it presented, having been graduated in 1881 with high standing from the engineering course of the United States Naval Academy. It is interesting to note that Sprague, Duncan, Hasson, Cahoon, Greene, S. Z. Mitchell, Wilkes, Eyre, Emmett and several others known in the electrical field were all at the Naval Academy during parts of the same period. After several years' service at sea abroad a man-of-war, Mr. Shallenberger resigned his commission in 1884 to accept a position with the Union Switch & Signal Company, and the next year was selected by Geo. Westinghouse, Jr., who had just purchased the Gaulard and Gibbs American patents, to develop the alternating current system. How in a very short time he constructed from the crudest of elements the alternating current system of to-day, forms one of the most creditable chapters in electrical history, and one too familiar to require further notice here. Later he transferred his activities entirely to the field of invention, and in rapid succession produced a whole series of alternating current station measuring instruments, the shunt coil for series alternating current operation, and the meter known by his name—the latter one of the finest electrical inventions of the age. About 1891 the health of Mr. Shallenberger began to fail, and the condition of his lungs made it necessary for him thereafter to spend his winters in Colorado, where, in 1896, he found it advisable to take up a permanent residence. Notwithstanding the state of his health, he continued his professional work, and at the time of his death was engaged, as president of the Colorado Electric Power Company, on a scheme, now well under way, for the distribution of electric power throughout the Cripple Creek mining district. Of an extreme intellectual modesty and somewhat retiring in disposition, he was not, as those who enjoyed the pleasure of his friendship so well know, lacking in any of the attributes of human kindness and sympathy. In fact, it may be said of him that, though of determined character and strong will, he had no enemies, and that none who met him but rendered a tribute of admiration to his sterling qualities of mind and character.

Consulting Engineers.—In the course of a paper read before the New York Electrical Society at the January meeting, Mr. S. Dana Greene said that in the electrical field the consulting engineer, as in other engineering fields, is a necessary and proper connecting link between the manufacturer and purchaser. Broadly speaking, the function of the engineer is to see that his client who buys apparatus and installs it, selects, first, the system best suited to his particular local conditions; and, second, that purchasing he secures the best (though not necessarily the most) for his money. It is, however, equally his duty to learn what the manufacturer can reasonably be called upon to make, to consult with him freely and to obtain the benefit of his experience; also, to give him credit for work well done, and insist that bad work shall be promptly corrected. He referred to the fact that many consulting engineers, especially those who have only recently commenced practice, seem to think that it is improper for them to consult with the manufacturer, to examine his plant or to ask him for information or advice, through fear, apparently, that in so doing they may be accused of partiality or undue bias, or that such a proceeding would be derogatory to their dignity as independent engineers. The inevitable result is that specifications often contain provisions which are a source of annoyance and expense to the manufacturer and purchaser alike, and Mr. Greene adds that for the former to ask the engineer or purchaser to make modifications is a proceeding always difficult and delicate to undertake, and often results in trouble for all concerned. Mr. Greene said he feels satisfied that no reputable establishment would refuse admittance to engineers who desire to obtain necessary information concerning their apparatus with a view to the intelligent preparation of specifications. As an instance of the general neglect to keep in mind standard apparatus when drawing up specifications, he referred to the record of the estimates supplied for such apparatus by one firm in a single year, amounting to 300 for direct current, and 300 for alternating current apparatus, besides which there were between two and three times as many preliminary estimates required to answer inquiries of customers, all the above being in addition to the regular work of the engineers of this company on standard lines of apparatus, of which there are over thirty. Mr. Greene believes that if the requirements of electrical machinery under the headings of efficiency, heating, regulation, sparking and insulation were formulated under some general rules, and if the methods of tests to determine results were uniform, the work of consulting engineers and manufacturers would be vastly lessened. Such, unfortunately, is not the case at present, and specifications on these points vary widely, both as to requirements and as to methods of tests. It is consequently believed that this forms a matter calling for action from some scientific non-partisan organization. The American Institute of Electrical Engineers is pronounced just such a body, and could render a great service to the entire electrical business by taking up the matter for consideration and action.

Small and Large Transformers.—Some recent data on the saving secured by the substitution of large transformers of high efficiency for old types of small capacity, illustrate the importance to central station managers of looking closely into the transformer question. In one case, 57 small transformers built in previous years were supplanted by 18 of one of the latest types. The total light capacity of the superseded apparatus was 1499 lights, and of the newly installed transformers, 1624. The total core loss of the old transformers was 5866 watts, of the new only 1348. The saving in dollars and cents is estimated at $527.70, or equivalent to a saving per light-capacity per year of 36.2 cents. Neglecting all the advantages of the change except those accruing from the decreased core loss, the expense of the change will be met in one year and nine months, while the light capacity of the plant is increased 9 per cent. In another instance, 40 new type transformers supplanted 53 old ones. The total light capacity of those replaced was 1135 lights, of the new, 1070. The core loss in the old type transformers was 4845 watts, of the new type 1343 watts. In this case the annual saving is about $409, and corresponds to a saving per light per year of 35.2 cents. The expense of the change, counting core loss alone, will be covered in two years and nine months. 3502 additional watts are available for sale, increasing the income by $525 per year, while by the use of lamps of a higher economy, some 535 KW-hours additional are also available for sale. In another case the regulation of the station had been very poor and the lamp bills had increased to such an extent that the question demanded immediate attention. While the saving was comparatively small, the beneficial results brought by the change have proved highly satisfactory. In still another case, 81 small transformers of old type were replaced by 3 of a new type. The core loss of the old transformers amounted to 2568 watts, of the new ones 280 watts. The resultant saving per annum is $267, the saving per light capacity per year being 25.74 cents. This is an all day station, and it is calculated that only eight and a half months will be required to wipe out the investment. In another plant, 193 old type transformers were superseded by 37 new ones, the total light capacity of the former being 6035 lights, and of the latter 8210 lights. The total annual saving is $683, and the total saving per light capacity 14.68 cents. In five years and two months the cost of the change will be fully covered. The capacity of the plant has been increased 36 per cent., the energy required to operate it decreased 47.1 per cent., and 116 additional light capacity obtained without adding to the station apparatus. If these lights were burned but three hours daily, the result would be an additional annual income of $960. On account of the improved regulation entailed by the change, high efficiency lamps are now used, which adds $109.46 to the total annual saving. In a Western central station by centralizing the transformer distribution, the rate of switchboard income was changed from 4 cents to 12 cents per KW-hour. Another Western plant had its 1140-volt circuit equipped with old style transformers, which showed 6 to 7 amperes in the day time, while with the new transformers only a fraction of an ampere is shown.

New Serial Articles.

With this issue is begun the publication of two serial articles—on armature windings and on interior wiring—which, we believe, will be much appreciated by our readers. The first-mentioned will take up all the usual types of windings in turn, and while the main object is to give a thorough understanding of the principles concerned, the information will be in sufficient detail for practical guidance in winding. The articles on interior wiring will be comprehensive in their scope, including detailed plans for wiring all classes of buildings, from a small cottage to the largest office building. According to the policy of this journal, each installment will be, as far as practicable, complete in itself. The attention of new subscribers is called to the series of articles on "American Telephone Practice," which forms unquestionably the most valuable contribution yet made to the practical side of telephony.

Fuses and Circuit Breakers.

In this issue is published the conclusion of the discussion on "Circuit Breakers vs. Fuses," though our columns remain open to those who took part for any rejoinders they may consider necessary, and to others who may have something new to say on the subject. The discussion has, we believe, been of value in bringing out fully the particular merits of the devices under consideration, and in making the electrical public acquainted with a new type of fusible cut-out which, we believe, will finally entirely displace the unsatisfactory open-air fuse. As to the relative merits of fuses and circuit breakers, the conclusion to be drawn would appear to be, that each type of cut-out has its own field, and that neither will displace the other. The discussion, in fact, bears some resemblence to that which took place upon the introduction into the commercial field of the alternating-current system, when partizans on one side maintained that the direct-current system was doomed, while those on the other could scarcely find terms sufficiently strong with which to characterize the imperfections of the new comer.

An Important Electric Railway Decision.

The recent decision of Judge Wheeler sustaining the Sprague patent on the method now employed for the suspension or electric railway motors, will, if sustained on appeal, be of far-reaching effect. The opinion of Judge Wheeler is very brief, and its reading does not at all make clear the grounds upon which he based his decision. It is stated that if the Sprague patent was for merely hanging and centering one end of a motor upon the axle of the driving wheels, and suspending the other by a spring from the body of the vehicle, or the truck, it would be wholly lacking in novelty, and void. The opinion then proceeds to say that no one had before hung a field magnet at one end upon the axle of the driving wheels, and at the other end upon a spring from the body of the car, or truck, "and an armature axle upon the pole pieces of the magnet, parallel with, and geared to, the axle of the driving wheels for driving a car by a current of electricity." The context would seem to imply that the vital point is therefore the use of electricity as a motive power in combination with a spring suspension for the motor, or possibly that together with the use of an armature axle having a bearing in the pole pieces of the magnet and geared to the axle of the driving wheel. On account of this vagueness, the present decision cannot be considered to foreshadow the conclusion that will be arrived at on appeal.

The Power Factor.

That the power factor should be considered a somewhat mysterious quantity is perhaps not surprising in view of the fact that it is often defined as "the cosine of the angle of lag." When an alternating current passes through a choke coil, for example, having, say, a power factor of .9, the mind of one not instructed in alternating current mathematics can be brought to conceive without much difficulty, that an opposing inductive E. M. F. inside the coil may cut down the energy to .9 of that due to a direct current of the same value and voltage. If, however, he tried to connect the idea of an angle of 65 degs. (the cosine of which is .9), with the current flowing and the E. M. F. existing at the binding posts, in all probability he would most promptly give it up and consider alternating current phenomena too difficult for his comprehension.

In fact, the use of an angle and the cosine in connection with the power factor is entirely an artificial conception. If, in a particular case, the impressed E. M. F. is 100 volts and the power factor is .9, then the free E. M. F. is 90 volts, and the actual energy is $90 \times 100 = 9000$ watts. That is, the inductive E. M. F. set up in the coil requires 10 volts of the impressed E. M. F. to balance it, leaving but 90 volts free to do work. It should be added that the actual value of the inductive E. M. F. in this case would be 42 volts, but the direct reaction between it and the impressed E. M. F. is but 10 volts, for reasons that may be made apparent by laying down the sine curves of the two E. M. F's. However, the point to be borne in mind is that the power factor is a fraction expressing the part of the alternating E. M. F. measured at the terminals of an inductive circuit, which is free to do work. If the voltage is 50 and the current 10, with no inductance in circuit the watts consumed in the circuit would be $50 \times 10 = 500$; with a power factor of .6, the watts would be $30 \times 10 = 300$, for the reason that 20 volts of impressed E. M. F. are "held up" through the presence of inductance, in the same manner that the useful E. M. F. of a battery of 25 storage cells would be reduced from 50 volts to 30 volts, if 5 of the cells were connected in opposition.

Inefficiency of the Steam Engine.

One of the most persistently held errors is that the steam engine is a shamefully inefficient machine, and one of the speakers at the recent Northwestern Electrical Convention went so far as to say that "the best type of modern stationary steam engine only yields power equivalent to, say, about 13 per cent. of the energy of good steam coal, *leaving 87 per cent. for improvement.*" The first part of the statement is approximately correct, but this inefficiency is not the fault of the steam engine, but a result of the operation of the inexorable second law of thermodynamics, according to which only a fraction of the heat supplied—the ratio of the range of working temperature to the maximum absolute temperature—is available for transformation into another form of energy. This law applies not only to the steam engine, but to all machines and processes for the transformation of heat, including gas and air engines, thermo-piles, thermo-electric batteries, thermo-magnetic engines, etc. It follows from this, that the part of the above statement italicised is absolutely incorrect.

Let us determine the real efficiency as a machine, of a steam engine generating a horse power on 1.7 lbs. of coal per hour, the steam having an initial pressure of 100 lbs., and exhausting into a condenser maintaining a vacuum of 26 ins.; further, assume that the coal has a thermal value of 14,000 units, and the boiler an efficiency of 70 per cent. The number of heat units in 1.7 lbs. of coal is therefore 23,800, and since the heat equivalent of a horse power hour (as found by dividing the foot-pounds by the mechanical equivalent of heat) is 2,545, the efficiency on this basis is but 10.7 per cent.

The absolute temperature of steam at a pressure of 100 lbs. is 797 degs., and that of vapor at a tension corresponding to 26 ins. of vacuum, 587 degs. Therefore, the amount of heat available for transformation into work is $(797 - 587) \div 797 = 26.2$ per cent. which is another efficiency of the steam engine—its thermal efficiency or the percentage of heat delivered which it could transform into mechanical work were it a perfect machine.

As the boiler only utilizes 70 per cent. of the heat in the coal burned in its furnace, but $.7 \times 23{,}800 = 18{,}660$ units of the heat in the coal is delivered to the steam engine, and of this only 26.2 per cent, or 4889 units are available for transformation into mechanical work. But a horse power is equivalent to 2545 heat units, and consequently the engine under consideration has an efficiency as a heat transformer of 52 per cent. This latter, and not 10.7 per cent. or 26.2 per cent., is the true efficiency of a steam engine working under the conditions given, and the figure approaches 70 per cent. for the most economical types of modern engines. While between 100 per cent. and 50 per cent. or even 70 per cent., there is a considerable margin, it should be borne in mind that heat is a form of energy that, unlike electricity, cannot be directed into one desired channel alone, so that wastes by by-paths are everywhere occurring. For this reason it is unfair to compare the efficiency of any heat engine, with, say, an electric, weight or spring machine, as electricity, gravity and resilience are forces that can be exactly directed.

The Hunter Alternating Current Patents.

In another column we print a communication from Mr. R. M. Hunter, in which he takes exceptions to some editorial comments which appeared in our January issue, concerning several patents recently issued to him and purporting to "cover broadly the alternating current system." The comments in question referred to the absurdity of a patent issuing at the present time purporting to broadly cover a system that has been in commercial operation for years; of which every fundamental principle had been known a half a century or more, and their application to electric light and power distribution covered by patents antedating the date of application of the Hunter patents, with the exception of one relating to the operation of transformers in parallel—this issuing, however, twelve years previous to the date of the recent Hunter patents.

To particularize, the transformer principle was embodied in the apparatus used by Faraday in his memorable discovery and demonstration of electro-magnetic induction, and afterwards applied by Ruhmkorff and Varley in the induction coil. The method of stepping up and stepping down alternating current voltages was so well known a half a century ago as to form the subject of a text-book description. The transformer as applied to telephony, was described by Berliner in 1877, and a patent on a similar arrangement granted to Rossetti in 1880, and a year later the Deprez patent for electrical distribution by the aid of step-up and step-down transformers was issued. In 1882, or a year before the date of the application for Mr. Hunter's earliest patent, the celebrated demonstration of the Gaulard & Gibbs alternating current system was given at Westminster Aquarium, London, and the Zipernowski-Deri patents on the structure and arrangement of transformers for use in parallel were issued a few years later—the novelty of these latter patents, however, being questionable in view of the practice already established of direct current parallel distribution.

In the face of these facts, there is every reason to view with suspicion patents issued in 1897 claiming to "cover the entire art" of alternating current operation and "all of the apparatus employing transformers for reducing potential now in use or likely to be used"—a suspicion which becomes more accentuated when it is seen that the first mentioned patent is merely based on a division of an application for a telephonic arrangement, which arrangement, judging from an accompanying patent office drawing, is in itself a mere rehash of the earlier work of Berliner, Rossetti and others. But Mr. Hunter maintains that the justice of his claim to the prior invention of the alternating current system is upheld by the Patent Office, and he mysteriously remarks that "there is a great deal relating to the alternating current system which the public knows nothing about, but will in due time possibly be more enlightened."

In reply it may be said that, in view of the adverse fate met by so many patents when brought up in court for adjudication on their merits, a Patent Office search or grant predicates little or nothing as to the real value of a patent, which is issued on a prima facie showing and not upon a judicial determination of all the facts; and that if much is yet unknown concerning the alternating current system, the Hunter patents certainly disclose nothing but what was well known even before the date of the earliest Hunter application. As to the Hunter railway patents, the reason given why litigation has not been carried on under their broad claims is scarcely valid in view of the history of the case of the Thomson-Houston Company against the East Reading Railway Company, which case was founded on the Hunter patents, but subsequently abandoned and new suits instituted under the Van Depoele patents for substantially the same invention.

A SENSITIVE MIRROR GALVANOMETER.

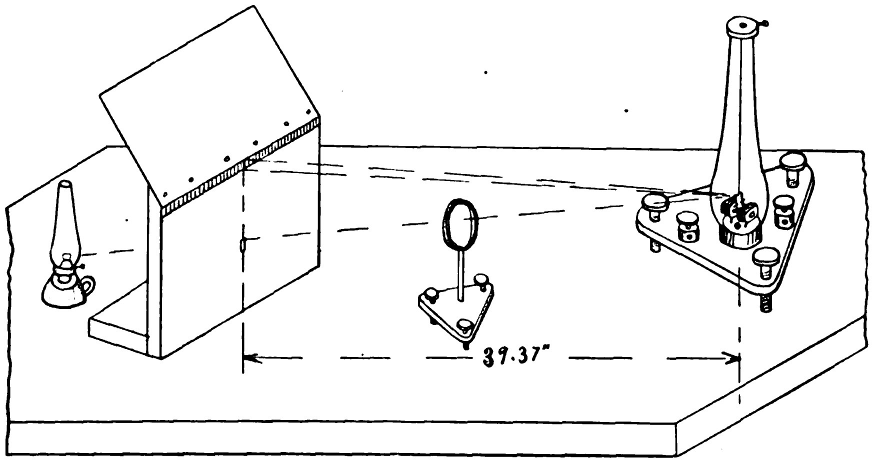
BY JAMES F. HOBART.

The several galvanometers recently described in the AMERICAN ELECTRICIAN possess many points of merit for particular and different kinds of work, but their construction is a matter of considerable difficulty, and requires accurate and high-grade work on the part of the constructor.

The instrument described herewith is intended to obviate, almost entirely, the necessity for skilled manipulation, upon the principle which pays so well in the machine shop, viz., that the whole be so designed in its several parts, that the machine work shall be reduced to a minimum, or even dispensed with altogether, save a little drilling, etc.

The above scheme has been adopted in making the galvanometer, which, after having been turned out "with jack-knife and pliers" will give results closely approaching those received from a more elaborate and costly instrument. Fig. 1 gives a view of the instrument complete. It consists of four parts—the lamp, the screen, the lens, and the coils and needles.

For the lamp, a bicycle lamp leaves nothing to be desired, though a common kerosene hand lamp, as shown in the engraving, answers every purpose. The vertical board is as high as the lamp, and the scale is attached to the top edge of the board. The scale may be an ordinary yardstick, or ruler fastened to the board, or it may be a strip of paper ruled to milimeters, and shellaced to the board.



[FIG. 1.—SENSITIVE "HOME-MADE" GALVANOMETER.

The tin shade is simply to cut off some of the light which otherwise would be reflected over the top of the scale, and dim the bar of light. A clean, sharp slit may be made by cutting a somewhat large hole in the board, and covering it with a bit of cardboard or brass, in which a slit of the size, found by experience to be best, has been cut.

The lens may be an ordinary reading glass, or it may be one of the cheap lenses to be obtained in almost any shop, for a few cents. Almost any form of lens can be made to answer, but preferably, it should be a double convex, of very long focus—16 ins. to 18 ins. If a reading glass is used, it may be mounted by placing the handle through a hole in the base-board as shown. If a plain lens is to be used, a cheap mount is shown by Fig. 2. A bit of board is cut out as shown, and the hole through it is just a trifle smaller than the lens. A narrow V-shaped groove is then cut around the center of the inside of the hole, and a saw kerf run into the board as shown. This allows the lens to be pressed into the groove, and the spring of the wood holds it there.

The six leveling screws are common brass wood-screws, 4 ins. long, about ¼ in. in diameter, with the top of the head filed off flat. The edges of the disk thus formed may be milled in pretty good shape by rolling the edge of the head under a single-cut file of the required degree of fineness. Place the screw on a hardwood board, or better yet, on a sheet of lead, and by rolling under a file, the milling can be quickly done. By all means, use a lathe if you have one, in preference to the file method.

The third member of the family is built on a bit of board cut about 8 ins. on a side of triangular shape, as shown. Three leveling screws are let in, and two binding posts are placed in connection with the coil. These posts are shown in the engraving. A common medium-sized lamp chimney is procured and fitted to a circular piece of wood ¾ in. thick. The wood is screwed to the base, and the coils are fastened to the wood; the mirror must be placed one meter (39.37 ins.) from the scale.

Another circular piece of wood is fitted to the top of the chimney, as shown in Fig. 1. A detail plan and section of this piece is shown by Fig. 3. It is bored out to fit on the chimney, and a ½-in. hole is bored in the center, completely through the wood. A wire with a sort of thumb-head is bored into the wooden cap so as to pass through the center of the ½ in. hole. A bit of cardboard is glued into the bottom of the large hole, and a pin-hole, punched through the exact center, permits the suspension fibre of the needle system to be carried to the wire and wound up by turning the thumb-head above described. The coils may be made according to the work to be done. I have three sets of coils with my instrument. The first is made of about 50 ft. of single-silk, copper magnet wire, of such size that it has a resistance of about 8 ohms to the 1000 ft.—about No. 18, or No. 19, B. & S. gauge.

A form for winding the coils is shown by Fig. 4. It is made of wood, held together with two screws. A couple of binding wire are laid in before the coil is wound. About six layers of the wire above mentioned can be made out of one-half the 25 ft. mentioned. Two of these coils are used, connected in series and to the binding posts. After winding, the binding wires are fastened, the coil is drenched with shellac and placed in the cook-stove oven for an hour. The core is then removed, additional binding placed on the coil if found necessary, and again baked at low heat for two or three hours. This holds the coils permanently. Two coils are to be used, and the needle system suspended between the coils, which are placed ⅜ in. apart.

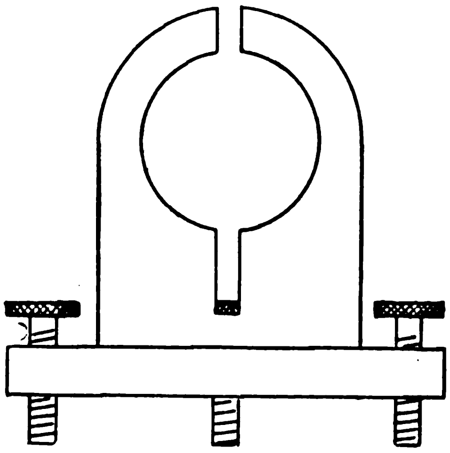


FIG. 2.—METHOD OF MOUNTING PLAIN LENS.

I have three coils with my instrument, two in each set, and use either set, as the work demands. I have also three sets of needles, which will be described later. The second set of two coils is wound of No. 33 or No. 34 wire, and has a resistance of about 10 ohms, or 20 ohms for the complete set of two. The third coil is wound with No. 36 wire. Nearly ¼ lb. was put on the two coils, and the combined resistance of the complete coil is about 1000 ohms—500 ohms each.

For the needles with the low-resistance coils I use a common sewing needle. The temper was drawn, the eye and point filed off, leaving a bit of wire 1¼ ins. long. A nick was filed in the center, then the needle was hardened and magnetized, and broken through the nick, thus giving two needles magnetized pretty near alike. A piece of cardboard 2 ins. × ½ in. was pierced, and the needles stuck through it, as in Fig. 5, and held by a drop of hot sealing wax.

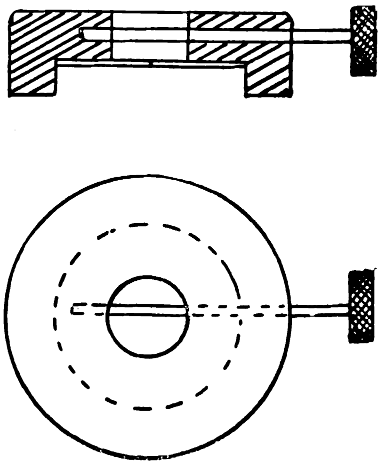

FIG. 3.—CAP FOR TOP OF GLASS CHIMNEY.

A bit of mirror, *m*, was waxed to the top of the cardboard, and the suspension fibre fastened between the mirror and the cardboard, as shown. The upper end of the fibre is carried to the cap on top of the chimney, attached to the thumb-head wire, and wound up until the lower needle hangs in the middle of the coil, and the upper needle clears the top of the coil about ¼ in. The instrument is now ready for setting up and adjusting in the usual manner.

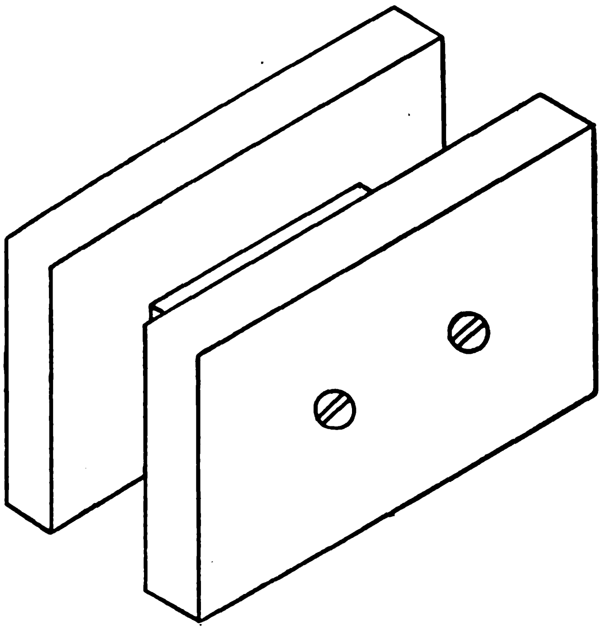

FIG. 4.—FORM FOR WINDING COILS.

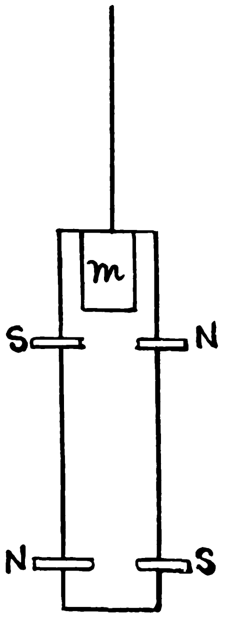

FIG. 5.—NEEDLE SUSPENSION.

The second set of needles is made in the same manner, except that I used pieces of fine watch spring, less than ⅛ in. wide, and placed three pieces together with a single thickness of paper between, for each needle. The pieces were file-marked, hardened, magnetized and broken in pieces, the same as the needles.

Finding that the light needles and the low-resistance coils gave an instrument readily affected by thermal currents, I made the third set of needles of steel tape about ⅜ in. wide, and used five pieces in each needle, separating each with paper. All the needles in the three systems were ⅝ in. long. The third set made a very heavy set, but in connection with the 1000-ohm coils, proved very sensitive, although slow moving.

Different effects were secured by using either set of the needles with the other coils, making six possible combinations. Where extreme sensitiveness is not required, I found it desirable to use a directing magnet, and not depend upon the torsion of the suspension, or over-strength of one of the needles, to return the beam of light to zero.

With 1000 ohms in each arm of the bridge, and 6 volts in the battery, a considerable deflection is obtained by changing *R* a single ohm, and with the bridge arranged 1000 to 1, at *a* and *b*, the galvanometer readily deflects down beyond the capacity of the bridge, which was .001 ohm, with 1000 ohms galvanometer resistance.

For the suspension in this instrument, I used a hair. It was quite fine, micrometered about .002 in. in diameter, and was probably from the head of a dark-haired lady. From the needles to the point of suspension, there were about 8 ins. of effective hair. Just how much better the instrument would be with a raw-silk fibre, I have no means of knowing at present, but it was as delicate as will be required for any ordinary work.

As to the "figure of merit," I have not had opportunity to determine that point, but will do so, and report later. The "efficiency" of the low-resistance instrument is rather greater than that of the high-resistance form, while the "figure of merit" is greater, the more turns of wire are placed on. For measuring very low resistances, the low-resistance coils will give perhaps the best results.

* * *

INTERIOR WIRING.

INTRODUCTORY.

BY CHARLES E. KNOX.

In the series of articles of which this is the first installment, we shall start at the point where the electrical engineer or expert commences—with the floor plans—indicating and outlining the method of procedure in "laying out" the outlets and circuit wiring, and following it up with the electrical contractor through the various stages of installation, to and perhaps beyond, the point where the current is turned on.

It is not the purpose of this introductory article, to give the history of interior wiring. This has been done by others far better qualified and in such a manner as to leave little to be desired. It will rather be our intention to present and discuss the methods and practice of interior wiring in vogue at the present day.

We will begin then, where we would start in actual practice, and outline the procedure followed in locating the various outlets, selecting, by way of example, a typical building, and also discussing the questions of chases for the risers, and locations of the distributing centers.

Before selecting a concrete example, however, let us consider the various ends we may accomplish in properly distributing the lights. All kinds of ordinary lighting may be divided, empirically and for convenience, into three groups or classes, as follows: 1st. General Illumination; 2d. Local Lighting; 3d. Decorative Lighting.

Under the first head are included all kinds of lighting the object of which is to so arrange the lights as to provide a diffused illumination through a given space, as, for example, a parlor, dining room or ball room.

In contradistinction to the first class, the second has for its end, the illumination of some particular object. The lighting of draughting rooms (when drop lights used) and business offices, are types when is essential to arrange the lights with reference to tables and desks.

The name of the third group indicates the function it has to perform, and includes dome and tower lighting, illuminated signs, etc. In this case the lights are generally arranged so as to accentuate some architectural feature of a building, following some of the more prominent architectural lines.

Having thus briefly outlined the various kinds of lighting, which we will meet later, let us begin at once with the subject particularly set aside for present consideration.

Suppose, we have before us a set of building plans, and that in conjunction with the architect or owner we are called upon to mark on the plans the location of the electric light outlets.

As we are in a position to choose, let us select a simple case, and assume that the building to which our attention is called is a private dwelling.

Commencing at the bottom of the house, the cellar first attracts our notice.

The lighting of this floor is distinctively of the first class or group, and as the various portions of the cellar are generally allotted to their several purposes at the time the lights are located, its disposition is a simple matter. It is well to bear in mind, however, that the stairs leading from the cellar should be properly lighted by an outlet either at the foot or head. If it be placed at the foot, it should be controlled by a switch located at the head of the stairs. Many a damage suit for injuries sustained by accidents, occuring on stairways and in passages, has hinged proof, whether the stairs or passages were properly and sufficiently lighted.

In the laundry, very little light is required as the work here is generally done during the day. The lights here also should be located with reference to the objects which they serve to illuminate. In this connection it might be proper to remark that the lighting of the service and servants' portion of the house should be limited to that amount only which is necessary and proper for the work to be carried on. It is unwise to provide extra outlets in these places, for the reason that, as a rule, servants use their own discretion in lighting, and should you give them more than the amount necessary, they will not fail to use it.

If the range in the kitchen has a hood, it is well to provide for outlets under the hood, as it is otherwise difficult to provide adequate lighting. Outlets should be placed over the sinks, tables, etc. Lights should also be placed in all closets deep enough to require them; in placing such outlets preference is given to the ceiling, thus avoiding interference with the shelves. The lights in the butler's pantry should be so placed as to light the closets properly from the outside, as the closets are generally too small to admit having the lights placed inside.

The problem of lighting the dining room is a very simple one. Notwithstanding the fact that architects and others of artistic tastes, always object to ceiling lighting, that is invariably the way it is done, because it is the only way to illuminate the room sufficiently. Of course, the ceiling lights may be supplemented by others, but we must depend on the ceiling for the general illumination. The lights may be grouped in one or more chandeliers, or, if the ceiling is paneled and the design admits it, single lights may be placed between or in the center of the panels. Sometimes a floor outlet is desirable for the purpose of providing a source of current for decorative lighting on the table itself.

Passing on to the library, we find that we are again forced to place dependence chiefly on the ceiling, for the reason that the wall space is generally occupied by the bookcases. If there is any opportunity for locating a couple of side brackets, they are desirable. Here also a floor outlet may be needed for table or desk lights.

In the parlor and reception room it is wise to provide for both ceiling and side lighting. The side lights should be so located as to avoid cutting up the wall space to such an extent that they will interfere with hanging space for pictures. Plug outlets are frequently placed in the base-board for flexible connections to piano lamps, torchère lights, etc.

The lighting of the main hall and the stair halls is generally accomplished by a ceiling outlet in the main hall, and by a side outlet placed in the center of the hall wall, in each of the upper floors.

Taking up next the lighting of the bedrooms, let us state at the outset, that the only proper method of locating the lights in rooms of this character (where the lighting depends almost entirely on the location of the furniture) is to make paper templates of the same scale as the floor plan, of the different articles of furniture and lay them out on the plan. When this has been done and a satisfactory arrangement has been made, the outlet may be located.

A light should be placed on each side of the bureau, the outlets being from 4 ft. 6 ins. to 4 ft. 10 ins. between centers. Sometimes a single outlet is placed over the center of the bureau for a two-light drop fixture. This is not as satisfactory in most cases as a single light on each side. Except in fairly large rooms, ceiling lights can be readily dispensed with, because the bed generally interferes with their usefulness. It is wise to provide plug outlets for connections for a table light next to the bed and for other table lights should they be so desired.

In the bath room, one bracket light near the wash basin, is generally sufficient. Avoid placing this outlet over the center of the basin, as this would interfere materially in the placing of a mirror.

In the servants' bedroom, a single bracket light near the window usually answers all purposes.

Having satisfactorily arranged the location of the outlets, let us consider for a few moments the question of the number of lights we should provide at the various outlets.

In the first class of lighting (general illumination), the total number of lights to be placed in any given space, depends primarily on two variables: First. The total cubical contents of the space to be lighted. Second. On the color and character of the decoration of walls and ceilings.

In the calculations for determining the amount of light in a given space, a 16-CP lamp (having a clear-glass globe) is adopted as a unit.

It is a difficult matter to formulate any rule for ascertaining the exact number of these lamps required, but with the lamps exposed to view (*i. e.*, the lamps being so arranged as to afford direct light and not reflected light) the number of cubic feet per lamp will vary between the limits of 300 and 1000 cu. ft. The former figure will serve for cases, such as ball rooms, banquet rooms, etc., where unusually brilliant lighting is required. The latter figure may be used for cases where only a fair amount of light is needed, the ceilings and walls being white. For the average case, where the space must be well but not extravagantly lighted, the color of the decoration being fairly light, it is safe to allow from 500 to 700 cu. ft. per lamp. Where the decoration is dark, the number of lamps should be increased, as the light-absorbing quality of the color scheme increases. As was stated above, these are not hard and fast rules, and must be used with discretion.

Quite frequently the architect will object to the conventional side-bracket or chandelier and will say, "Can't you get up some scheme so you can place the lights where they won't be seen, and yet have the room evenly and brilliantly lighted?" To do this successfully is quite a difficult task. Theoretically speaking, the ideal illumination would be attained by the distribution of a very great number of small light-giving bodies distributed over the space to be lighted, keeping the light density constant and producing a diffused illumination of the entire space. The effect produced in this way would be delightful to the eye, as it would avoid the production of "spots" of light and also prevent the distracting effect of the present methods of lighting.

If, however, the architect objects to the usual methods of lighting, his services must be enlisted in order to break away from them; for if *special* lighting is to be provided, special provision should be made for it in the architecture of the room, for its successful accomplishment.

An attempt to produce the effect referred to above, is frequently made by dividing the light into a great number of units, using receptacles, or wall-sockets, hidden behind cornices or placed above or behind a translucent material, such as ground or opalescent glass. In the last case, the ideal is more nearly attained, but the number of cases where this method can be carried to a successful conclusion are extremely rare. Another method still is to expose the lights, but weaving them in with the artchitecture so that they are less noticeable.

If the architect is sufficiently interested in the result sought for, to go so far as to modify his designs where the circumstances and conditions admit it, the effect produced generally contributes no less to the beauty of the architecture, than to the success of the lighting. It is never wise, however, to adopt any of these methods unless the conditions readily lend themselves to this type of lighting. There are enough "horrible examples" around the country, where lighting by the use of single lamps, arranged in geometrical or other forms, has been attempted, where the conditions neither demanded this method nor warranted its use.

Having satisfactorily located the various outlets, there still remain two other subjects for discussion and consideration with the architect, and these are the locations of the chases for the vertical portions of the feeders and the points suitable for placing the centers of distribution.

We will take these up here only so far as they interest the architect in making provision for them.

In both cases the best method of procedure is to ascertain what places are available for the purpose, leaving the selection of the particular ones to be used until the circuit work is partially laid out.

In regard to rising points for the feeders in mains, the following precautions should be used in seclecting chases:

First. The space should be amply large to accommodate all the feeders and mains likely to rise at that given point. This seems trite and unnecessary, but it is the most usual trouble with chases for the risers. Formerly architects and builders paid little attention to the requirements for chases for electrical work, but in these latter days of 2-in. and 2½-in. conduit, they realize that these pipes are not as invisible and mysterious as the force they serve to contain, particularly when they have twenty or more such conduits to stow away in a building where no special provision has been made for them.

Second. If possible, the space should be devoted solely to electric wiring. Steam pipes are objectionable on account of their temperature, and these and all other pipes are objectionable in the same space as the electrical conduits, for if the space proves too small, the electric conduits are the first to be crowded out. The phrase, "The electrical contractor can 'string his wires' anywhere," is heard too frequently to need comment.

The chase should be continuous from the cellar to the roof, or as far as needed. This is necessary in order to avoid unnecessary bends or elbows, which are objectionable for many reasons.

In similar manner, the location of cut-out cabinets or distributing centers should fulfill the following requirements.

First. They should be accessible at all times. Never place a cut-out cabinet where you would have to disturb a man when he is taking a bath, to replace a fuse. He will be mad even if the fuse serves to protect a circuit in his own room, but he will be madder still if it is for some other room. Put the cabinets therefore, where you can quickly and easily get at them at all times.

Second. They should be placed sufficiently close together to prevent the circuits from being too long.

Third. Do not place them in too prominent a position. This is objectionable from the architect's point of view.

Fourth. They should be placed as near as possible to the rising chases, in order to shorten the feeders and mains supplying them.

MERCHANT MARINE WIRING.

BY E. W. COUNTISS.

Wiring for electric lights on ship-board is very different from wiring on shore, not so much in principle, as in details. The average first-class wireman on shore is not so good on board ship. The rules that govern the case of one ship will not apply to all, but certain precautions must always be taken to avoid fire risks from short circuits, leaks and grounds, whether the plant be large or small, and it is the object of this article to point these out.

Much judgment must be used as to when is the best time to begin wiring a ship. If you wait too long, extra work will have to be done, which could have been avoided by starting sooner. If started too soon, the probability is that some of the wire-ways will be in the way of some necessary joiner work, and have to be removed. By having one or two men on hand, holes can be bored, tubes and moulding put in place while the panel work is being set up, thus sometimes saving a week's extra work. This applies to a new ship in course of construction, but on an old ship it is a case of "make the best of it."

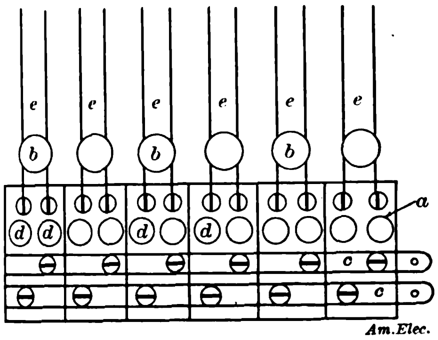

FIG. 1.—DISTRIBUTING CENTER.

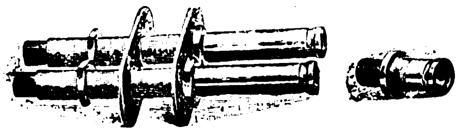
As the cabins and state rooms are finished in the best style, it is here that the greatest difficulty is encountered. The location of the lights is marked out by some representative of the ship's owners, and the question arises how to get the wires to them, without disfiguring the surroundings. The feeders will give the greatest trouble, as a clear run for a moulding to take a No. 00 or No. 000 wire, is not always just in the right place. To find a place for it sometimes even a smaller moulding gives trouble.



FIGS. 2 AND 3.—DECK AND BULKHEAD TUBES.

The mouldings must be placed so that they will be almost undistinguishable from the ship's finish. A board of inspection on one of the new cruisers was standing in the ward room, and seeing the fixtures asked the question, "Where are the wires run?" The moulding carrying the mains for this particular case were $2\frac{1}{4}$ ins. wide, placed on the outside of the panel work, and yet they were hardly discernible.

The distributing centers, if judiciously placed, will save both time and expense. As the contract specifies that there shall not be more than 2 or 3 volts drop at the lamp situated the greatest distance from the switchboard, these centers must be well located; and as there are allowed only six or eight lights on a circuit, the fewer these centers are in number, the more compact will be the system. If properly located, it is possible to take in a nest of state-rooms and also some of the cabin lights on two decks, and so cover considerable space. No. 14 B. W. G. wire is a good size to use, starting from the fuse blocks, as it is easily spliced and easy to fasten to the socket and fixture terminals, as well.

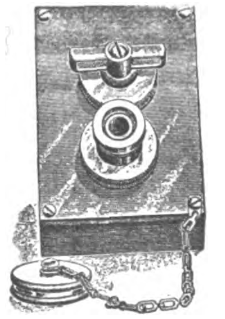


FIG. 4—WATER-TIGHT SWITCH AND RECEPTACLE.

The feeders preferably should be stranded, as they are then more easily handled and adapt themselves to the various turns in the mouldings, besides being more flexible and lessening the danger of fracturing the conductor. These feeders should have a double pole fuse and switch at the switch-board, and every distributing center its own feeder. Fig. 1 gives an idea of the arrangement of the feeder and circuit switches of a distributing center. *a*, are double-pole cut-outs; *b*, double-pole switches; *c*, connecting bars; *d*, double-pole fuses, and *e*, circuits to lamps.

Wherever possible, keep the mouldings inside of the state rooms, as they are less seen there than anywhere else; but where it is necessary to cross the saloon to a light, run the moulding on the bottom of the deck-beam. If it is flat and level you will have no trouble, but if it is cased in with a fancy moulding, make a deal with the master-joiner and have him plow enough out of it to make a wire casing. This permits all the beams to look alike. Screw this moulding on, so that it can be removed at any time; for if is nailed on, it is more trouble to take off, besides the danger of damaging it beyond further use.

Where a moulding is run on a bulkhead or across a panel, do not make it look like a patch. It may be that the wires pass through a bulkhead, 6 or 8 ins. from the deck or bulkhead; run the moulding from deck to deck, which gives it the appearance of a pilaster; or if run horizontally, let it extend from one bulkhead to the other.

Wherever the wires pass through wooden bulkheads or beams, they should be protected by hard rubber tubing, the sharp edges being removed on the inside at the ends. Wherever the wires pass from deck to deck, water-tight tubes should be used. No matter how staunch the ship, there is bound to be some give to the different parts, and as the wires become a fixed part of the ship, every precaution must be taken to secure the wires from injury. The best insulation will wear through with continual chafing, so extra precautions must be taken where vibration takes place. Only the very best rubber-covered wire, further reinforced with a strong and durable braid, should be used. Water has caused as much trouble as almost anything else, whether the source be rain or salt water from heavy seas; and extra precautions must be taken to keep this from the conductors. Wherever a joint is made, it should be well soldered, the flux thoroughly removed, and then reinsulated with a first-class tape, over which a good coat of insulating paint or varnish is applied.

Figs. 2 and 3 illustrate a pair of deck tubes and a bulkhead tube respectively. The method of applying the deck tubes through wooden decks needs no comment; but if the deck plank is laid over and on top of a sheet of iron or steel, as in the naval ships, it is well to take still further precautions to secure water-tightness, as the deck may leak at a seam 10 ft. from the tube, and water work down around the tubes, flowing on top of the sheet of metal and below the planking.

The plan adopted by the writer is to drill a hole the size of the tube at the root of the thread, then tap the hole so that the tube will fit tightly. Before putting in for good, red-lead both hole and tube, and you are safe from leakage. The lower washer plate can then be set up with the lower nuts, but first put red lead on the washer plates both top and bottom.

Wherever it becomes necessary to carry the wires outside, always use a water-tight tube. The bulkhead tube is used for passing through water-tight metal bulkheads, and is secured in place the same way as the deck tube. These tubes are lined with hard rubber their entire length. At one end, the hole is enlarged so that a moulded soft rubber gasket may make the inside tight where the wire passes through. The gaskets can be secured of any inside diameter to fit the wire used, and are forced home by means of a gland nut on the end.

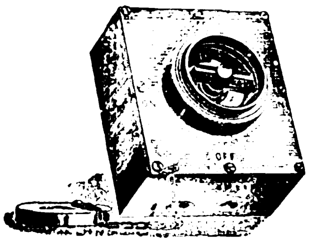

FIG. 5—WATER-TIGHT SWITCH.

When using these tubes, coat the wire and the inside and outside of the rubber gasket with an insulating compound or paint, and you are safe, when set up. Some of my readers may think that some of these details may be superfluous, but seven years' experience has almost convinced me that it is impossible to do too much.

If you will notice the joiner work, you will see that there is not a right angle or a straight line anywhere. Everything is curved and beveled. When you run your moulding make it parallel with the surface or finish to which it is the nearest. This will make the intervening space parallel and add to the good looks of the job.

In the shaft alleys and between decks, it is better to run lead-covered wire. The fumes of acids, oils, etc., attack the braid of ordinary wires, and in a short time it is gone. Branches can be taken off of the mains by using branch water-tight junction boxes, or by means of soldered joints. The latter method is the cheaper, and just as good, if properly done, which is as follows:

Remove the lead for about 1½ ins., then ⅜ in. or ½ in. of insulation. Make a solder joint of your branch (using lead-covered wire for it), and have the lead set back about the same distance as in the mains, and solder. Wrap this securely with tape so that there are no weak spots. Take a piece of sheet lead of the same thickness as the lead on the wire, about 2¼ ins. square. Form this around the joint closely and with a blow-torch (small jet) or soldering iron solder the joints where the wire is surrounded. Trim off the surplus metal on each side of the branch, and solder the edges. If neatly and properly done, the joint will not be over 3/16 ins. larger than the main line. Water-tight fixtures ought to be used in all places exposed to moisture.

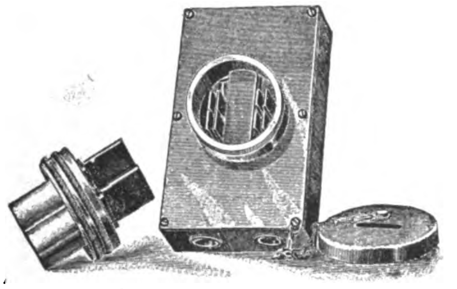

FIG. 6.—WATER-TIGHT SWITCH.

Where wires cross each other in the mouldings, a method employed was to bore a hole in the back of the moulding, sink a hole in the foundation woodwork, and lace the branch under the opposite wire, and thus leave ¼ in. of wood between the two wires.

Where lights are not needed constantly, or not always in one place, portable lights, such as cargo reflectors, are provided. Water-tight receptacles are installed, into which a plug can be inserted when the light is required, and the opening closed when not needed. Fifty feet is a good length to allow for the cord, which should be what is now known as double-conductor hemp portable.

Fig. 4' shows a water-tight combination switch and receptacle, used for the attachment of a portable lamp.

Fig. 5 shows a water-tight 40-ampere gang switch. These will be dwelt on more fully in a later article.

Fig. 6 is a search light receptacle, which is seldom, however, used in merchant work.

◆

Ozone.

In a recent paper Prof. Blondin states that theoretically 2.24 lbs. of ozone can be produced by 1 HP-hour of electrical energy. By the older methods only about 2 per cent. of this amount could be generated per HP-hour, but recently an efficiency as high as 15 per cent. has been attained. The principal loss is in the heat developed in the process, which consists in sending a current of air through passages between whose sides electric discharges are maintained—usually sparks from one pole over a glass partition to the other. The voltages used vary from 6,000 to 10,000. Ozone is employed industrially principally in the oxidation of hydrocarbons. The most important commercial application at present is in the production of vaniline from iso-eugenol.

ELECTRICAL APPARATUS FOR AMUSEMENT.—II.

MAGICAL CANDLESTICKS.

BY NEVIL MONROE HOPKINS.

The magical candles and candlesticks represented in the following illustrations, were designed for the purpose of furnishing light, and a source of flame, for the modern conjurer's table. They are capable of mysteriously extinguishing and relighting themselves as many consecutive times as may be required, at the wave of the magician's wand, and, if brought forward near the edge of a small stage, create a very surprising effect when exhibited on a light board placed across a pair of trestles, small round tables, or other equally innocent looking rests or supports.

The appearance of these magical candlesticks mounted on a light trestle, is shown in Fig 1, viewing them from the audience. The effect of this trick is perhaps enhanced by standing the candlesticks on pieces of newspaper, and covering them with tall glass shades, giving the appearance in a very marked manner of absolute isolation from things surrounding. In addition to this the shades may be covered with silk handkerchiefs or colored scarfs, allowing the candle flame to be seen through the colored silk, as it apparently jumps from one candle to the other, through the glass shades, silk scarfs, and intervening atmosphere. The candles can be made to answer queries, and count out the spots on cards, in addition to numerous other tricks which may occur to the performer.

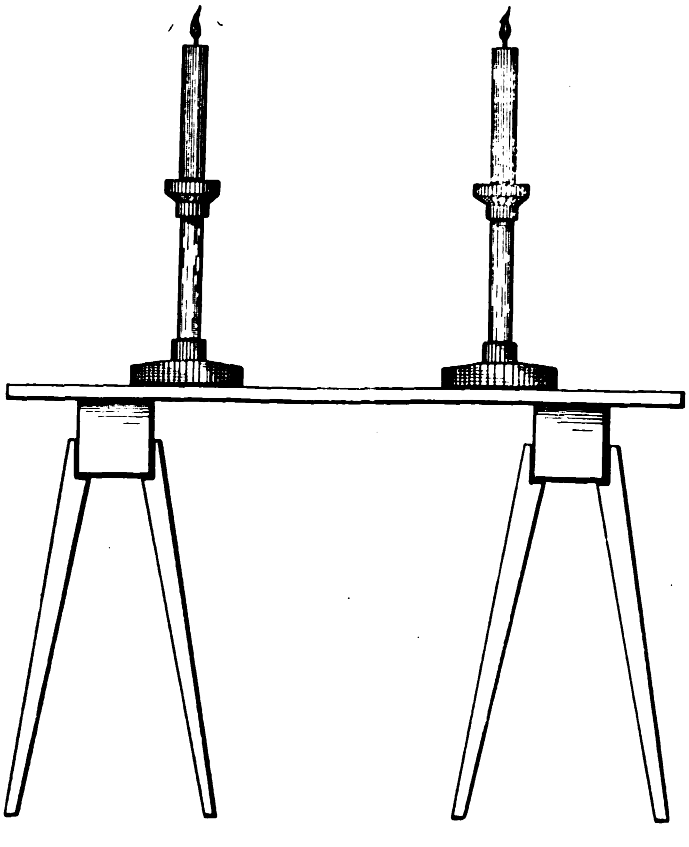

FIG. 1.—MAGICAL CANDLESTICKS.

The supports or stems, of the candlesticks, are made of glass for effect, as they serve to discourage electrical theories as regards the lighting of the candles, and add to the effect of total isolation. These glass stems are very conveniently cut from glass tubing, known to chemists as combustion tubing. This tubing is rather thick, but may be cut, as the average reader doubtless knows, by running a notch around with a sharp triangular file, using turpentine, to promote its biting. The tube is then very easily separated at the file cut, if made sufficiently deep, by pulling on the two pieces in addition to the breaking or bending strain.

A cross-section through one of these candlesticks is represented in Fig. 2. The base, *A*, and the top, *B*, are turned up on the lathe from thoroughly seasoned hard wood, and cemented on the glass combustion tubing. Walnut is an excellent wood for this purpose, if thoroughly seasoned and dry, As the high-tension discharge from an induction coil, or plate machine, is employed to light the tiny gas jet at the candle tip, it will be readily seen how important the matter of insulation is, requiring only the best and driest materials.

The base contains three leaden weights, (two of which are shown in section at *C* and *D* cast in the auger holes, *HH*, to serve as weights and contact plates), the two shown in the sectional view being connected to the ends of the stout wires, *GG*, by casting. Two small gimlet holes, as shown, join the auger holes with the little opening under the glass stem, through which the wires pass.

Two very fine, bare copper wires, No. 36 or No. 40, are soldered to the ends of the heavy wires, *G G*, and carried up through the glass tubing and soldered to the ends of two stout wires, *F F*, which pass through the wooden cap as illustrated, terminating with soldered joints, with the little copper plates, *E E*. The joints of this fine wire soldering should be sponged off with water, if zinc chloride has been used as a soldering fluid, as it would not take it long to corrode the fine wire away if left unwashed. It is next to impossible to detect the presence of these fine wires in the glass stem, even upon close examination, although they are amply large to carry the high-tension current employed.

The copper plates, *E E*, are attached to the inside portion of the wooden cap by soldering on a little sharpened spur in the center, and pressing the spur into the wood. If the inside of this cap is well shallaced, it will tend to hold the plate in place, in addition to adding increased insulation. A little metallic tube, *M*, fits tightly in a small gimlet hole in the wooden cap and is cemented around the joint.

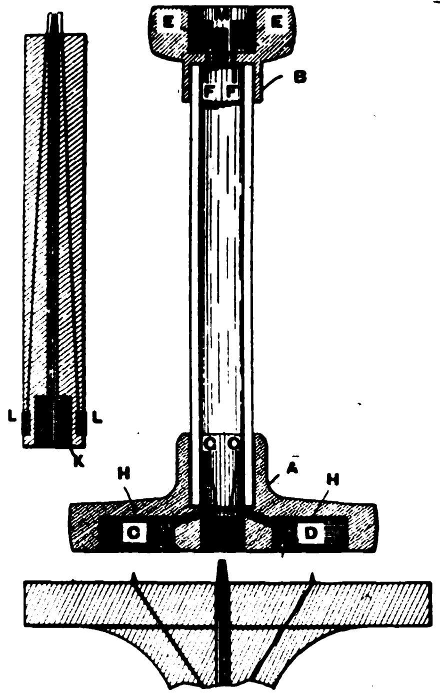

FIG. 2 AND 3.—DETAILS OF CANDLESTICK.

It can now be readily seen how electrical communication is established between the wires and the sharpened points in the little table top, partly shown in section, and the little contact plates in the cap of the candlestick.

By referring to Fig. 3, a section through the electrical candle can be seen. This can be made from a real wax candle, but is much more durable if made from wood and enameled. This also must be of the driest material for the sake of insulation. A tiny brass tube runs through the center, as illustrated, ending in a fine point, or tip, at the top, and terminating in a little auger hole or recess at the bottom, with a soft-gum stopper, *K*, having a tiny hole through its center, pushed in as shown. Two little contact plates, *L L*, are let into each side of the candle after soldering on two fine insulated wires and boring fine holes through the candle, as illustrated.

It is desirable to shellac the covering on these wires before pulling them through, giving them the best possible insulation. The little tip at the end of the brass tube should be blackened to resemble a candlewick, and the fine wires which run to the top must have platinum tips where the wire bends over the tube, in order to stand the heat when the gas is ignited. It will also be evident that the soldered joint must not be very near the flame, as it would be better economy to invest in a couple of inches of platinum wire and have the joint away from the flame, than to have tips that are too near the little gas jet, melting the solder and putting the magical candles out of service. The little plates, *L L*, must be about the size of the ones in the cap of the candlestick, in order to make proper contact, and the size of the candle at the base must fit the candlestick.

Let us now examine the system for the gas supply from the little table, to the tip of the platinum wires. The small brass tube with the tapering point, as fitted to the little round table in Fig. 2, projects about ½ in. above its top, as shown, entering the soft-gum stopper in the recess of the base of the candlestick, when the magician places it carefully on the table. The gas ascends through the glass stem to the cap, and passes through the little brass tube, *M*, with its own tapering point, which in turn enters the soft-gum stopper in the base of the candle.

It is now clear how the electrical connections are established between the sharp points in the table top and the platinum tipped wires at the top of the candle. It will be readily seen that the candlesticks may be lifted up from the table at any time during their exhibition, and the candle taken out in order to impress on the audience that they are only "ordinary candlesticks and candles." It is also very evident that the placing of a newspaper under the candlestick would in no way interfere with the lighting of the candle, as the tapering tube and sharpened points would immediately puncture the paper and make the necessary connections. It should also be observed that the glass shades and colored scarfs have no effect on the working of the trick, as the tiny flame requires but little oxygen, and will burn for a long time under a large shade. Of course, for the sake of the shade it must be large and not come too near the little flame.

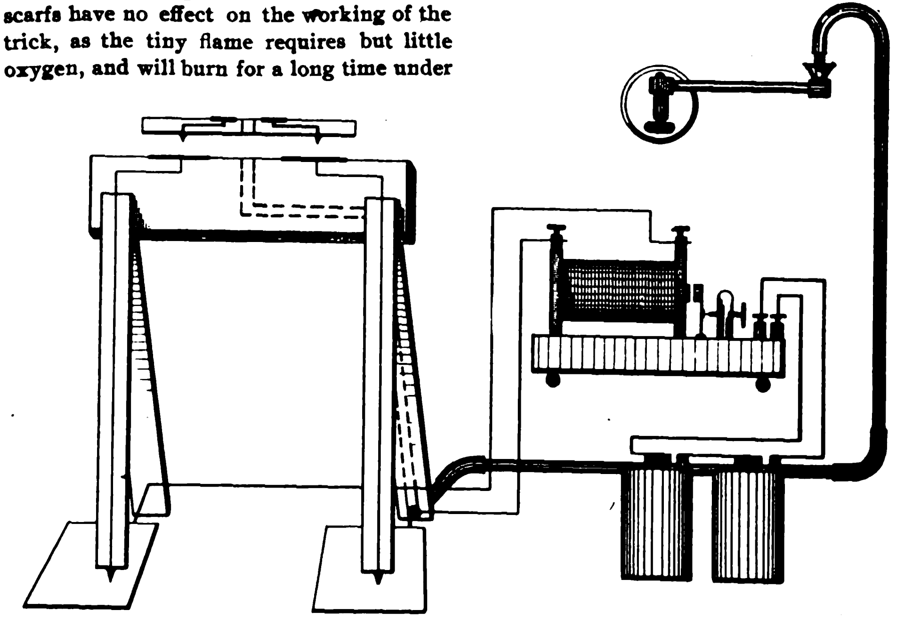

FIG. 4.—CONNECTIONS OF APPARATUS.

These candles with very minute blackened tubes, filed down to the size of mere wicks, with a gentle gas supply, resemble so closely real candles that a distance of only a few feet from the front of a small stage, renders detection very difficult. It is also readily seen that the bottoms of the bases of the candlesticks can be covered by gluing on dark green baize, covering the weights entirely, allowing only a tiny slit for the gas tube to pass through, which allows of the candlesticks being examined very closely if real candles are skillfully put in the place of the electrical ones.

Fig. 4 illustrates the connections for a "doctored" pair of trusses and light board. While small round-topped tables are much easier to equip with the necessary wires and gas tubes, the light board and trusses present, perhaps, a more innocent appearance. This arrangement is shown only as an example, however, for varied means of exhibiting the candles are sure to suggest themselves to any one making the candlesticks and equipping them with the electrical requirements.

The floor-contact plates in this illustration are shown uncovered, but, of course, are worked under a thin carpeting, the sharpened points on the bottom of the truss legs pricking through and making the necessary contact. It is seen that the board in this illustration is also equipped with sharp points which are designed to make contact with little copper plates on the truss. The gas is supplied by a small tube let into a groove in one of the legs and covered with putty and painted over. The leading-in wires from the induction coil must be of the best rubber-insulated type, and the floor-contact plates should have a thin coat of shellac on both sides, relying on the points to cut through the shellac on top in order to make metallic contact. The rubber stopper joint must be duplicated in the board where it rests on the truss and must be fitted with a little tapering tube as described in connection with the candlesticks. An induction coil capable of giving a 2-in. spark is necessary, or else a large plate machine.

In working the trick, the gas is first turned on and regulated from the key at the burner to give the proper sized flame at the "wick." The induction coil or plate machine, is kept running all the time, but at sufficient distance from the audience to prevent the sound from the buzzing of the coil or the running of the plate machine being heard. Having regulated the key at the burner to give the proper pressure, the candles are extinguished by compressing the rubber tube which may be employed to make the gas connections, or in any other convenient manner. With two candles, it is, of course, necessary to have two entirely independent gas supplies and electrical circuits.

To light the candles it is only necessary to allow the gas to flow (provided the coil is in constant operation) by releasing the pressure on the tube. By alternately compressing and releasing the rubber connecting tube, the candle is extinguished and relighted. By equipping two candles with independent gas supplies, and furnishing a thoroughly insulated switch for the induction coil, in order that the same coil may alternately supply the two candles with the electric spark, the candle flame may be made to "jump from one candle to the other." Should these candles fail to work at first, examine the insulation, determine if the induction coil is in good condition, and see where the current leaks away.

If the directions given have been carefully followed the high-voltage current may be made to appear in the form of a useful spark at the tip of the candle "wick." It is always a good precaution to use shellac wherever a high-tension current is employed, as it is one of the most reliable insulating materials. The wooden portion of the candlestick should, for effect, be gilded and given a light coat of protecting shellac.

◆

TESTING DYNAMOS.

MISCELLANEOUS METHODS.

In the previous articles, the most largely used methods of testing dynamos were laid down. There are, however, a number of other methods, some of which are mere modifications of standard ones, in order to allow for the peculiarity of the construction of the dynamos, while others are radically different. Where the machine is very small indeed, the friction of any extraneous device is relatively so large and so difficult to estimate, that tests using such methods will be practically worthless.

One of the most convenient methods for testing the efficiency of a small machine, such as a fan motor, or indeed any machine up to ⅓ HP, is the following:

The machine is mounted with the ends of its armature shaft on the centers of a speed lathe, and is connected to the line center by the ordinary dog and face plate method. The armature being on the centers in the lathe, the field magnet is therefore free to revolve about it, and will naturally fall so that the heavier side will be the lowest. Weights should be attached to field magnets in such a way as to bring its center of gravity in the line of the shaft of the armature, and the position of this weight can be accurately enough estimated, by adjusting it until the field magnet will stay in any position, with reference to the armature shaft.

Such an arrangement is shown in Fig. 1, the tail-stock being removed so as to show it more clearly. If the added weight be of iron, care must be taken to so place it that it does not magnetically short-circuit the field magnet. Lead is the best material to use. Now, if the lathe be started up, the dynamo will begin to generate, and if the wires are connected, it may be loaded to its full capacity, and there will be a strong tendency of the field magnet to turn with the armature, so that it will be necessary to secure it in some way. If we can measure its tendency to turn and also the speed of the armature, we shall have the torque of the machine, from which we can readily calculate the input in horse power.

We may measure the speed by an ordinary speed-counter in the usual way, and the tendency to turn may be measured by the pull which the field magnet exerts. To this end, bolt a small flat lever to some part of the machine and connect it to a spring-balance, as shown, providing also a pointer and scale. From the under side of this arm there should be hung a rod, to the lower end of which is secured a flat disk, very much after the fashion of the weight pan on a set of heavy scales. This disk should be immersed in a circular vessel filled with water, as shown in Fig. 1.

The position of the balance should be adjustable, so that when the dynamo exerts any effort on the weight arm, the latter may be brought back to zero by lifting the spring balance. This may be conveniently arranged by a screw support, or if the machine is a very small one, by means of a cord passing through a pulley and attached to a tackle block. The distance to the point where the spring balance is attached, to the lever from the center of rotation of the system, should be accurately measured.

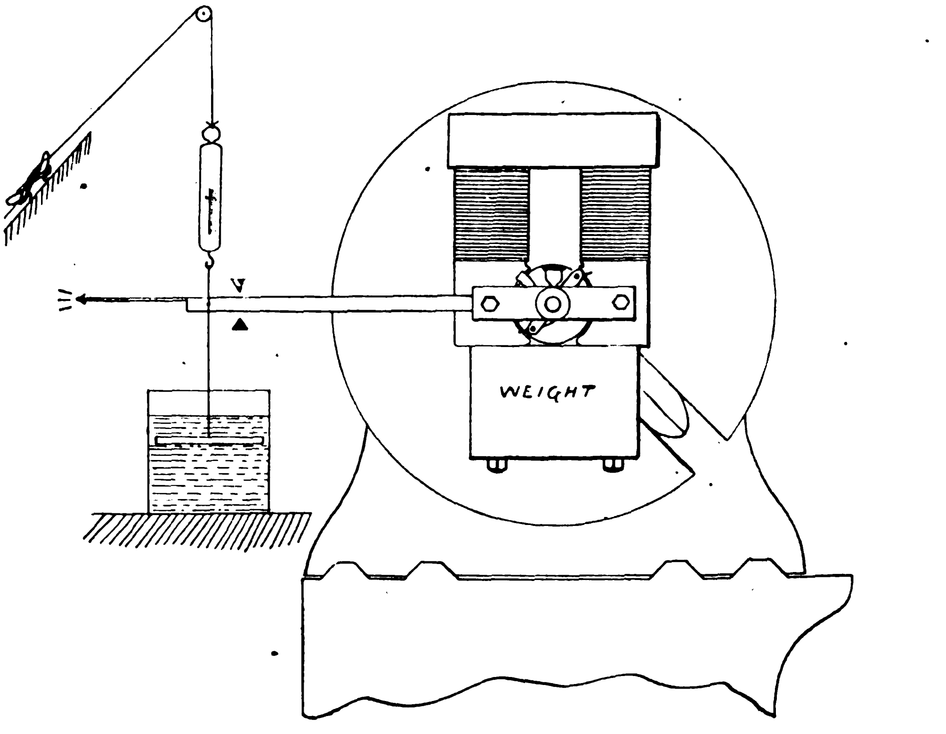

FIG. 1.—TESTING BY TORQUE METHOD.

This may be conveniently done if the lathe has a tool carriage, by placing a pointed tool in the tool post and adjusting the carriage so that the point of the tool is the same distance from the center, as the point to be measured. The carriage should now be longitudinally moved away, and the distance subsequently determined by tracing a light circle on piece of hard wood bolted to the face plate, and measuring the diameter of that circle and dividing by two. A lead pencil may be substituted for the pointed tool, if only soft wood is obtainable. To test the machine proceed as follows:

With the machine at rest, adjust the balance until the pointer of the arm is at zero, and take the reading; then start the machine and bring it up to full load conditions, and adjust the balance by the device provided till the point is at zero once more, and take the new reading of the balance. Measure the current and voltage that the machine is delivering, and having taken a sufficient number of readings for a check and general average, and accurately ascertained the speed, the observations are complete. It will be found that the action of the water dash-pot very much steadies the reading of the balance, without detracting from its accuracy.

The power the machine has received is equal to the pull exerted on the lever, multiplied by the number of feet per minute that the point on the arm to which the balance was attached would have traveled had it been free to turn with the armature. The pull is obviously equal to the difference of the balance readings, and the number of feet per minute is equal to 2π times the length of the balance arm in feet, times the number of r. p. m. We therefore have the foot-pounds per minute or $2\pi L N$, where L is the length of the balance arm, and N the number of r. p. m.; and if we divide this quantity by 33,000, we shall have the HP.

The HP output of a machine may be measured by the product of the volts and amperes divided by 746, and the ratio of the output to the input is the efficiency.

Another method of testing dynamos is illustrated in the diagram (Fig. 2). Its chief interest is its unique character, but the experience of the writer has been, that it is not a very accurate method and is a very troublesome one. The dynamo is surrounded by a box, which is constructed so as to be as nearly as possible an insulator of heat. It is therefore heavily battened with hair felt or woolen blankets. Two tubular entrances are provided in this box, one in the bottom on one side, and one in the top on another. The lower opening is connected by a system of piping to a blower, and thus air can be forced through the box.

The temperature of the air as it enters is taken by a thermometer piercing the pipe and as near to the entrance of the box as convenient, and in order that its indications shall truly represent the temperature, a system of vanes is provided, which is calculated to break up the currents and make the resulting temperature of the entering air more uniform. As it emerges from the upper opening, the temperature of the air is again taken by a thermometer, similar precautions being observed to break up the currents. The volume of air driven through the box is measured by an anemometer. The test is made as follows:

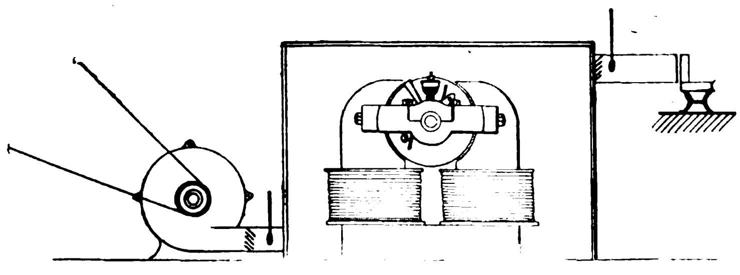

FIG. 2.—THERMAL TEST.

The dynamo is loaded and driven for several hours, until commercial conditions have been attained and the two thermometers have come to rest, the air being forced continuously through the box. The thermometers, the anemometer, the voltmeter and ammeter should now be simultaneously read eight or ten times, so as to get a reliable general average.

From the anemometer reading and the size of the outlet the number of cubic feet of air per minute that has been forced through the box can be calculated. The difference in temperature of the two thermometers shows the degrees the air has been raised, and if we multiply this by the specific heat of air and by the number of cubic feet heated per minute, we shall have the losses of the dynamo in heat units per minute. This gives all the losses. If the thermometers are Fahrenheit thermometers and the specific heat of air used assumes the cubic foot for a unit—that is, represents the quantity of heat necessary to raise 1 cu. ft. of air 1 deg. F.—the result will be in British thermal units, each one of which is equal to 778 ft. lbs. As the result of the observation will be obtained in the British thermal units per minute, it can be easily transformed into foot-pounds per minute, or horse power.

The losses being known and the output, the efficiency is calculated by dividing the output by the output plus the losses.

The specific heat of 1 cu. ft. of air may be taken at .0189 B. T. U., assuming a barometer pressure of 30 ins. Absolute accuracy would demand that this value be corrected, for temperature and existing barometer pressure, and similar corrections would have to be applied to the mechanical equivalent of work 778. The method as a whole is subject to greater inaccuracy than these corrections entail, so that applying them is like measuring distance with a clothes line with a micrometer attachment.

To take a concrete example, suppose that we are thus testing a 20-KW dynamo supplying 180 amperes at 110 volts, an output of 26.54-HP. Suppose that the delivery pipe was 0.25 sq. ft. in area and the anemometer registerd a velocity of 320 ft. per minute. Assume also that the difference in the thermometer readings was 60 degs., 80 cu. ft. of air were therefore forced through the box per minute, and the B. T. U. given to that air equals 80 × 60 × .0189 = 90.72 B. T. U. This is equal to 90 72 × 778 = 70580 ft. lbs. per minute = 2.14 HP, and the efficiency of the dynamo would be, 26.54 ÷ (26.54 + 2.14) = 92.5 per cent.

WORM GEARING AND RAILWAY TRACTION.

It is probable that the principle laid down in this article will be severely criticised, for it is a defense of the method of connecting railway motors to car axles by means of worm gearing. The worm gear is admitted by all engineers to be an uneconomical device, using a great deal of power, but present electric railway traction has demonstrated that there are other considerations besides those of efficiency, and it is the complete realization of these other considerations that makes the worm gear a type that will one day find a much larger use in the traction field.

Had the late Anthony Rackenzaun lived, it is highly probable that we would to-day be much nearer the use of worm gears than we are, for he was their most stalwart champion; his work remains, however, and will undoubtedly have its effect in the future.

The desiderata in a railway motor are: Powerful torque, noiseless operation, light weight, especially that part bearing on the car axle, small cost and low repair bills. Efficiency is a secondary consideration. To gain these other features and that of complete inclosure, the efficiency of railway motors has been sacrificed till it now seldom reaches over 85 per cent., and from that 10 per cent. is absorbed in the gears.

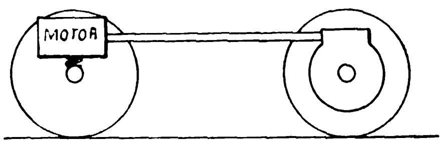
The first and most obvious advantage to be obtained by the use of worm gearing is the possibility of employing a motor of high speed as compared with present practice. High speed means great output with light weight, no matter what the motor. Nothing illustrates this more effectively than the steam turbine. A small steam turbine running at 20,000 r. p. m., having dimensions of less than 20 ins. in diameter and 5 ins. in thickness, can easily exert 15 or 20 HP; similarly, if we can employ a motor running at a high speed, we may expect a much lighter machine for the same power; in fact, with careful design we can almost cut the weight of the present motors in two.

The second advantage we obtain is the very light weight that bears directly on the axles. It is practically only that of the worm, the gear and their housings, which is about the same as the ordinary gear case of a modern motor—a mere fraction of the total weight that the axle supports. Fig. 1 will assist in understanding this. The motor itself can be placed at a considerable distance from the axle; in fact, in the case of a double truck, the motor driving one axle may rest directly over the other, but by a spring support to obviate rigid riding.

The next advantage is a commercial one. Small motors cost less than large ones, and if the money now expended on a large motor was put into one of smaller size and same power, driving a car by worm gearing, a much better motor could be produced. Wrought iron forgings could be afforded for field frames, laminated pole pieces could be used, and everything necessary to produce a strong field and hence a powerful torque. It is probable that the efficiency of the worm-gear motor could be raised to such a point that the tractive pull per ampere would not be such an unfavorable comparison with modern spur gears after all. The motor riding higher than its spur-gear competitors, will not be nearly so liable to be damaged by obstructions in the roadbed.

In action on the road this motor would have a number of advantages. As the worm gear is not a reversible combination, it follows that the car would stand still on a grade without a brake. If the car should get beyond control, it is simply necessary to pull down the trolley and the car would stop, for it could not coast down hill and drive the motor by means of the worm. A band brake applied to the motor shaft would stop the car with an effort that is trivial by comparison with ordinary braking methods; and if the device of short-circuiting the motors on themselves, or an adjustable resistance were used, it would hold the car under more complete control than the same device applied to modern motors.

A single disadvantage, aside from the inefficiency of the device, might be mentioned. If the motor should become disabled, it would be impossible to tow the car without detaching the worm gear from the car axle. This should not be a real difficulty, for ready means for liberating the car axle can be devised.



ARRANGEMENT OF WORM GEARING.

A serious problem in electric railway traction will find a solution in the worm gear. Heavy electric railroading demands motors of such size that they cannot be conveniently installed under the car floor, making recourse to the locomotive an absolute necessity. Two hundred HP seems to be about the limit of the size of motor that can be installed in double equipments on an ordinary bogie truck. The reduced size of the worm-gear motor will enable much more powerful equipments to be placed underneath the car floor, should future traction requirements demand.

The repair bill must be considered. Small motors are easier to repair than large ones and cost less, while in the matter of gearing the worm has another advantage, which is that the worm may be made of bronze, and the gear, which is the more expensive member, of steel; in fact some such combination would be necessary, for rubbing friction now takes the place of rolling friction. The worm has a better grip on its car wheel than a pinion, for it can bear against more teeth, and thus a softer metal will endure, where it would be entirely inadmissible in spur gearing.

It seems to the writer that these advantages are those which are eagerly sought by every railway designer, and for which he has been ever ready to sacrifice a few per cent. in efficiency.

The stock argument that the worm gear has been tried and has not proven satisfactory, is not a valid one. Single-reduction was tried and abandoned in favor of double-reduction, and after a time it again became, first popular and then universal. The worm gear holds out too many advantages to the designer of street railway motors to be relegated to the realms of unsuccessful devices. It will, doubtless, presently be brought forth again, exhaustively tried and, the writer ventures to predict, will succeed. The practical disadvantages which have been urged against it are short life of the worm and great friction. The same argument could be used against the screw and nut for continuously operating mechanical devices, yet Mr. F. J. Sprague boldly solved the problem by a ball-bearing screw. Rolling friction in the case in hand is not an inconceivable device, and it has not yet appeared that it is necessary in worm gearing, for practically no attempts have been made to develop the efficiency of that mechanism.

◆

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

BRANCH TERMINAL MULTIPLE BOARDS.

As was pointed out in the last article, the series arrangement of jacks in multiple switch-boards is subject to grave defects, and does not represent the best practice in telephone exchange working of to-day. The branch terminal system was designed to remedy the defects inherent in the series system and possesses many advantages over it, chief among which are the facts that when a connection is made with any line the balance of that line is in nowise affected, and that the liability of open contacts in the jacks, which is such a serious defect in the series system, does not exist. The branch terminal system, moreover, lends itself more readily to the use of self-restoring drops, as will be described later.

In Fig. 1 is represented one type of the branch terminal system, sometimes called the three-wire system. In this figure three distinct line circuits are shown passing through three sections of board. The wires, k and k', of each line have branch wires leading off to a jack on each board; the branches from wire, k, leading to the contact thimbles, f, and the branches from wire, k', leading to the short springs, c, in the same jacks. Bridged across the two wires of each line is the line coil, n', of the individual annunciator belonging to that line. This coil is high wound in order that it may be left permanently bridged across the line without materially affecting the efficiency of the system in talking.

A third wire, t, passes through the board in parallel with each line. From this wire branch wires are run to the test thimble, g, and to the spring, b', in each jack belonging to that line. The test wire, t, after passing through all of the boards, runs through a low-resistance coil, n_2, on the drop of the line to which that particular test wire belongs, and then passes to ground through a battery, o, common to all test wires. These test wires are represented by dotted line in the figure in order to distinguish them more readily from the line wires. The remaining spring, b, in each jack is permanently connected to a ground wire, G, common to all of the jacks.

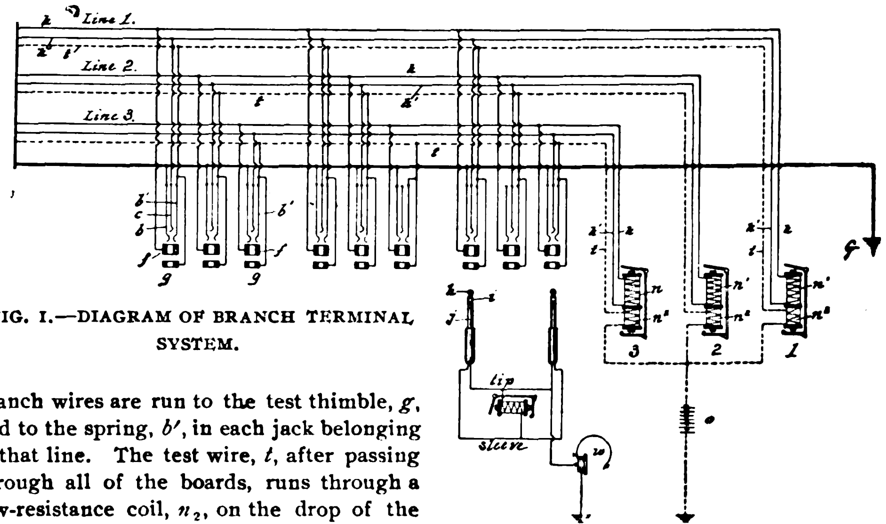


FIG. 1.—DIAGRAM OF BRANCH TERMINAL SYSTEM.

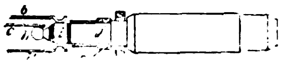

FIG. 2.—PLUG AND JACK.

Each plug in this system is provided with two contacts, h and j, which form terminals respectively of the sleeve and tip strands of the cord circuit. The tip, h, registers with the spring, c, when the plug is inserted into the jack (see Fig. 2), and the sleeve, j, registers with thimble, f. A conducting ring, i, entirely insulated from all other portions of the plug, registers with the springs, b and b', in the jack, and connects them together electrically.

Three general results are accomplished by the insertion of a plug into a jack. The tip and sleeve strands of the cord circuit are connected respectively with the sides, k' and k, of the line, thus continuing the line circuit to the cord circuit. The connecting of springs, b and b', by the ring, i, completes the circuit of the battery, o, through the restoring coil, n_2, of the annunciator, to the ground wire, G, and thus allows current from this battery to energise the coil, n_2, and restores the shutter of the annunciator. Lastly, the connecting of springs, b and b', by the ring, i, connects the test thimble, g, to ground by a short circuit, so that when an operator at any other board touches the test thimble of that line with the tip of her plug, a certain signal is given so that she may know whether the line is free or not.

The test in the particular system shown differs from that described in the last article in that a click on testing indicates a free condition of the line, silence, on the other hand, indicating that the line is busy. In the normal or idle condition of a line, the test ring, g, is electrified to a difference of potential from the earth by the battery o, which finds circuit through the restoring coil n_2, of the annunciator of that line to all the different test rings, g, belonging to that line at all of the sections of the board. If when the line is in that condition the tip of the test plug, which is grounded through the operator's receiver, be applied to the test ring, the circuit will be completed from the test ring touched to the operator's telephone and thence to earth, as is clearly illustrated in the diagram.

At each application of the tip of the plug to the test ring, a click will be produced in the operator's telephone receiver, indicating to her that that line is free and that the plug may be inserted. When, however, the line has been put into use by the insertion of a plug into the spring jack thereof, the springs, b and b', are crossed together by the contact ring, i, carried on the plug, whereby all the test thimbles, g, belonging to that line are connected directly to earth through a short circuit, and therefore no difference of potential exists between them and the earth. Thus, when a test is made on a spring jack of that line there will be no flow of current through the operator's receiver to ground, and silence will be the result. The operator then inserts the plug with which she has been making the test into the spring jack of the line tested, and the connection between the two subscribers is completed.

Fig. 1 is stripped of all unnecessary detail in order to enable the general underlying principles to be more readily grasped. In Fig. 3 the same system is shown more in detail as to circuits, connections and apparatus. Fig. 1 will give the reader a better understanding of how the jacks are grouped into sections, and of the relative location of the parts, while Fig. 3 will enable a better study of the circuits.

In this figure two subscribers, 1 and 2, are shown connected by line wires, k and k', with the exchange. Jacks, l and l', at sections 1 and 2 of the board, are shown in connection to the line leading from Station 1. Jacks, l^2 and l^3, are shown connected at the same sections with the line leading from Station 2. In the line leading from Station 1 is bridged the line coil, n', of the annunciator, this annunciator being placed at Section 2 of the board. The line coil of the annunciator of line 2 is similarly bridged across the two sides of the line, and is placed at section 1 of the board. A little study will show that the circuit of the line wires and the test wires are the same in Figs. 1 and 3, although represented in an entirely different manner. Like letters correspond to like parts in these two figures.

Two pairs of connecting plugs and their accessory appliances are shown complete, one at each section of the switch-board. The tips of the two plugs of a pair are connected together by one of the conductors, q, of the flexible cord, and the sleeves, j, are likewise connected by the conductor, q', of the same cord. Included in circuit between the two plugs of a pair are two callings, r and r', each adapted to disconnect both contact pieces of one of the plugs from those of the other, and to connect them to the wires, s and s', which form the terminal of the calling generator, *P. G.*

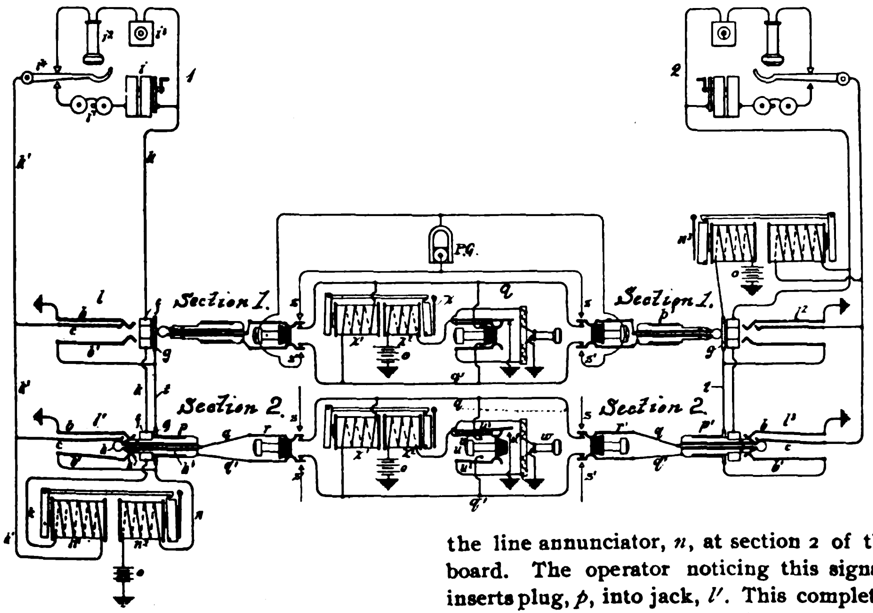

FIG. 3.—DETAILS OF BRANCH TERMINAL SYSTEM.

A listening key, u, is provided for each cord circuit, having contact points or anvils connected with the conductors, q and q', as shown, and having its contact spring, u', and u_2, connected with the terminals of the operator's telephone, w. When the plunger of the listening key, u, is allowed to rise, the operator's telephone is connected in a bridge across the two sides of the cord circuit, as is shown at section 1. A wire is connected from the middle point of the coil of the operator's telephone receiver to ground, so that when a test is made of any line, as was described above, a circuit will be completed from the contact thimble, g, of the jack through the tip strand, q, of the cord circuit, and thence through one-half of the operator's receiver coil to the ground. As this wire leads from the center part of the operator's receiver coil, it may be left connected permanently, as it does not destroy the balance of the line.

A clearing-out annunciator, x, similar in construction to the line annunciator, has its high-resistance coil, x', bridged permanently across the two sides of each cord circuit. The restoring coil, x^2, is connected in a normally open local circuit, including the battery, o, and terminating in the ground on one side, and in a spring, u^3, on the other. This spring, u^3, is arranged in conjunction with the listening key in such a manner that when the key is raised, the spring will make contact with a grounded anvil, d. Thus, whenever the operator listens in on any cord circuit she at the same time restores the clearing out drop if it happens to be down.

In order to give the reader a clearer understanding of the system so far described, it will be well to follow the operation in connecting one subscriber with another. Suppose subscriber 1 desires connection with subscriber 2. He operates his generator, i, and the current therefrom passes over the ine wires, k k', and through the coil, n', of the line annunciator, n, at section 2 of the board. The operator noticing this signal, inserts plug, p, into jack, l'. This completes the circuit from from ground, through battery, o, coil, n^2, of the line annunciator, thence to spring, b', through the ring, i, on the plug to spring, b, and to ground. The front armature of the annunciator is therefore attracted and the drop restored.

The operator then connects her telephone across the cord circuit by raising the key, u, and communicates with subscriber No. 1 in order to scertain his wishes. Having found that he desires a connection with subscriber No. 2 she takes up plug, p', of the same pair and tests to find out whether line No. 2 is not connected to at some other board. If it is not, a current will pass from battery, o, to the test ring, g, on jack, l^3, thence through the tip strand of the cord and through one-half of the coil in the operator's receiver, to ground. This will produce a click, which will indicate to her that the line is free. She then thrusts the plug entirely into the jack, in which position it is shown in the figure, and depresses the key, r', in order to throw current from generator P. G. upon the line of subscriber No. 2.

The two subscribers are now connected for conversation. When either rings off the current passes through the coil, x', bridged across the cord circuit, and actuates the clearing-out drop. The operator, noticing this, again listens in, by raising the key, u, in order to find out whether they are through talking, or whether one of them desires another connection. The act of listening in closes spring, u^3, against anvil, d, and thus restores the shutter of the clearing-out drop. If the subscribers have finished talking, the plugs are removed and placed in their normal resting place.

If, while subscribers 1 and 2 were connected together at section 2, as above described, some one at section 1 had desired connection with, say, line No. 2, the operator at section 1 in applying the tip of her plug, p^2, to the test thimble, g, as shown, would receive no click in her receiver for the reason as pointed out above, that contact, g, is connected to the ground by a short circuit by the plug inserted in jack, l^3. No difference of potential would, therefore, exist between thimble, g, and the ground, and hence no current from the battery, o, would pass through the télephone of the operator making the test.

* * *

VALVE GEARS.

Ever since the first steam engine was built, engineers have met difficulties in getting steam into and out of the cylinder to suit them. To construct a valve gear which will give a perfect distribution of steam and not contain mechanical defects, has proved a very hard problem.

The first steam engine had no valve gear. A boy opened and closed the valves as nearly as he could at the right time, and in providing this sort of a "ready-made valve rigging" the early engine builders escaped a good deal of trouble and worry. It was only after the lazy boy, in order to have more time for play, attached the valve cords to portions of the mechanism which moved in right direction at the right time—it was only then that the woes of the engine builders commenced.

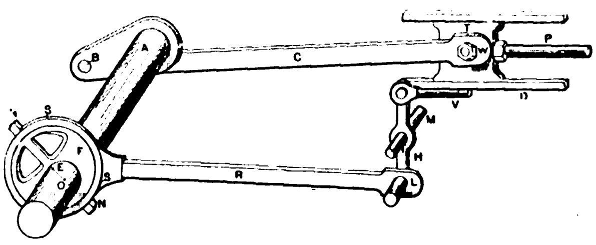

FIG. 1.—THE PLAIN SLIDE-VALVE GEAR.

Then they had to design a valve gear, and the more they designed, the more obstacles came more than half way to meet them. Probably the first attempt was the locating of a center and the forming of another crank on the main shaft for the purpose of operating the valve. This called for two cranks, and evolution enlarged the valve crank-pin until it would slip on over the shaft, thus forming an eccentric, instead of a crank, somewhat as shown in Fig. 1.

This diagram shows about all there is to a plain slide-valve gear. The rocker arm is not necessary except to bring the valve connection into the plane or level of the shaft. The great objection to this form of gear, aside from the trouble of obtaining an economical cut-off and consequent expansion of the steam, lies in the angularity of the connecting rod and valve stem, which, if less than forty times the eccentricity, will so distort the movements of valve and piston, that steam cannot be cut-off at the same point during both the out stroke and the return stroke of the piston.

A valve rod could be made 80 ins. long for an engine of 12-in. stroke, but how would the builder manage to arrange a connecting rod 20 ft. long? That problem has not been solved yet, and therefore the angularity of the rod and stem still disturbs steam distribution in our engines.

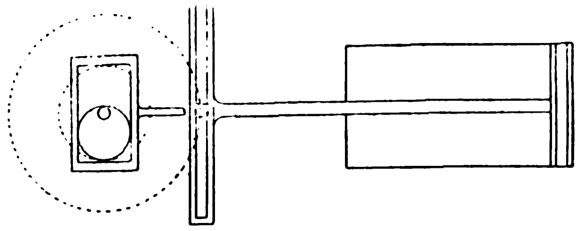

FIG. 2.—A PERFECT MOVEMENT GEAR.

There is a way whereby the above noted errors can be obviated, and that is by the use of the slotted cross-head, as illustrated by Fig. 2. With this form of connection, the valve can be made to cut off at half stroke, at both ends—something which the ordinary slide valve will not do, owing to the angularity of the rod.

A much more modern, and a better rig also, is illustrated by Fig. 3. This is the typical wheel-governor valve gear, with the exception that this shows still another variation from the average, in that the valve contains a cut-off inside, which is operated by a twisting action of the valve stem through the action of the governor.

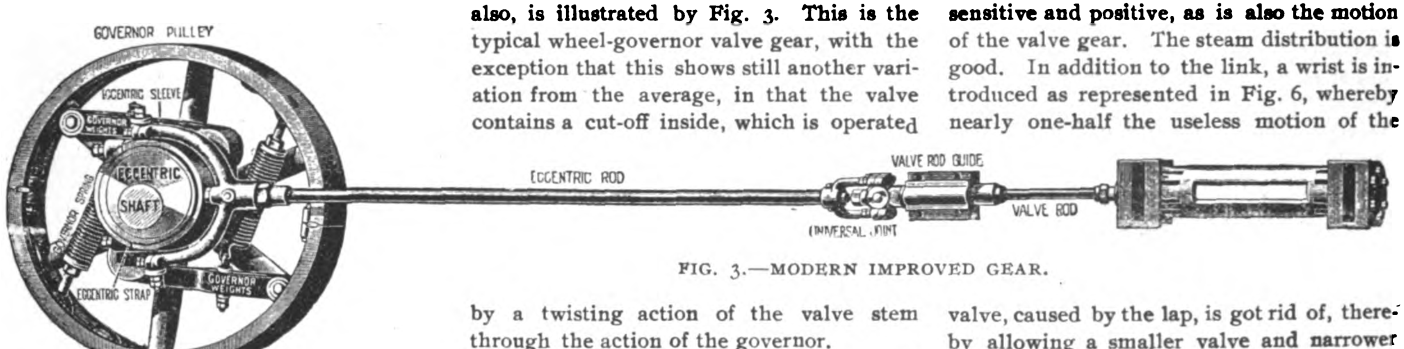

FIG. 3.—MODERN IMPROVED GEAR.

The link motion shown by Fig. 4 is still the most common form of valve gear in use when the engine must reverse. It is merely two eccentrics so set that one will drive the engine ahead, the other drive it backwards. By shifting either the link or the block, the engine is driven either forwards or backwards, at will. Cutting-off is done by shortening the stroke of the valve, which takes place as the block is placed in a central position, as in the engraving. Then there is little movement of the valve in either direction; hence the engine cannot run at any speed.

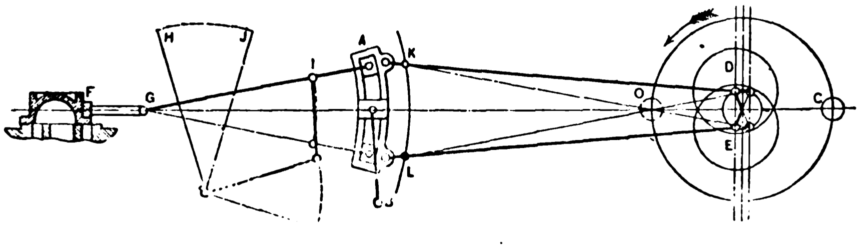

FIG. 4.—ACTION OF THE LINK.

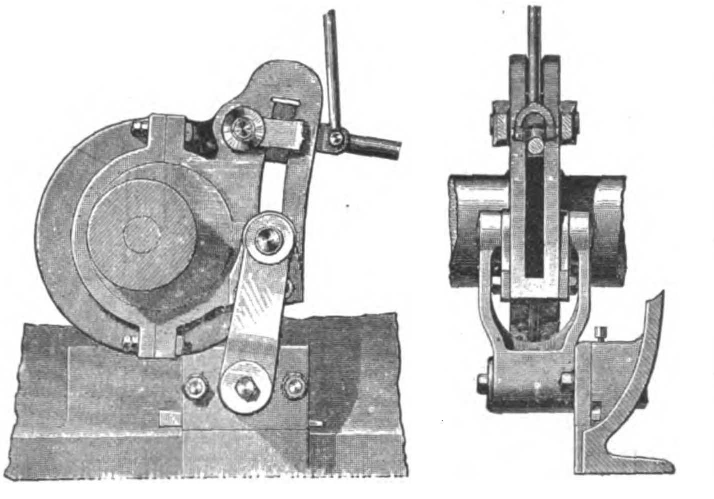

FIG. 5.—A POSITIVE, EQUAL-MOTION GEAR.

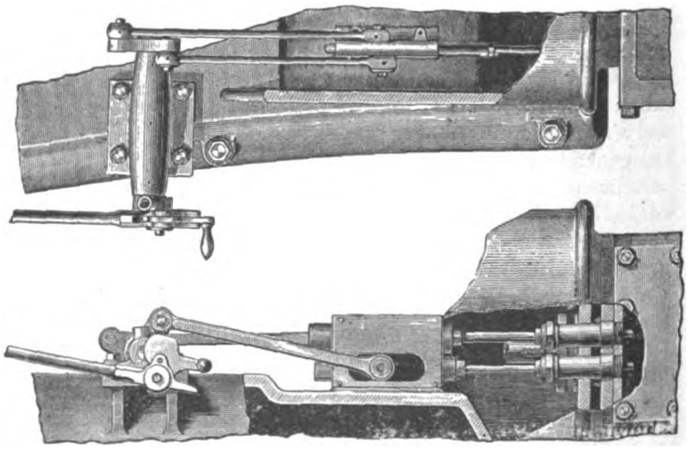

FIG. 6.—DIFFERENTIAL MOVEMENT FOR CUT-OFF.

In this form of valve gear, complications arise in connection with the angularity of the rods, and the lead of the eccentrics. But the shifting link has been applied to counteract the error in distribution occasioned by the angularity of the rod, etc. In the form shown by Fig. 5, it was applied to the first of the modern high-speed engines, and used in connection with four valves to the same cylinder, an efficiency was obtained approximating that of the Corliss-engine form of distribution.

In the engraving, the position of the link shown is adjusted by the direct action of a very heavy governor, which is possessed of great power through its weight and high rotative speed, thus making the governing sensitive and positive, as is also the motion of the valve gear. The steam distribution is good. In addition to the link, a wrist is introduced as represented in Fig. 6, whereby nearly one-half the useless motion of the valve, caused by the lap, is got rid of, thereby allowing a smaller valve and narrower seats.

The valve is driven positively, with uniform precision on both strokes, making it impossible for any irregular motion to occur, and the velocity of the closing, as well as the opening of the valves, increases directly with the speed of the engine. It will be noted that a detaching valve—like that of the Corliss type, for instance—would close no quicker when the engine was running 100 r. p. m., than when it was running at 50. The later the cut-off, the swifter the motion of the valve, and the quicker it closes—something not accomplished by almost any other valve actuated by a single eccentric. Not only is this valve thus actuated, but the cut-off is also worked by the same eccentric also.

Provision is also made for detecting and stopping any leakage, and the valves can be adjusted and made tight whenever necessary. A peculiarity of this valve gear is that it secures, at the end of each stroke, a compression that completely fills the end clearance in the cylinder, no matter what power the engine may be called upon to develop. Considered from all points, this valve gear is one of the most, if not *the* most remarkable in use upon steam engines.

A modification of this gear, using the same link and governor, is shown by Fig. 7. The end sought here is to apply the movement already described, to the operation of ordinary rotary valves of the Corliss type, whereby separate valves at each "corner" of the cylinder may be operated with all their own advantages, together with those of the positive distribution which have been described above.

By the action of the forked levers seen at the right of the engraving, and marked W_1, the valves are made to suddenly catch and spring open, closing again immediately, in something of the same manner that a snap switch used for turning on electric lights, is worked. In both, much the same action is followed: The pressure is put on the valve or switch, as the case may be, and the action takes place in an instant, doing all the work quickly, and lost motion during the rest of the movement caused by the eccentric, serves to let the lever follow the movement of the valve rod, and be in position to make another snap movement of the valve at the instant demanded by the governor.

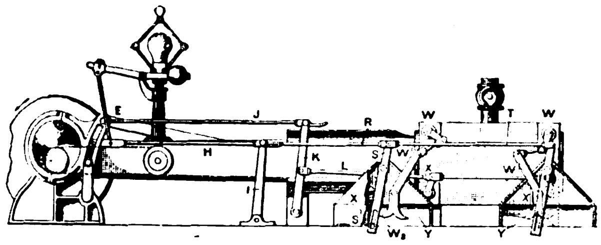

FIG. 7.—EQUAL CUT-OFF WITH CORLISS VALVES.

* * *

English Conservatism.

The question, Are tramways a nuisance? is not, an English mechanical contemporary ventures to think, an unnecessary one. Nearly every cyclist—if not all—would vote, it says, for their abolition if possible, and most of those who have carriages would do the same. As an example of the evils entailed, it is related that "the other day the Earl and Countess Spencer had a narrow escape, by the wheel of their carrirge being forced off by fowling the tram lines when being driven into Northampton." This incident, it appears, has aroused British public opinion, which asks, "what will be the chances of a safe journey through our streets when they have a network of overhead wires, together with their supports." Our contemporary adds that one way out of the difficulty is that offered by the motor car, "which is quite independent of rails, carries its own supply of energy, and is consequently independent of the trolley wire." It is not surprising that among a people so conservative, when the electric railway is by the force of circumstances imposed upon them, their engine and dynamo builders are found unequal to the occasion, and the greatest export machinery manufacturing country in the world has to send to America for its power house equipments.

LESSONS IN PRACTICAL ELECTRICITY

INDUCTANCE AND CAPACITY.

To illustrate the principles relating to inductance and capacity developed in the several preceding lessons, some problems will be solved which are not without practical interest. Indeed, we know of nothing that would be more instructive to those interested in alternating currents, particularly central-station superintendents, than to make an apparatus after the indications that will be given in this and the following article. Besides being instructive, such an apparatus would make an excellent exhibition piece, for to the lay mind most striking paradoxes would be presented in the various combinations that may be made with it.

It will be assumed that we have access to a 100-volt, alternating-current circuit with a frequency of 133, or about 16,000 alternations per minute. In a given case the frequency may be obtained exactly by taking the speed of the alternator; the number of r. p. m. found, multiplied by the number of poles, will give the number of alternations, and these reduced to one second and divided by two will give the frequency.

In Fig. 1, a 50-volt incandescent lamp is shown in series with an inductance, consisting of an iron core wound with wire. If the lamp is of 50-watt efficiency at normal voltage, it will take 1 ampere at normal candle power, and from Ohm's law we see that this corresponds to a lamp resistance of 50 ohms. Assuming that .7 ampere flows in the circuit, we will proceed to calulate the value of the inductance.

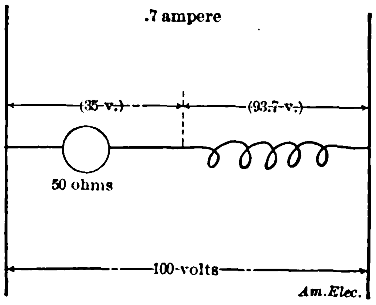

FIG. 1.—LAMP AND INDUCTANCE IN SERIES.

Since .7 ampere is flowing, this will produce a drop of $.7 \times 50 = 35$ volts in the lamp.

Referring to our inductance triangle (Fig. 2), $B\,O$ is the free E. M. F. just calculated, and $A\,B$ the impressed E. M. F. or the voltage of the circuit. Therefore, $A\,O$ or the inductive E. M. F., is $(100)^2 - (35) = (93.7)^2$ volts. Instead of assuming the current, a voltmeter might have been connected across the terminals of the inductance, which would at once have given the inductive voltage of 93.7 above calculated.

To find the value of inductance in henrys corresponding to the above E. M. F., we divide 93.7, first by $\frac{\pi}{2}$, in order, as explained previously, to bring the sine-wave alternating current to the terms of a uniformly varying current; second, since there are $4\,n$ variations per second, we further divide by 4×133; third, since the current is .7 amp. while the definition of the henry refers to 1 ampere, we divide finally by .7. Performing these various operations, we get for the value of inductance, .160 henrys.

The same result might have been obtained by substitution in the formula $E = 2\,\pi\,n\,L\,C$, where n is the frequency, L the henrys, C the current and E the inductive E. M. F.; or by substitution in the formula

$$E = \frac{2\,\pi\,n\,L\,C}{1000} \qquad (1)$$

if we wish the result to be in millihenrys or thousandths or a henry. As inductances usually are smaller than a henry, we will adopt the latter formula, which gives us the value of 160 millihenrys.

Taking up capacity, Fig. 3 represents a 50-volt lamp in series with a condenser on a 100-volt alternating circuit having a frequency of 133, the current flowing being 4 ampere.

Proceeding as before, the free E. M. F. will be $.4 \times 50 = 20$ volts, and we find from our capacity triangle (Fig. 4), that the capacity E. M. F., $o\,a$, is 98 volts. As in the previous case, instead of assuming the current, a voltmeter might have been placed across the terminals of the condenser, in which case the voltage of 98 would have been obtained direct.

We will obtain the capacity of the condenser in terms of microfarads, which is the commercial unit, there being 1,000,000 microfarads to the farad. That is, 1 ampere in one second would charge a microfarad condenser to 1,000,000 volts.

As the current is alternating, to reduce it to the terms of a uniform current we must multiply .4, as explained in a previous article, by $\frac{2}{\pi}$; second, as there are $4\,n$, or 4×133 charges and discharges per second, $1{,}000{,}000 \times .4 \times \frac{2}{\pi}$ must be divided by this quantity; third, as the capacity voltage is 98 and not unity, as required by the definition of the microfarad, a further division by 98 must be made. Performing these operations we find the capacity of the condenser to be 4.88 microfarads.

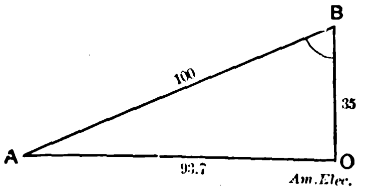

FIG. 2.—INDUCTANCE TRIANGLE.

This result could have been arrived at direct by substitution in the formula

$$E = \frac{1{,}000{,}000\,C}{2\pi\,n\,K}, \qquad (2)$$

in which K, is the capacity of the condenser, E, is the inductive E. M. F., C the current, and n the frequency.

The capacity above found is somewhat large to produce, requiring about 700 sheets of tin-foil 6 ins. square. The inductance is also somewhat large, requiring possibly in the neighborhood of 1500 turns of conductor on a core, 1 in. in diameter, of soft-iron wire.

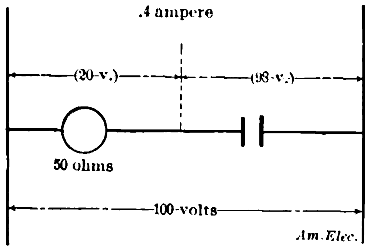

FIG. 3.—LAMP AND CONDENSER IN SERIES.

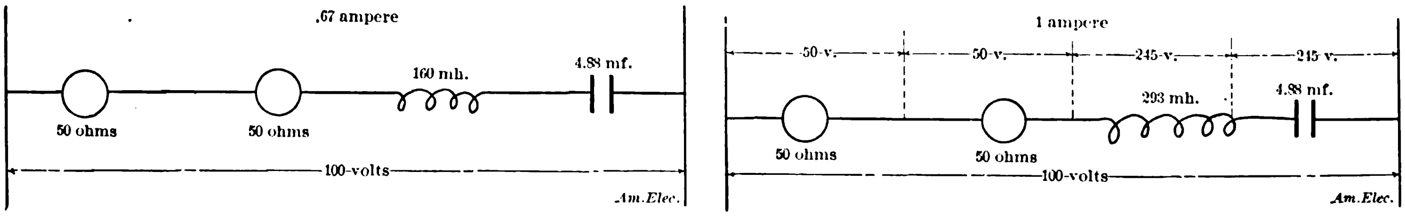
We will now see the effect of placing two 50-volt lamps in series with both the above inductance and capacity, as shown in Fig. 5. Assuming that 1 ampere flows, the drop through the two lamps in series will be 100 volts, which will be the perpendicular in the triangle (Fig. 6). The inductive E. M. F. for 1 ampere may be found by substituting in formula (1); or it will be greater than in the case of Fig. 1 in proportion to the currents, or as 1 : .7; calculating by either of these methods, we find that the inductive E. M. F. will be 134 volts.

Similarly, the capacity E. M. F. for 1 ampere may be found from formula (2); or it will be greater than the 98 volts found in the case of Fig. 2, in proportion to the respective currents or, as 1 : .4. Calculating by either of these methods, we find that the capacity E. M. F. will be 245 volts.



FIGS. 5 AND 8.—TWO LAMPS, INDUCTANCE AND CONDENSER IN SERIES.

It has previously been shown that the E. M. F. generated in a condenser is directly opposed to the E. M. F. generated in an inductance. In Fig. 6, if *oO*, represents the capacity E. M. F., we subtract from it *AO*, the inductive E. M. F., which gives a resultant of *oA* or 111 volts. Solving the triangle which results, we find that the impressed E. M. F. is 149 volts. The voltage of the given circuit, however, is only 100 volts, and therefore the current passing through it will be reduced in the proportion 144 : 100, and will therefore be .67 ampere.

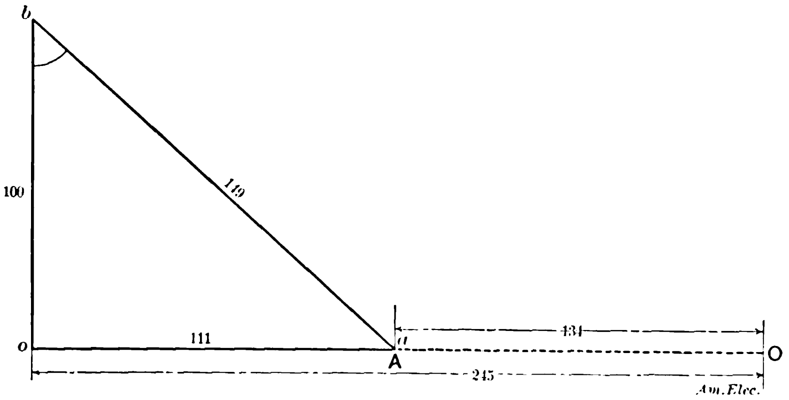


FIG. 6.—INDUCTANCE AND CAPACITY DIAGRAMS.

That is to say, with two lamps, the inductance and capacity all in series, the current flowing (.67 ampere), will be very little less than in the case of one lamp and the inductance in series (.7 ampere), and considerably more than in the case of one lamp and the condenser in series (.4 ampere).

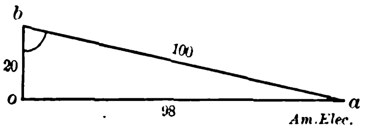

FIG. 4.—CAPACITY TRIANGLE.

It will be seen that this follows from the fact that part of the capacity E. M. F. opposing the impressed E. M. F. in Fig. 4, is nullified by the inductance. If the inductance were the greater factor, then part of its E. M. F. would be nullified by the capacity, the difference being that in the first case the current leads the impressed E. M. F. and in the second case it lags behind this E. M. F. It will thus be seen that if the inductance and capacity are such that one directly neutralizes the other, the circuit will act as if neither was present in it. We will illustrate this by an example.

In Fig. 7, suppose the inductance is such that if a voltmeter is placed across it the same voltage will be indicated as across the capacity in Fig. 2—that is 98 volts—when a current of .4 ampere flows.

The inductance corresponding to 98 volts may be calculated from formula (1) by submitting .4 for *C*, 98 for *E* and 133 for *n*; this gives us as the value of the inductance, 293 millihenrys.

Since now the inductance and capacity give the same E. M. F.—98 volts—for .4 ampere, they will also be equal for 1 ampere; and as they are opposite in direction the one will nullify the other.

Referring to Fig. 7, since the capacity and inductance are nullified, the current will flow which corresponds to the two 50-volt lamps in series on a 100-volt circuit, or 1 ampere. Since with .4 ampere the inductive and capacity E. M. Fs. are each 98 volts, for 1 ampere they will be increased in the proportion of 1 : .4, and will thus become each 245 volts.

We now have the very curious anomaly that whereas when a condenser and one lamp were in series on a 100-volt circuit, as in Fig. 2, only .4 ampere flowed; yet in Fig. 7 with two lamps and an inductance in series with the condenser, 1 ampere flows. The voltages in circuits are 50 volts for each lamp, 245 for the inductance and 245 for the capacity, the two latter, however, being nullified in the same manner that the E. M. F. of one series of primary cells placed in a circuit may be nullified by another series of cells of the same number, but connected in opposition.

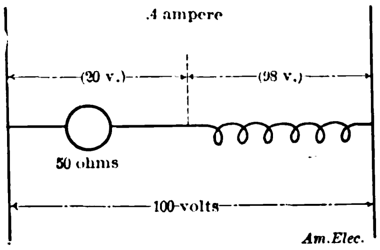

FIG. 7.—LAMP AND INDUCTANCE IN SERIES.

Some further paradoxes will be developed in a succeeding article on capacities and inductances in parallel. In the mean-time, should any reader having access to a 100-volt alternating current wish to construct an apparatus to show the above effects, he may do so from the following indications:

First, make as large a condenser as is practicable. If much smaller than the one above calculated, there will be the disadvantage that when in series with a single lamp the filament will not glow; in addition, the smaller the condenser, the greater stress will its insulation have to withstand. Having made the condenser, place it in series across the alternating-current circuit with two 50-volt incandescent lamps, and with a trial inductance coil. The latter may be constructed by winding, say, No. 18 to No. 22 wire on a core, 1 in. in diameter made up of soft-iron wire. For a coil of 300 mh. not far from 2000 turns of wire will be needed.

With an alternating-current voltmeter measure the voltage acoss the terminals of the coil and also across the terminals of the condenser. If the former voltage is greater or less than the latter, add or substract turns from the coils until the voltages are equal.

In all the above cases, the resistance of the inductance coil has not been taken into consideration, for the reason that in any practical case it would only affect the value of the inductive E. M. F. by a fraction of a volt, and that of the lamp by only 3 or 4 volts, if No. 22 wire is used, and much less, of course, for No. 18 or 20 wire. This fact is of significance in showing how slight a factor ohmic resistance is in gas-lighting and induction coils, the drop from it being there usually entirely overshadowed by the inductive drop, so that the E. M. F. to apply depends practically on the inductance and not thetresistance.

Letters on Practical Subjects

One Way of Connecting up a Meter.

To the Editor of American Electrician:

Having run across a curious wiring combination, I thought it might interest some of your readers to know how lighting companies are sometimes cheated out of the proper amount of their bills by careless wiring and a lack of knowledge of electric circuits.

I had for some time thought that the bills for a certain hotel were too small for the amount of light that was being used, so I had the meter taken down and tested, but found that it registered correctly. I then began to look elsewhere for the trouble and found it. I discovered the building was being fed by a 100-light, three-point transformer, it having been installed shortly before I took charge of the company, and happened to be the only transformer of the kind in town.

This is where the trouble proved to be, for they had wired the house on two circuits, using the middle leg of the transformer as a common return for the two, and had placed the meter, which was an ampere-hour instrument, on this middle leg.

Taking the Edison three-wire system as an example, it is, of course, well known that if the system is evenly balanced by an equal number of lamps on each side, no current will flow over the middle or neutral wire; and if unbalanced, only that amount of current passes over it back to the dynamos, which is due to the difference in load on the two sides. In the case here mentioned, if the two circuits in the house had the same number of lights on each, there would have been no registration of the meter; but it so happened that the down-stairs circuit had the larger number, and the difference between the two was the amount registered. The remedy, of course, was to place a meter on each of the two outside legs.

Durango, Col. R. H. STERLING.

Principle of the Wheatstone Bridge.

To the Editor of American Electrician:

Your explanation of the principle of the Wheatstone bridge, in the December issue, impressed me as being very ingenious and easily understood. I recently had occasion to demonstrate the working of a bridge to a pupil who was especially hard to convince, and did not even see the matter clearly with your diagram before him. To make the matter still more plain to him, I connected an ammeter into each arm of the bridge, together with the resistances there marked, and he saw the actual indication of the passage of current as the several resistances determined their flow. He had no further trouble in understanding the matter. GEORGE EASTLAKE.

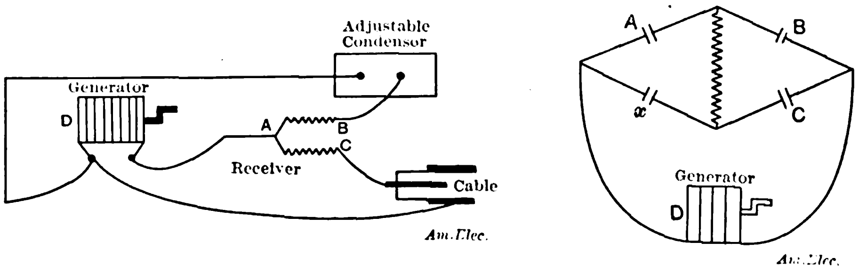
New Brighton, S. I.

Measuring Capacity.

To the Editor of American Electrician:

Would some of the readers of your valuable paper give their opinion as to the feasibility of the following scheme for measuring capacity. As I am not in possession of an adjustable condenser, I never had a chance to try it. The following instruments are needed: 1°. One telephone generator (or an alternating current). 2°. One telephone receiver with two coils of exactly equal resistance and ampere turns and highly insulated from each other. 3°. One adjustable condenser.

The two windings of the receiver are connected up so that no sound will be heard if the current strength from *A* to *B* (in Fig. 1) is the same as from *A* to *C*. It is evident that if you adjust the condenser so that no sound in the receiver is heard the reading on the adjustable condenser will show the capacity of the cable.



FIGS. 1 AND 2.—MEASURING CAPACITY.

I believe an arrangement similar to the Wheatstone bridge could be made, by substituting for the battery an alternating-current generator, and for the galvanometer a regular telephone receiver and condensers for the resistance coils. The connections are shown in Fig. 2, in which *A* represents the adjustable condenser; *x* is the unknown capacity; *B* and *C* are the "short arms" of the bridge—of course, also condensers; *R* is the telephone receiver and *D* is the electrical source. HENRY P. J. VAN DETH.

Montclair, N. J.

A Generating-Room Signal.

To the Editor of American Electrician:

In a certain isolated plant with which I at one time had a good deal to do, there are numerous circuits which carry very heavy loads. One of these supplies a very large auditorium which is most abundantly lighted —in fact, 1200 amperes are required for this purpose.

Unfortunately for the arrangements of the engineer, it is the proprietor's pleasure to go into this reception room at unseemly hours with parties of chosen friends, and throw all of the switches to exhibit the lighting of the hall—a natural enough desire in gratifying his personal pride, but one which creates consternation in the engine room whenever it is consummated. It was finally decided that some communication must be had with the engineer before inflicting him with a load of 240 HP without his knowledge, and a telephone was suggested. The necessity of this expense was averted, and a very much simpler device was substituted, which performed the office of notifying the engineer that it was desirable to have the auditorium lighted, without causing the slightest inconvenience to whomever turned on the lights in that apartment.

The circuit-breaker in the engine room which controlled that circuit was left open, and its jaws were bridged by a red incandescent lamp. The result of this is easily seen. When the proprietor's vanity was such that it required a little electrical display to tone it down, and he stepped into the auditorium and began to throw switches, the red lamp in the engine room would light, but the lights in the auditorium would not. The engineer seeing the light, knew that power was required on that circuit and could cast an eye about his station to see whether or no he had sufficient machines to meet the load, and having arranged matters to his satisfaction, could close the circuit in the usual manner. This device did not cost in toto more than $1, it can never get out of order or repair, and has proven so satisfactory, that I believe that some of your readers might like to apply it in similar places. R. L. BROWN.

New York.

Magneto for Firing Fuses.

To the Editor of American Electrician:

Referring to the letter from R. H. Sterling in the January issue, I wish to state that the method of connection and the form of switch illustrated with his letter, are the same as those used in the magneto described in my November letter, but it would not work. When the rack plunger was descending with the magneto short-circuited, it required a very great power to operate the instrument, the magneto seeming to be under a very great back-pressure, but when the switch was opened, the fuse would not go off.

The magneto seemed to be larger than that used in a similar machine with which I have exploded a dozen caps in series at once.

And it was a magneto, pure and simple, not a constant-current generator as Mr. Sterling describes. It was wound with No. 34 silk-covered wire, and seemingly the machine was as able to do the work as was the "store" machine, which was in daily use. Thus far, none of the replies to my November letter have helped me out.

I desire to thank Mr. A. W. Lee for the neat solution of the three-wire, two station circuit problem. His scheme for the control of lamps on a three-wire circuit fills the bill fully, as far as the requirements of the problem are concerned, but would the inspector of an insurance company permit the third wire to be run direct as in the sketch (January, page 38), and remain alive at all times, whether the lamps were in use or not?

It seems to me as if the inspectors would require that the third wire should run through the switches also, something which could doubtless be easily managed by using three instead of two-pole switches. I do not contend that this arrangement would be any better than the one given by Mr. Lee, which seems to do the work properly, but the inspectors require many things which practical people do not expect. They are in business for the elimination of possible risks, and all honor to their profession, but disgrace be the lot of the inspector who orders fool changes simply for the purpose of showing his authority.

Brooklyn, N. Y. JAMES L. FRANCIS.

Electrical Sport—Fun with the Boss.

To the Editor of American Electrician:

I note with interest the remarks of Mr. Jos. H. Smith, in regard to "Electrical Sport," and also notice his delicately implied hint to "take some one of your size." It is always the safest to use humble means for our fun, but if, as Mr. Smith intimates, the bigger the game, the greater the sport, he could probably have much more fun with the manager or superintendent, than with anybody else connected with his environment.

To "have some fun" with "the old man" it is only necessary to doctor one of the incandescent lamps in his office. Any broken lamp will do, the filament being carefully removed through a hole cut in one side of the globe. A piece of fine wire is carefully attached to the stubs of the filament connection, forming a wire loop in the globe. Let the wire loop be long enough to reach to the side of, and lie against the bottom part of the lamp globe when in place.

Put two or three teaspoonfuls of magnesium powder, such as used by photographers for taking flashlight pictures, in the lamp, and make sure that the wire loop lies in the powder when the lamp is in place in the Super's room. Rig an electro-magnet to a camera in such a manner that when the lamp is turned on, current will pass through the magnet, and spring the shutter of the camera. Place the camera on some convenient case or cabinet in the office, and focus it on the space a man would occupy when he is in the act of turning on the doctored lamp. If the camera can be outside the office, and command a view of the interior through some convenient hole, so much the better.

If carefully prepared, the apparatus noted above will secure a photo of the manager, in a most unstudied pose, and full of life and vigorous action. It might not be safe to immediately show the negative to the honored victim of our sportive proclivities unless some other situation was immediately desired. T. L. JOHNSTON.

Chicago, Ill.

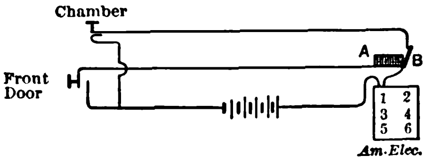
An Electric-Bell Arrangement.

To the Editor of American Electrician:

Here is something new to me, and perhaps may be of interest to your readers, as other things in your correspondence column have been to me.

A prominent physician in this town recently leased a house which was fitted with a six-point annunciator, which had been wired before the house had been lathed and plastered. The drops were connected as follows: Front door, side door, dining room, library, front chamber and north chamber.

Having frequent night calls, he was desirous of a bell in his chamber from the front door, but the owner of the house would allow no wire to be run. He, therefore, wished the annunciator push removed into his chamber and a bell attached to the wires and so arranged as to ring from the front door push.



ELECTRIC BELL ARRANGEMENT.

It was at first pronounced impossible, but I accomplished the result in the following manner:

A is a small coil with swinging armature; *B* is a pin to which the wire that formerly ran to No. 6 in annunciator is attached. When the front door push is pressed, *A* draws its armature to *B*, but the vibrator in the annunciator causes the armature of *A* to vibrate, as they are in series, which causes a current to flow to the bell substituted for the chamber push-way, but is broken as often as the vibrator in the annunciator acts. Thus with a single-stroke bell in the chamber, both annunciator and bell vibrate in unison. Five cells of battery only were required. ROY J. TOMPKINS.

Janesville, Wis.

Behavior of Dry Cells.

To the Editor of American Electrician:

Will some of your readers rise to explain the working of some dry batteries that behave as follows: They are of the Crosby type, and I have sixteen of them, and when attached to a voltmeter each gives a deflection of a trifle over 1 volt. When connected in series, eight will give only 5½ volts. I obtained the cells for the purpose of the experimental working of a new sysrem of duplex telegraphy, and working through a certain resistance with six cells, it was necessary to obtain twice the current.

To do this, I connected up twelve of the dry cells in series, but the experiment failed miserably. It was after this occurrence that I attached the voltmeter to eight of the cells, as above described. Can some one among your readers rise to explain this discrepancy? The connections between the cells are large No. 16 wire, and they are very short. The current from the eight cells is a little less than ½ ampere, and the current from a single cell is a trifle more than ½ ampere.

Philadelphia, Pa. N. T. JARVIS.

Electrical Sport.

To the Editor of American Electrician:

Some electrical sport which we have not seen mentioned in the AMERICAN ELECTRICIAN was tried by us some time ago with considerable success.

A large kerosene lamp was emptied of its contents, cleaned and fitted with an incandescent lamp. The whole was placed on a table in front of a parlor window, so as to appear as if it had been upset, the white shade concealing the incandescent lamp from view from the street. The concealed operator made and broke the circuit with a rapid, irregular motion, producing the effect of a flickering, sputtering kerosene lamp, perhaps about to explode.

An acquaintance of ours, passing by, saw it, and in evident alarm sprang to the door and, ringing the bell violently, hastened to apprise us of the danger. We had a good laugh at our friend's expense, who, however, joined in as soon as he understood the joke.

On another occasion, the same lamp was used temporarily to light a hall organ, where it was placed in an inverted position, producing at first sight a rather striking and ludicrous appearance.

Berkeley, Cal. CLARK BROTHERS.

Magnetizing Galvanometer Needles.

To the Editor of American Electrician:

In the description of the Thomson astatic galvanometer, as given in the January issue of this journal, I am impressed by the amount of apparatus made necessary for magnetizing the needle. The method there described seems to be to carry with it a large amount of mechanical (or electrical) "red tape," and I am at a loss to understand why a much more simple method would not answer equally as well as the elaborate one described, and illustrated by Fig. 12, page 28.

I will state that in magnetizing needles for several astatic galvanometers—in fact, for the same ones described elsewhere in this issue—I used a simple coil of No. 16 wire, containing about fifty turns. It was wound up for the occasion, upon a bit of ⅝-in. brass tubing which happened to be at hand. The needles were made in lengths of two, both the wire ones and those of steel tape, and before being hardened, were marked with a file pretty deeply where they were to be divided.

A number of pieces of iron wires were cut off—enough, in fact, to fill the brass tube. The pieces of wire were cut about 2 ins. longer than the steel for the needles, and the coil above described was slipped upon one end of the bundle of iron wires. The

LI . RY

pieces to be magnetized were laid lengthwise along the wire core, and current from a six-cell storage battery was turned into the coil and continued until the coil became pretty warm.

Before cutting off the current, the hardened steel pieces were one at a time slowly removed from the wire core, taking care to carry them away *sidewise* until at least 4 ft. from the core. In this manner, I obviated the necessity of exposing the magnetized steel to the lines of force of an opposite polarity which it must pass through if pulled off the core endwise. By taking the steel off before current was cut off, it was not exposed to the returning lines of force at the instant of breaking the current in the coil. I have given no thought to the technical analysis of this way of magnetizing needles, but I found that by breaking the steel where marked, two needles of mighty near the same power were obtained.

Brooklyn, N. Y. JAS. F. HOBART.

Brush Arc-Machine Controller.

To the Editor of American Electrician:

Mr. Jos. A. Maloney, chief engineer of the Mobile Light & Railway Company, recently called my attention to the erratic behavior of the ammeter on an arc circuit fed by a Brush machine, when the door of the controller of the machine is closed, as is intended, and to the steadiness of the current when the door is left ajar.

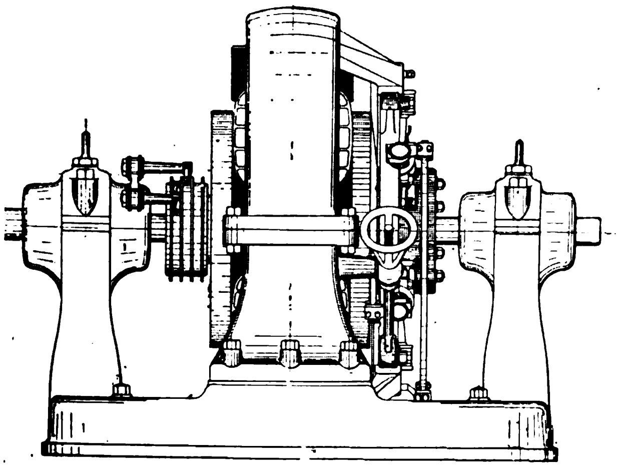


FIG. 1.—ROTARY TRANSFORMER.

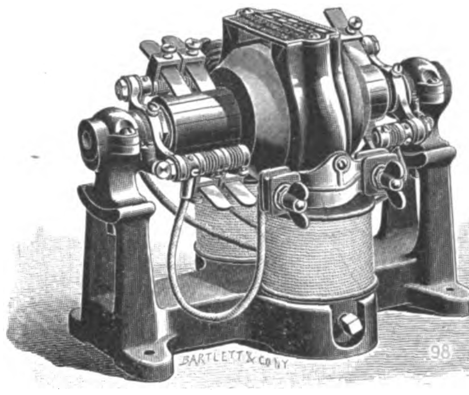

FIG. 2.—DYNAMOTOR.

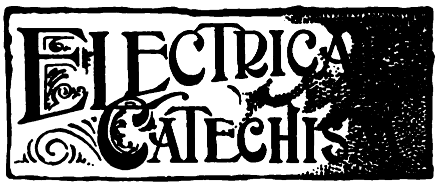
This fluctuation of the current is no doubt due to the shunting of the magnetic lines of force in a greater or less degree away from the cores of the solenoids, thereby rendering the regulation defective. As is usual, this door is of comparatively heavy iron, as is the rest of the case. No doubt if the entire case was made from a non-magnetic material, the regulation would be almost perfect, as the back of the regulator must act upon the solenoids in a similar manner, being similarly placed.

I have never heard of just such another case, but mention it for the benefit of any engineer having similar trouble. Mr. Maloney discovered this fact shortly after the installation of the machine.

Mobile, Ala. REESE HUTCHINSON.



183. What is a rotary transformer?

A rotary transformer is a machine for changing an alternating current into a continuous current, or *vice versa*. It is practically a continuous-current motor with a set of collecting rings at one end like the rings of an alternator. If continuous current is supplied at the commutator, alternating current may be taken from the collecting rings. On the other hand, if the machine is supplied with alternating current at the rings, continuous current may be taken from the commutator. The machine is often supplied with a pulley so that it can be used as a motor to furnish power, or may be driven as a dynamo to generate either continuous or alternating current. Such a machine is illustrated in Fig. 1, in which the commutator for continuous current is seen between the field magnet and the bearing at the left, while the four collecting rings for taking off two-phase alternating current are seen at the left beyond the bearing.

184. What is the difference between a rotary transformer and a rotary converter?

These are simply two names for the same thing. They are often called simply "rotaries."

185. What is a motor-generator?

A rotary transformer might be called a motor-generator, but this term is usually applied to a machine having a double winding on its armature or having two armatures on the same shaft. These machines are generally designed to change from a continuous current at one voltage to a continuous current at another voltage.

186. What is a dynamotor?

Dynamotor is simply another name for a motor-generator. The shorter name is more commonly used. (See Fig. 2.)

187. For what purposes are dynamotors used?

Numbers of dynamotors are used in large telegraph offices for supplying currents at various voltages. One armature winding is designed for the 110-volt lighting circuit, while the other winding is suited to deliver current at one of the various voltages desired. Dynamotors are sometimes used to obtain current for incandescent lighting at 110 volts from a power circuit at 500 volts. Other machines are used for obtaining heavy current at low voltage, such as is required for electroplating or electrotyping, current for the motor end being taken from the regular circuit at 110 or 500 volts.

188. Is there not a great loss in changing the voltage by a dynamotor?

Not so much as one might at first think. In a moderately small machine, say of 10-KW capacity, the efficiency of the motor part will be about 90 per cent., and that of the dynamo end about the same. The combined efficiency of the combination will be the product, or 81 per cent. For example, if 10,000 watts be supplied at the motor, about 8100 watts may be obtained at the dynamo end.

189. When a dynamotor is used to reduce the voltage, is it possible to obtain a larger current from the dynamo end than is supplied at the motor end?

Yes. It is possible to take out a larger current than is supplied. This is possible because the larger current is at lower voltage than the current supplied. The power is the product of current by voltage, and these two might have any values so long as their product was less than that of the current and voltage supplied at the motor end. For example, suppose the motor takes 20 amperes at 500 volts; the power taken is 20 × 500 = 10,000 watts. The generator end might deliver 73.6 amperes at 110 volts, making a product of 8100 watts, or 81 per cent. of that furnished at the motor end.

190. What becomes of the difference between the 10,000 watts supplied and the 8100 watts delivered?

It is used up by unavoidable losses in the machine, such as friction at the bearings and brushes, heating in the armature wires due to their resistance, the current necessary for exciting the magnetic field, and heating of the armature core due to hysteresis and eddy currents in the iron.

QUERIES AND ANSWERS

NOTE.—*Only the queries of subscribers are answered, and must be accompanied with full name and address for identification.*

Can I run a $\frac{1}{12}$ HP motor as a dynamo? F. S.

It is rather doubtful if such a small machine will self-excite. Belt it and try; should it fail to excite, its field may be supplied with current from a battery.

What strength of spring is required for a 220-volt voltmeter? W. M. B.

The strength of sping depends entirely upon the magnetic field and the coil used, as it balances the force exerted between these; it may therefore vary from a hair spring to one comparatively strong.

In the answer to the query of D. B. in the January number, he is advised to rewind the field of a dynamo when halving its voltage. Could not the same result be obtained by throwing the fields in parallel, if the dynamo is a bipolar one? G. S.

Yes. The answer as given would only refer to a one-coil machine, or to a bipolar machine already connected in parallel.

I wish to get an artificial load for a three-phase, 4500-volt, star connected alternating-current generator. How can I construct a water rheostat or choke coil for this purpose? L. R.

See December issue for data of water rheostats. A choke-coil would merely introduce a back E. M. F. in circuit, the ohmic drop in its coils being the only load it would give.

Where can I procure small field steel castings from patterns, and stamped soft iron armature desks? J. N. L.

The former may be procured from the American Steel Casting Company, Thurlow, Pa., and the latter from the Cherry Electric Works, 27 Third Avenue, New York, or the Miamis Electric Company, Miamis, Conn.

1°. What is the commercial efficiency of the small motors described in the February and April issues? 2°. Has the strength of a coil any relation to its resistance? C. D.

1°. About 60 per cent. 2°. If the product of the amperes and turns of two similar coils are the same, their strength will be identical. Ampere-turns correspond to watts in the respect that the turns and current (like the volts and current) may be varied to any extent without change, provided the product remains the same.

What should be the dimensions of a 1½ in. spark induction coil, and how much secondary wire is necessary, using No. 33? H. K.

Use a core 6 ins. long, ¾ or 1 in. in diameter, and made of soft iron wire. There should be at least a half inch clearance between the secondary and primary. Use filter paper between the layers of secondary, wind loosely and surround with paraffine. If made according to indications given on page 18, January, 1897, issue, 1½ lbs. of No. 36, or 3 lbs. of No. 33, wire will be sufficient for the secondary. The old rule was 2 lbs. of No. 36 per inch of spark.

What is the trouble in a transmitter which makes the voice sound as though the speaker were talking through his nose? M. L. C.

A. The contacts of the instruments may partially break on the louder sounds, thus causing a sound similar to the one described. The diaphragm of the transmitter or of the receiver may not properly lend itself to the vibrations of the voice, having a fundamental tone of its own, slightly above the pitch of the human voice, which would probably produce the sound described. To correct for the latter defect, use a little thinner or softer diaphragm.

1°. What causes static electricity in belts, and is it liable to cause any damage to dynamos? 2°. In starting two direct-current machines, the polarity of one was changed. Is there any harm in running it as it is, and how may the original polarity be regained? D. A. B.

1°. The static electricity is caused by the friction of the belt on the pulley belt, and may puncture the insulation of the machine. It may be removed by a metal comb nearly in contact with belt and well grounded. 2°. No harm will result; the polarity may be charged by means of current from the other machine, the connections being made by trial, using a compass or magnetized piece of steel.

How may I make a 1-KW rotary converter to convert a 110 volt single-phased alternating current into a 110-volt direct current? G. A. C.

By connecting two rings to diametrically opposite segments of a continuous-current machine, you will have a single-phased rotary converter. The machine should be multipolar, as the speed will be the number of alternations divided by the number of poles. Such a converter, however, will have to be brought to synchronism by external means in starting. To obtain a continuous-current of 110 volts, the alternating current will have to be supplied to the rings at 77 volts, the ratio between the two voltages being fixed.

I have a 20-light Sperry type arc machine, and of late the flexible cord commutator lead wire burns off, generally near the bars, but once at the commutator. They burn off suddenly and while the machine is operating perfectly. What is the cause? J. S. J.

The back of the commutator is probably dirty and has a deposit of copper dust and oil which gradually accumulates until a section is short-circuited and the leads burn off. The leads should be much smaller in carrying capacity than the armature, so that they will burn off before the armature goes. In cases where the leads burn off near the armature, the deposit of dirt and copper may be anywhere between the commutator and armature.

What would you recommend as a systematic course in electrical reading for one who understands elementary algebra? K. S. P.

1°. Read Thompson's "Elementary Lessons in Electricity" to obtain a knowledge of principles. 2°. Next, take up Slingo & Brookers's "Electrical Engineering" to obtain a general view of the practical field. 3°. Finally, read Thompson's "Dynamo-Electric Machinery," after which the reader will be excellently prepared for special treatises, such as Wiener's "Practical Calculation of Dynamo-Electric Machinery," Bell's "Electrical Transmission of Power" and "Power Distribution for Electric Railways," Crocker's "Electric Lighting," Jackson's "Alternating Currents," etc.

Is it possible to use more bridged telephones on a metallic line than on a grounded line, the two being of the same length? M. L. C.

A. Theoretically it would be possible to use more bridged telephones on a grounded line than on a bridged line, as the resistance of a grounded line is but approximately one-half that of a metallic circuit line (the sizes of the wire being equal). But there is always some resistance in ground connections which will under ordinary circumstances about even the matter up. In practice, the noises from induced and earth currents on grounded lines make the talking qualities of the line much inferior to those of a metallic circuit line, and therefore the number of instruments which could be used in practice on a grounded line would not be so great.

1°. Please give the field and armature windings and construction of commutator for the motor of which a sketch is enclosed; what would be the capacity of this motor? 2°. What kind of a battery is suitable for running a small motor? E. L.

1°. See February and April issues, 1897, for construction of small motors, battery windings for which are given on page 358 of September, 1897, issue. We cannot undertake to furnish windings for amateur designs of fields. Of a score or more of the latter sent us, scarcely one has been of correct proportions. Besides, to send a drawing of a field and ask for windings, is like sending to an engine designer the drawing of a piston and ask for the design of the complete machine. 2°. The Gordon-Burnham and Edison-Lalande are closed circuit batteries. A powerful and cheaply constructed battery is described on page 324, August, 1897, issue.

How does a bridging generator for telephone service differ from a common series generator except in the way it is connected on the line? H. O.

A. A series generator should be designed to develop a small current at a rather high E. M. F. Its armature is therefore usually wound rather high—from 500 to 800 ohms. Bridging ringer magnets are of high resistance—usually of about 1000 ohms—and therefore a considerable E. M. F. is necessary to properly actuate them. Moreover, enough E. M. F. must be generated to overcome the resistance of the line, which is distributed between various instruments. A bridged generator should be wound for producing a large current at a comparatively small E. M. F. Its armature, therefore, should be wound to a low resistance with a comparatively large wire, the requisite number of turns being obtained by making the armature core larger.

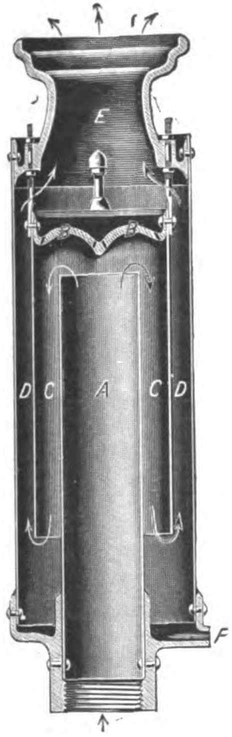
What is the greatest number of bridged bells (1000 ohms) that will work satisfactorily on a grounded line? M. L. C.

A. This depends entirely on the make of the instrument and on the personal equation of the party who must decide what "satisfactory" service means. In general it may be said that it is poor policy to use more than 10 bridging instruments on any sort of a line. It is stated on good authority that as many as 40 instruments have been used on a single grounded line giving fairly good ringing and talking results. The ordinary bridged instrument, however, will not give anything like these results. Ten instruments on a 1000-ohm line is a fair limit. A greater number of instruments, even were the talking and ringing to be perfectly satisfactory, would be very undesirable owing to the confusion arising in interpreting the code of signals which must necessarily be used to enable any subscriber to recognize his own call.

New Apparatus and Appliances

THE BUNDY EXHAUST-PIPE HEAD.

As is well known to all engineers, the functions of an exhaust head is to separate the water and grease from exhaust steam and discharge the former through a drip pipe with proper outlet, the latter being allowed to pass into the atmosphere to be dissipated without precipitation. It is placed as a crown upon the exhaust pipe, and should have as neat and attractive appearance as possible consistent with perfect performance. The makers of the exhaust head illustrated herewith claim that it completely removes the liquids and allows but a light feathery vapor to escape, which readily dissipates without precipitation.



EXHAUST HEAD.

The head is made of heavy iron, thoroughly riveted together, and so designed and constructed as to cause the steam in passing to change its direction three times, doing this, it is claimed, without causing the slightest back pressure on the engine or pump from which the pipe discharges. The three cylindrical shells of which the head is composed, are placed one within the other, and each is of greater area than the one next inside, full capacity thus being given throughout with the element of friction added. There is no crimping of the iron with its incident weakening at the point where the scale is necessarily broken, and as a result the head has long life without any liability of repairs.

Another feature worthy of mention is that the elongated shape greatly reduces the wind pressure, and also gives a maximum exterior condensing surface exposed to the atmosphere an advantage. The Bundy exhaust head described is made by the A. A. Griffing Iron Company, 66 and 68 Centre Street, New York, who will send a book entitled "Sure Cure for Wet Roofs," to those writing who mention this paper.

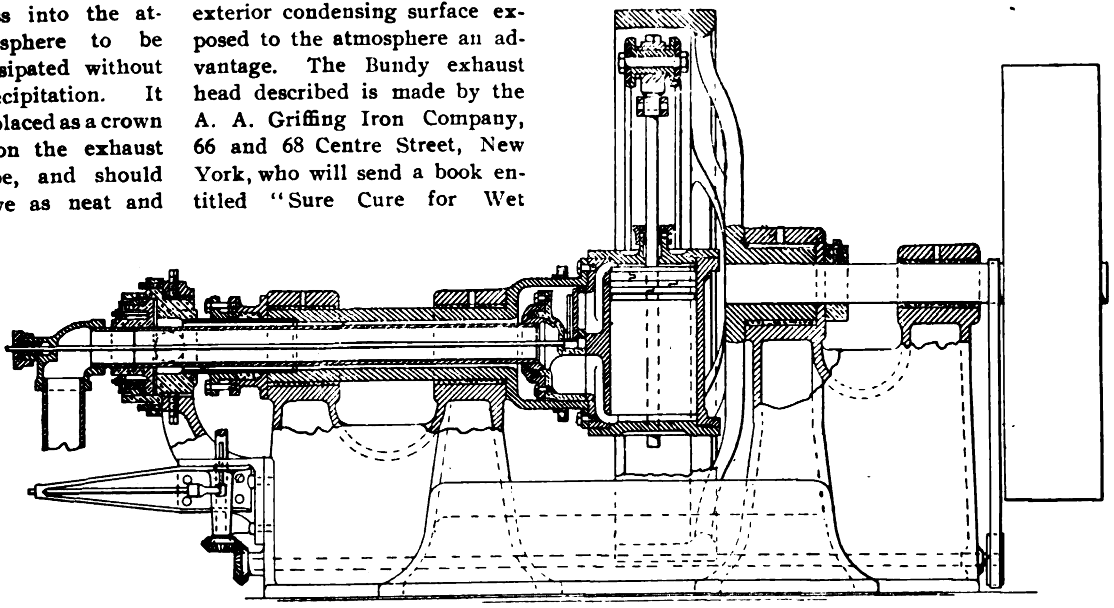


FIG. 2.—LONGITUDINAL SECTION OF RECIPROCATING ROTARY ENGINE.

RECIPROCATING ROTARY STEAM ENGINE.

The engine shown in the accompanying illustration consists of a main wheel or drum mounted to revolve with a horizontal shaft, the drive wheel being on the outer end of the same shaft.

The cylinder is connected to the end of a hollow sleeve and projects into the main drum with its piston rod connected to the inside of the rim of the drum by a yoke frame, all of which revolve together. The center line of the sleeve is parallel to the center line of the shaft of the drum, but below it the distance of one-half the stroke of the piston in the cylinder, as shown in Fig. 2, which represents a horizontal sectional elevation.

The end of the sleeve next the cylinder is enlarged and contains the valve, which is of disk form and is held stationary by a tube which runs back through the sleeve and is secured in a head or bracket rising from the base frame.

The valve is provided with two openings, one through the valve to the steam port face of the cylinder, the other leading into a head and thence into the tube by which the valve is carried. This latter forms the exhaust pipe, while the former constitutes the steam inlet from the sleeve or hollow malleable shaft, to the cylinder. The steam is fed into the sleeve direct from the boiler, entering the cylinder at full boiler pressure.

The steam admission passage through the

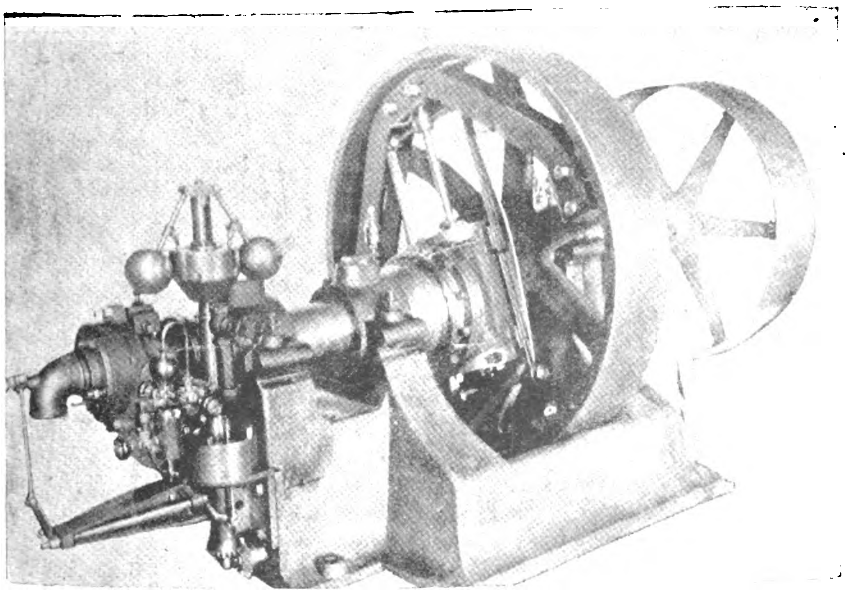

FIG. I.—RECIPROCATING ROTARY ENGINE.

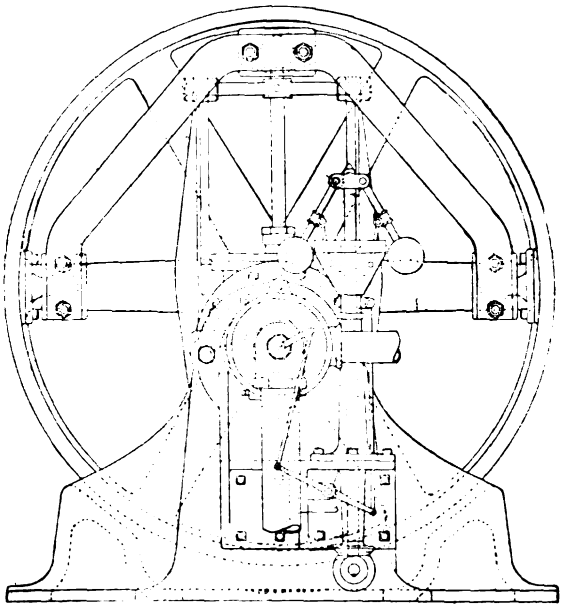

FIG. 3.—TRANSVERSE CROSS SECTION OF ENGINE.

valve is divided into radiating segments which, by means of the automatic arrangement of the governor valve, designate positive points of cutting off the piston stroke in the cylinder.

The governor valve is in the form of a segment and is adapted to be moved over the steam passages by an arm projecting at right angles from a rod running backward through the exhaust pipe, and thence out through a stuffing box, and so arranged as to be rocked by a governor as shown in Fig. 3, which shows an end elevation of engine.

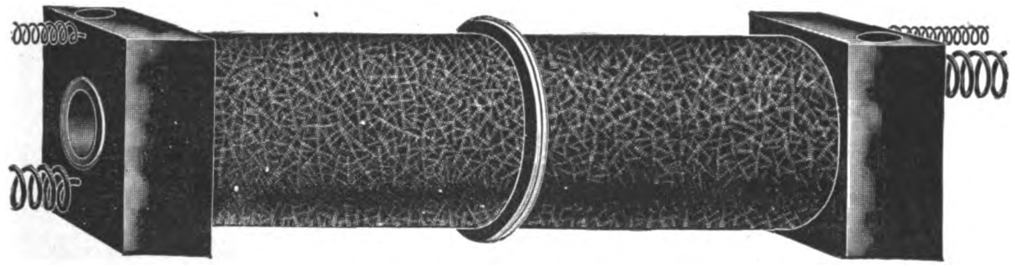

FIG. 1.—VARLEY TELEPHONE INDUCTION COIL, 500 OHMS.

FIG. 4.—VARLEY TELEPHONE MAGNET.

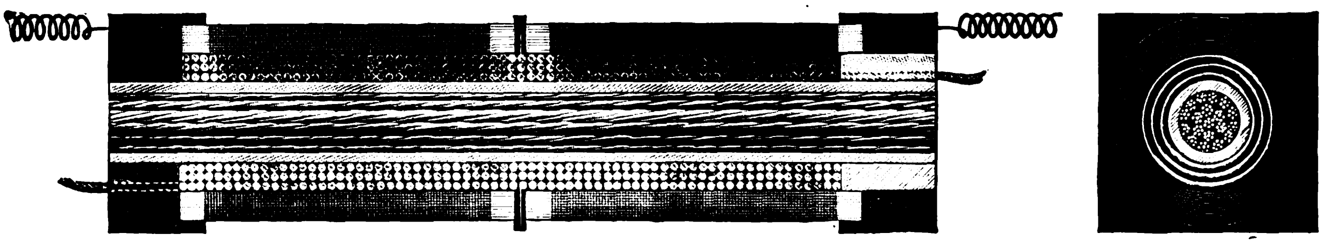

FIG. 2.—SECTIONAL VIEW OF VARLEY TELEPHONE INDUCTION COIL.

When the engine is running slow, and the balls are down, the segmental valve will lie low down on the valve, leaving the steam passage wide open; but when the speed increases, the rising of the balls will elevate the governor valve correspondingly and cut off the steam at an earlier point of the stroke, thus perfectly regulating the speed.

The makers claim that this forms a very compact and economical engine, doing away with many heavy moving parts of the reciprocating engine. The moving parts are all within the fly-wheel or drum, and there is an absence of the jar and friction of the ordinary engine, as all the parts are balanced within the wheel, and the piston stroke is accomplished without the usual back and forward movement.

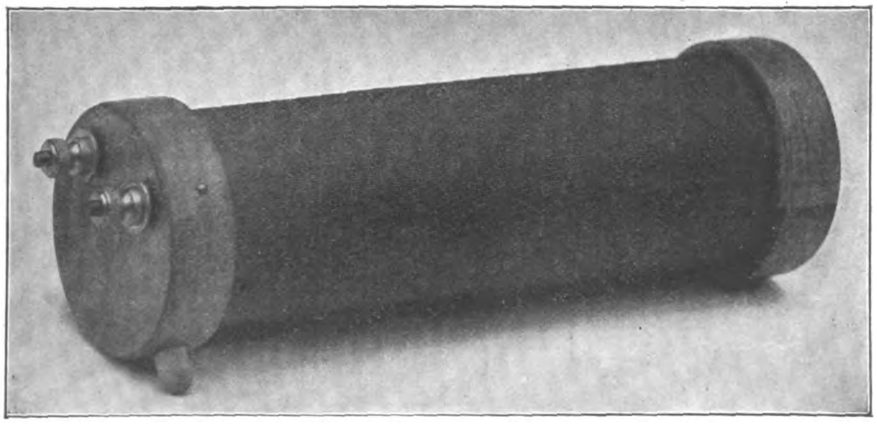

FIG. 3.—VARLEY GAS LIGHTING SPARK COIL.

The valve, called a "boiler pressure expansion balance valve," is claimed to control the steam as accurately as a Corliss valve.

In a recent brake test made by Reichard & Pattee, contracting engineers of Minneapolis, H. C. Kenning, engineer for the Minneapolis Chair Factory, and C. H. Hill, draughtsman for R. R. Howell & Company, the water consumption was found to be 35.46 lbs. per brake horse power, the duration of the test being three hours.

The inventor of the engine described is F. W. Reeves, 1920 Laurel Avenue, Minneapolis, Minn.

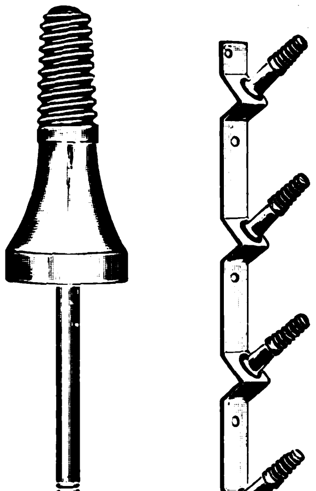
VARLEY ELECTROMAGNETS.

Fig. 1 gives a perspective view of a special Varley coil, Fig. 2 giving sectional views of the same. As will be seen from the latter cut, the coil is built after the manner of a Ruhmkorff coil, and no matter what may be the intensity of the current in the primary it is claimed that there will be no loss by brush discharge inside of the coil, which consequently acts as a highly efficient transformer. Another advantage is that the coil is wound in two halves, each half in an opposite direction, and the terminals of the secondary are consequently brought out from the top layer of each half, two fibre discs separating the two sections. After winding, the coil is thoroughly baked and boiled in paraffine. It is capable of producing with two dry batteries, a ¼ inch spark when used with a condenser which, it is claimed, would be impossible if the coil were wound in one winding for the reason that the actual distance between the top and bottom layer of the secondary would then be only ⅛ inch, which would involve considerable loss when the coil is working at a maximum.

Another new Varley specialty is shown in Fig. 3, being a design of a gas lighting coil containing several late improvements. Fig. 4 shows a telephone magnet having a compact, solid sectional winding. The coil shown has 40 ohms resistance, but the windings are made of any resistance and turns, and is slipped freely on any core. All the above described magnets are made by the Varley Duplex Magnet Company, 138 Seventh street, Jersey City, N. J.

INSULATORS AND INSULATOR PINS.

The triple petticoat insulator shown in the accompanying illustration is a glass insulator for potential up to 20,000 volts, and one very extensively used on high voltage transmission lines. Fig. 1 shows a steel



FIGS. 1 AND 2.—POLE AND BRACKET PINS.

insulator pin with a porcelain base, also used on high voltage power transmission lines. In Fig. 2 is shown a four-pin upright galvanized side bracket for attaching to the sides of buildings to support lines and at the same time to insure good insulation. The above insulator and pins are made by Fred. M. Locke, Victor, N. Y., manufacturer of insulators in glass and porcelain for all electrical purposes.

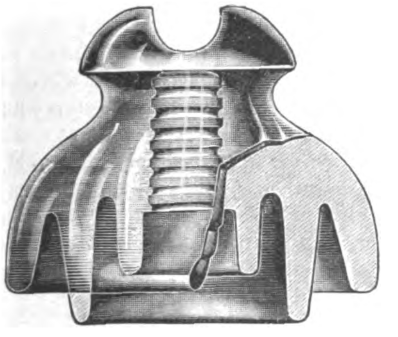


FIG. 3.—GLASS HIGH-VOLTAGE INSULATOR.

INTERIOR THERMOSTATIC ELECTRIC CABLES.

While the usual thermostats, based upon the differential expansion of metals, have their field of usefulness, it is a limited one for several reasons. To afford ideal protection the number of thermostats installed would have to be so large as to make the cost prohibitive in most cases, leaving aside the impossibility of so placing the devices that they would not deface an apartment. In addition, the adjustments are necessarily so delicate that, if the instruments are not regularly inspected, their reliability could not be depended upon.

A new system of automatic fire alarm, which is now being placed upon the market, would seem to obviate entirely the above objections and introduce numerous advantages. This consists in the employment of a cable which is in itself a continuous thermostat. Moreover, the cable, besides its thermostatic properties, also serves as an electrical conductor for an electric bell service, for burglar alarm systems, telephone circuits, etc.

This cable, whose construction is shown in Fig. 1, is made up of an inner copper wire coated with a metal that fuses at the low temperature of 374 degs. F. This inner conductor after being insulated, is wrapped with other conductors and the whole insulated by an outer covering, which may be the usual paraffine cotton insulation, a rubber covering, or any other outside insulation suited to special conditions. Some types of the cable are made with several outer wires, one of which may serve, for example, for bell service, another for fire alarm, another for burglar alarm, etc., the inner conductor acting as a common return.

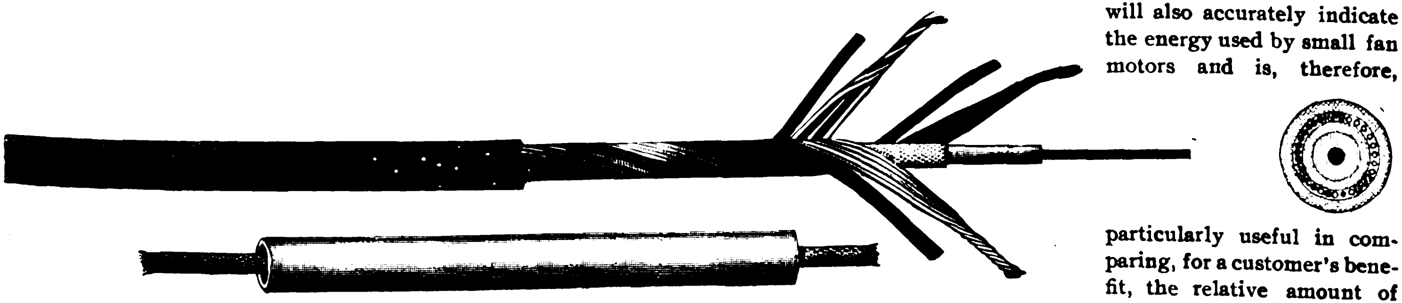

FIG. 1.—THERMOSTATIC ELECTRIC CABLE.

When the cable is exposed to an abnormal temperature, the heat fuses and expands the inner fusible coating and forces it into contact with the overlaying outer wire or wires, thus forming a metallic contact between the inner and outer conductors which completes an electrical circuit and rings an alarm. It should be added that the insulation between the central and enveloping conductors is such that it acts as a flux for the fusible metal, thus insuring, when the critical temperature is reached, an almost instantaneous short circuit.

Though the cable is intended more particularly for protection against fire, it also serves equally well for special protection against burglary, for the reason that if the wire should be cut, connection will thereby be made between the outer and inner conductors and an alarm sounded.

All the details for the use of the above described cables for fire and burglar protection have been worked out in a remarkably thorough manner. In simple house protection, for example, should a cable—whether conjointly employed for bell or burglar alarm service, telephone connections, etc., or for all of these purposes at once—be subjected to undue heat, a loud fire alarm signal will be sounded. Should there, however, be an ordinary short circuit on any of the lines, or, for example, a window raised when the burglar alarm circuit is not disconnected, or when a wire is severed by a sharp instrument, a different signal is sounded. Moreover, by a simple method of connection, the entire system or any part of it can be tested at any point without giving an alarm.

One of the most valuable features of the system is the automatic arrangement for transmitting fire and burglar alarm signals to a distance, the signal being received, for example, in a police station, central fire station or central telephone exchange. This is accomplished by means of mechanism shown in Fig. 2. In the case of fire, a telephone central is automatically called up and the signal delivered through the telephone in the form of distinct beats, indicating the signal number of the building; or a signal in the police or fire station is sounded, giving the signal number of the building. It should be added that the signal for an alarm of fire is entirely different from that for a burglar alarm, so that the attendant in any of the above cases can clearly distinguish between the two. An important point is that in the case of a telephone attachment, there is absolutely no interference with the ordinary telephone service and no special wire is required to be run from the house.

The cable, fire and burglar alarm system just described, has been placed upon the market by the Montauk Multiphased Cable Company, 100 Broadway, New York, which will be pleased to furnish to such of our readers who apply, further particulars concerning the same.

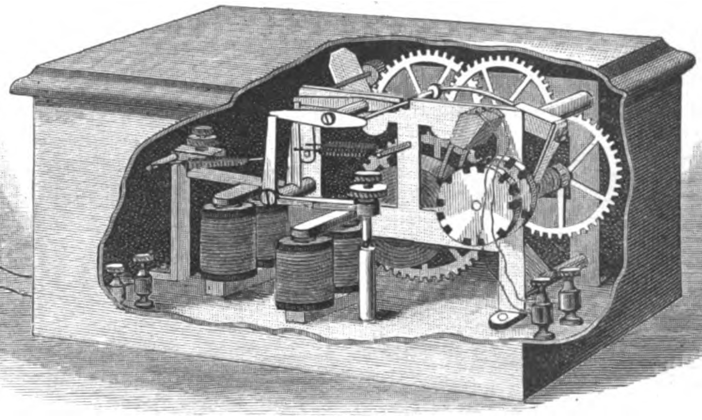

FIG. 2.—FIRE AND BURGLAR ALARM AUTOMATIC TRANSMITTER.

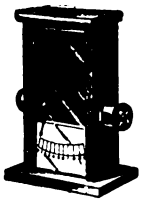
LAMP INSPECTOR'S WATTMETER.

A portable instrument to determine accurately and rapidly the watts required by a lamp is of great value in selecting new lamps and in testing lamps in service, and for this purpose the General Electric Company has recently designed and introduced the Thomson portable indicating wattmeter.

The indicating wattmeter will also be found valuable in testing lamps in barrel lots, either with or without a photometer. It will also accurately indicate the energy used by small fan motors and is, therefore, particularly useful in comparing, for a customer's benefit, the relative amount of energy required by a fan motor and an ordinary incandescent lamp. By supplying the secondary of a transformer with current, its core loss may be easily determined by the indicating wattmeter. The capacity of the instrument, which can be used with both direct and alternating current, is 150 watts.

INEXPENSIVE AMMETERS AND VOLTMETERS.

A type of inexpensive testing instrument for both students and practical electricians is illustrated herewith, made as a voltmeter reading from 0 to 10 volts, or an ammeter reading from 0 to 10 amperes. They are not toys because sold at a low price, but are well constructed practical instruments, and intended particularly for amateurs and others experimenting with batteries, dynamos, motors, or using current for any purpose, to whom the standard instruments are too expensive. These instruments are made by the Cherry Electric Works, 25 Third Avenue, New York.



A CHEAP AMMETER.

ELECTROSTATIC GROUND DETECTOR.

The General Electric Company announces a new ground detector to take the place of the transformer and lamp method, which, although hitherto extensively used, has never given more than a rough indication of the condition of the lines. In the transformer and lamp method of ground detection, the extent of the ground is indicated by a lamp in the secondary circuit of the transformer, but on account of the capacity of the lines, the lamp nearly always glows, and the actual condition of the line is difficult to ascertain.

GENERAL ELECTRIC CO.
SCHENECTADY
NEW YORK
U.S.A.
ELECTROSTATIC GROUND DETECTOR.

The new device here illustrated is a switchboard instrument, and is similar in construction to that of electrostatic voltmeters used in laboratory work. Briefly, it consists of four rigidly fixed sheet metal quadrants, between which is space for the accommodation of a vane carrying an indicating needle. The two lower quadrants are connected internally to the lower binding post for connection to the ground, and the two upper to the right and left binding posts, respectively, for connection to the lines. The vane with its needle is pivoted at the centre of the circle formed by the four quadrants, and is slightly counter-weighted to balance the weight of the needle.

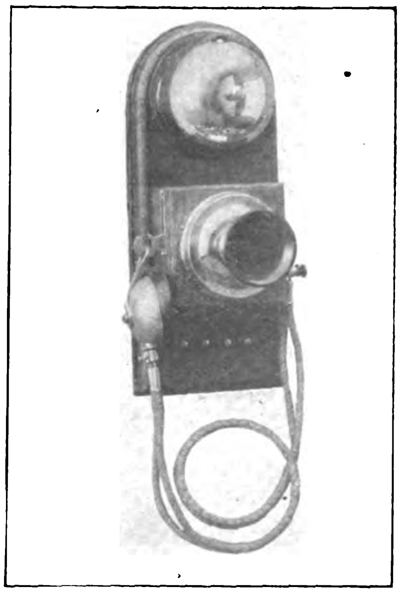
In common with all electrostatic instruments the operation of this ground detector depends on the tendency of the vane to place itself in the position giving the greatest condenser capacity. If no ground exists on the line, the vane lies across the shortest path between the positive and negative quadrants—the right and left upper quadrants—and the needle points to zero. If, however, either side of the system be grounded, the two lower quadrants cease to be neutral, the system is out of balance, and the vane, taking a new position, deflects the needle to the right or left, indicating the grounded side. A special feature of the construction is that the moving mechanism is insulated and has no electrical connection with either side or with the ground. If it were connected to either side of the line or to the ground, a burn-out might possibly result, but being insulated, the moving mechanism can come into contact with one of the quadrants without causing any damage. It may be used for temporary connection to any desired line, or one for each feeder may be permanently installed.

This electrostatic ground detector is constructed for 1000, 2000, 5000 and 10,000 volts, and is set in a black japanned case with cover finished in polished nickel.

INTERCOMMUNICATING WALL TELEPHONE SET.

For rapid communication between offices and floors in a building, a number of telephones advantageously placed and so connected that any one telephone station may call and converse with any other station, is coming to be recognized as a necessity.

An objection met heretofore in carrying out such an installation has been with respect to the complicated switch-board devices. In the telephone set illustrated, all switches, plugs, individual batteries, etc., have been eliminated, and to call the station required, it is merely necessary to remove the receiver and press on the proper signalling key.



INTERCOMMUNICATING TELEPHONE SET.

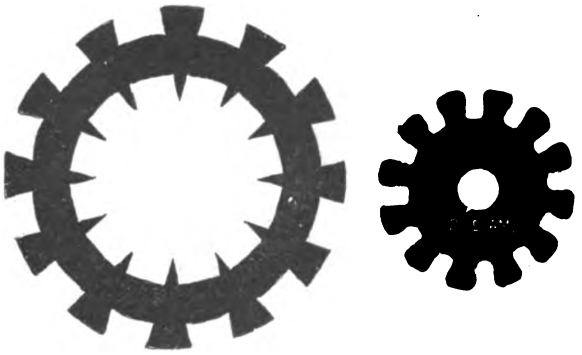
The telephones are provided with long-distance granular carbon transmitters and standard watch case receivers. They are easily set up and connected, and being substantially constructed and simple in operation, do not require re-adjustment or repairs.

Four ordinary carbon batteries, located at some convenient point, are sufficient for a four to eight station system, and will operate continuously from one to three years without recharging.

The system described has been brought to its present perfection principally from the designs and efforts of Mr. A. R. Hussey, chief electrician of the Allen-Hussey Company, 211 Randolph Street, Chicago.

SMALL ARMATURE PUNCHINGS.

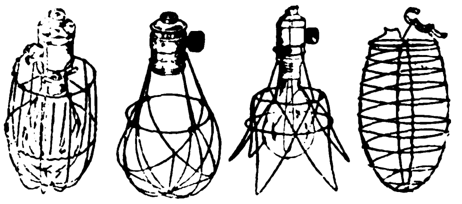
In making small motors, if a punching press is not available, one of the most tedious operations is cutting out the armature discs. The type of punching illustrated herewith is made by the Mianus Electric Company, Mianus, Conn., for the convenience of amateurs and others who wish to make a small or special type of machine. The punchings are 2 in., 3 in. and 3½ in. in diameter, and are of a special quality of soft iron.



SMALL ARMATURE PUNCHINGS.

WIRE LAMP GUARDS.

The accompanying illustrations show several different patterns of wire lamp guards, having the holder part of the guard, thus obviating the nuisance and expense involved with forms of guards which have to be fitted with holders. The guards are all made of tinned wire, the gage being such that sufficient strength is obtained with a minimum interference with the light. One of the forms, it will be noted, is a standing guard for desk or other use, and which also makes a frame for silk or paper shades. The guards illustrated are made by P. R. Wagor & Co., Springfield, Mass.



WIRE LAMP GUARDS.

TRADE PUBLICATIONS.

Dynamo Brushes. Chas. Wirt, 1028 Filbert Street, Philadelphia, has issued a new catalogue devoted to Wirt dynamo brushes and rheostats, and the Queen-Wirt commercial measuring instruments. Reprints are included of many flattering testimonials to the merit of Wirt brushes.

Correction. The General Electric Company desires to advise all holders of their complete Incandescent Lamp Catalogue, noticed in January issue, of an error in the appendix, in the table on page 58. The figures .662 in the column "Life Factors" should be .562. They request that all holders of the catalogue make this correction.

Motors and Generators. The Elwell-Parker Electric Company, of America, is to be congratulated on the excellent appearance of its new catalogue, and particularly on the execution of the accompanying half-tone engravings, which latter are of a quality rarely equalled. Various types of apparatus are shown, both separately and as parts of installations.

BUSINESS NEWS.

De Veau & Company have removed their office and factory from 32 Frankfort Street, to 27 Rose Street, New York City.

The General Electric Company is building thirty six additional 175-HP. motors for the Metropolitan West Side Electric Elevated Road.

Mr. Fred. L. Cross, until recently electrical engineer and manager of the electrical department of the Buffalo Engine Works, has opened an office as electrical engineer in the Mooney & Brisbane Building, Buffalo N. Y.

The Montreal Electric Company having outgrown their present long established quarters at 302 St. James Street, Montreal, will shortly remove to a more spacious place of business at 1819 Notre Dame Street, in the Balmoral Hotel Block.

Change of Firm Name. On January 1, the Partrick & Carter Company, 125 South Second Street, Philadelphia, changed its name to Partrick, Carter & Wilkins, the firm consisting, as formerly, of Messrs. Franklin S. Carter, Charles M. Wilkins and E Ward Wilkins.

The Safety Insulated Wire Company has closed a contract through Mr. E. J. Spencer, its Western agent, for all the conductors, inside wire, cable and underground cable, for lighting and power at the Trans-Mississippi & International Exposition, to be held at Omaha. Mr. Spencer has removed his office in St. Louis to the Laclede building.

Special Electrical Apparatus The Reading Electrical Manufacturing Company, Reading, Pa., does a jobbing business in supplies, and make small motors, dynamos and portable instruments for electricians and amateurs. The company is always glad to enter into correspondence concerning the construction of special apparatus, which it is equipped to build at prices within every one's purse.

The Electric Appliance Company, Chicago, reports that its new issue of General Catalogue No. 12 is now very generally distributed all over the country and is producing very satisfactory results. Certainly very few buyers could resist the temptation of ordering from such a handsome and useful publication. Such of our readers who have not yet obtained a copy may do so by sending their business card to the Electric Appliance Company.

Incandescent Lamps. The lamp department of the K. & W. Company, Pittsfield, Mass., is now in full operation. Many duplicate orders are now being received from sample orders placed in December. Only the most highly skilled workmen obtainable are employed by the K. & W. Company, which assures technical accuracy and mechanical finish. The company finds the outlook for future business very flattering.

H. B. Coho & Company, of St. Paul Building, New York, commence the new year with a most satisfactory budget of contracts. Among these may be mentioned a plant for the Lane Shoe Factory, consisting of 80-KW. dynamo and four motors; a 75-KW. alternator for Lancaster, Pa.; a complete plant for a Dye Works, at Lodi, N. J.; a complete plant for Frestburg, N. Y., and a water power plant for Long Island.

The Anchor Electric Company has recently had several changes in its personnel, Mr. H. C. Hawks and Mr. Phillip M. Reynolds having retired after selling their interests to Mr. Norman Marshall, Mr. George O. Proctor, Mr. Guy H. Proctor and Mr. Frank Ridlon. Mr. Geo. O. Proctor will hereafter be president, and Mr. Norman Marshall, treasurer. Mr. Proctor is equally well known in public and business life, having been a prominent member of the Massachusetts legislature.

Circuit Breakers v. Fuses. While the discussion rages over the question of whether circuit breakers are going to be used or not, the concerns making the favorite types of circuit breakers are working night and day, and with difficulty only are able to keep up with their orders. The Ward Leonard Company say they have all they can attend to in this line, and yet expect a still further increase in the demands upon their manufacturing facilities for circuit breakers.

The Central Telephone and Electric Company, of St. Louis, which recently succeeded the D. A. Kusel Telephone Manufacturing Company, has just purchased the stock of goods carried by the Missouri Telephone Manufacturing Company, and taken over the business of that firm. This enterprising firm has already become one of the principal forces in the telephone field, its energetic business methods and evident desire to furnish only the most reliable and highest grade goods being appreciated by the public.

Exposition Awards. Three diplomas of merit to one concern shows pretty well what the judges of the Tennessee Centennial Exposition (held at Nashville in November) think of the Robertson-Thompson indicator, Lippincott planimeter and Eureka packing. Jas. L. Robertson & Sons, New York, entered these three articles, and inform us they were awarded these prizes. They say that if engineers and steam users send for illustrations and descriptions of these goods, it will be both to their interest and profit.

Geo. W. Patterson has recently been appointed western representative in charge of the well known office of the American Circular Loom Company, at 1114 Marquette Building, Chicago. Mr. Patterson is well known to the trade through his connections as Western agent for the Gordon Burnham and Law primary and Ohio storage batteries, and Medbery Knife switches and Overhead Railway Material, which companies he will still represent. Mr. Patterson reports business good for the season with a bright prospect for the future.

A Gratifying Engine Business. The Fitchburg Steam Engine Company, Fitchburg, Mass., is receiving a very good share of the new work now being done in their line. Among the recent orders booked by this company are for a 600-H P cross compound engine with rolling mill beds for the Fitchburg & Leominster Street Railway Company; a 350-H P tandem compound condensing engine for a silk mill at Easton, Pa.; a 250-H P engine for a brick plant at Woodbridge, N. J.; a 125-H P engine for a cotton mill at Adams, Mass.; a 120-H P engine for a chair factory at Gardner, Mass., and a 120-H P engine for a paper mill at Newark, Del., beside several others.

The Thresher Electric Company, Dayton, O., for some time has been working a double shift of men in order to catch up with its orders and the constantly increasing business will soon demand a considerable extension of manufacturing facilities. The design of the generators and motors manufactured by this enterprising concern is such as to particularly adapt them for power work of all descriptions, which accounts for the many installations of Thresher machinery made for general and special power distribution in manufactories. Among the recent installations is one in a large printing house in New York City, of which we hope to print a detailed description in an early issue.

The Burnham-Hall-Chase Company 146 Franklin Street, Boston, Mass., is a newly incorporated company composed of several energetic young men well known to the electrical trade. Mr. F. A. Hall, president, has been associated with the engineering department of the General Electric Company for the past six years and is well known to the electrical fraternity. Mr. W. W. Burnham, treasurer and general manager, hardly needs an introduction, as through his connection with the Electric Gas Lighting Company and other electrical enterprises, he is well and favorably known throughout the trade. The new company will handle a line of electrical specialties, and do an electrical engineering business; it will make a specialty of primary batteries and also of storage battery installations.

Lamp Guards. P. R. Wagor & Company, Springfield, Mass., call the attention of supply dealers to the fact that they have the exclusive right to manufacture the "Acme" lamp guard, having in 1895 purchased of the patentee all rights under letters Patent No. 502,458, dated Aug. 1, 1893. Irresponsible manufacturers of Boston and Detroit, they state, are placing on the market similar guards of inferior make, and as all dealers handling such guards are liable as infringers their attention is called to the rights held under letters patent. The manufacturers of the "Acme" guard have received within a few days from the largest electrical supply house in the United States, a letter in which appears the following voluntary testimony to the superiority of these guards over all others. "We must admit that the guards made by you are superior to any in the market."

The Sprague Electric Company, of New York, has secured the contract for motors to be installed in the new works of the John Stephenson Company, Ltd., Elizabethport, N. J. This is a large and important contract and some forty-eight motors will be utilized, ranging from 3 HP to 40 HP, mostly large size machines. The motors will be of the well known Lundell type, and will be direct connected, belted or coupled to the latest types of wood working machinery. As is generally known, the Lundell motors are of the inclosed type and are admirably adapted for use in wood working machinery establishments where, of necessity, the atmosphere is filled with dust. Several large size Lundell direct-connected exhaust fan outfits will also be included in the equipment. The plant will be one of the largest of its kind in this country and will be equipped exclusively with the Lundell motors.

The Weston Electric Istrument Company, it is reported, is considering the construction of a large manufacturing plant near the Waverly, N. J., station on the Pennsylvania railroad. In an interview with a newspaper reporter, Mr. Edward Weston stated that the time when the work of erecting the buildings will be started will depend largely on the condition of his health. When completed a large number of men will be employed. There will be several factory buildings for the manufacture of electrical instruments and machinery, and a number of new inventions in the electrical line be produced. For the new machinery a line of special tools will be designed. According to the newspaper report, two companies have been organized and a third has nearly completed its organization; while nominally separate companies they will be a unit in making the undertaking a success.

American Institute Medals. The American Institute Fair, held at Madison Square Garden, New York City, last fall, has just delivered exhibitors' medals awarded them on their goods. The A. A. Griffing Iron Company, 66 and 68 Centre Street, New York, received medals on the following goods: Bundy heaters and radiators, steam traps, gravity pumps, feed water heaters, steam and oil separators, exhaust heads and low water alarms. Those who were fortunate enough to view the exhibit of the A. A. Griffing Iron Company were loud in their praise of the tasty manner in which the exhibit appeared. Occupying a prominent space in the exhibit was the Bundy gravity pump in actual operation, taking water from one tank, carrying 5 lbs pressure and putting it into another tank, carrying 100 lbs. pressure, after elevating the water through pipes for about 100 ft. towards the roof of the Madison Square Garden. There was also in actual operation the Bundy separator, which received high tribute at the hands of the judges.

Telephone Coils and Electromagnets. The Varley Duplex Magnet Company, 138 Seventh Street, Jersey City, believe that telephone manufacturing companies have enough troubles of their own in properly making special details of their apparatus, and therefore have little time to devote to the subject of induction coils, especially since such coils have to comply with many different specifications, such as for lines of variable resistances, variable electrostatic capacities, low insulation resistances, leaky paper cables, etc.; consequently this company has made a special study of induction coils, which they manufacture in forms best adapted to the various transmitters on the market and to comply with the various other conditions arising that are apt to baffle manufacturers. It has also, at considerable expense, perfected automatic machines for accurately winding induction coils and, in fact, all kinds of telephonic magnets, the machines producing not only absolutely reliable work but at an extremely low price. Telephone manufacturers will undoubtedly find it to their advantage to look up the matter of Varley magnets.

A Large European Order. The General Electric Company has received orders from The British Thomson-Houston Company, Limited, covering the complete locomotives for the Central London Underground Railway. The original contract between the two latter companies included, with the special gearless motors and other electrical equipment, thirty-two locomotives for this important underground system, but these it was supposed, would have been built in England. The decision to confide the construction of the locomotive cabs and trucks as well as the electrical equipment, to an American firm is, therefore, a very gratifying testimonial to American manufactures. The locomotives will each weigh about 45 tons, and will be equipped with a total of 800-HP. in motors. The trains to be hauled will be made up of five cars, giving a total load of 150 tons, 10 tons heaver than the ordinary Manhattan elevated trains. The schedule speed will be 15 miles an hour. The diameter of the tunnel being 11 ft. 6 ins. only, motor cars could not be used. The entire electrical equipment will, therefore, be placed on locomotives which will probably resemble in appearance those in use on the Manufacturers' Railroad in New Haven, Conn., and on the Hoboken Shore Road, Hoboken, N. J.

Recent Walker Contracts. The Walker Company is now building at its Cleveland works a 1600-KW direct-connected generator for the Union Railway Company of New York City. This, with the two now being completed for the Brooklyn Heights Railroad Company, will make three of these 1600-KW machines, finished in as many months. In addition to this generator the Walker Company is building for the Union Railway Company forty double No. 4 A street railway equipments. The equipments are to be fitted with the new type "S" solenoid blow-out controller, which has attracted so much attention. The current for these motors will be fed to the line from a Walker switch-board, now being built at New Haven. The Metropolitan Street Railway of Kansas City, which is now operated by a 1600-KW Walker generator, is about to increase its plant by the addition of a generator of 1200 KW capacity, and as a contrast to these immense machines it may be mentioned that the company is building a 25-KW lighting generator for Mr. J. J. Astor's new yacht. The foreign shipments during the next few months will include one hundred double 3 S street railway equipments, with 200 controllers, for Dresden, Germany; six double No. 3 N equipments with Type "S" controllers, and two double No. 3 N equipments. Besides these railway motors and accessories there will be one 150-KW belted railway generator with its switch-board, and a 75-KW belted booster for Japan, also with a switch-board. This makes over 7500 HP in street railway motors alone that are being built at the Cleveland works, to say nothing of the HP output in generators.

A Farewell Banquet. It having been decided to remove the auditing department of Westinghouse, Church, Kerr & Company from their New York to their Pittsburg office, it became necessary for Mr. Warren L. Murray, the auditor, and Mr. Gardner W. Kimball, his associate, to remove their residences permanently to the smoky city. Mr. Murray has been connected with the company for fifteen years, and Mr. Kimball nearly as long, and during this long service have so won the respect and love of their associates that the latter determined to give them a send-off in the shape of a farewell dinner. This took place in the large private dining room of Mouquin's Fulton Street Restaurant on the evening of Jan. 5, and was taken advantage of by all of the engineering force of the company who were within reaching distance of New York, there being twenty-two plates. During the dinner, Mr. W. C. Kerr referred in terms of high appreciation to the departing guests, and remarked that this was the first occasion on which the force had been gathered together in this way, and suggested that an annual, or even more frequent, dinner might be an excellent idea. After Mr. Kerr, the regular toasts were called by Mr. O. L. Williams, treasurer of the company, and these continued for the remainder of the evening, every one present being called upon to respond. Late in the evening presentations in token of the high regard in which Messrs. Murray and Kimball were held were made in the names of the members of the force, and thus ended one of the pleasantest affairs in the history of Westinghouse, Church, Kerr & Company.

MILWAUKEE CONVENTION NOTES.

F. H. Clark took good care of the interests of the Electric Storage Battery Company.

J. Gilbert Hickox and **F. W. Bacon** did the honors for the American Rheostat Company.

The Sawyer-Man Electric Company was represented by Mr. Clarence A. Ross, of Chicago.

Manager Donohoe and Western Agent Hammond represented the American Electrical Works.

Sargent & Lundy, engineers and contractors of Chicago, were represented by Mr. T. E. D. Retchie.

John Child took care of the interests of A. O. Schoonmaker, and explained the merits of India mica.

Mr. A. C. Foster, of Foster & Louis, Chicago, represented the Triumph Electric Company, Chicago.

The Perkins Electric Switch Manufacturing Company, was represented by Mr. Edward J. Patton.

The Safety Insulated Wire & Cable Company was represented at the convention, by Mr. M. B. Austin, of Chicago.

A. B. Conover, Jr., looked out in an efficient manner for the interests of the J. A. Roebling's Son Company

Filer & Stowell Company, Milwaukee, was on hand with several representatives who also acted as hosts to the out-of town visitors.

Mr. Edward R. Grier, Western manager of the Byrant Electric Company, did the honors for his firm in the most approved fashion.

Mr. Jacob Cloos, of the Cloos Electrical & Engineering Company, was one of the busiest men at the convention and was very much in demand.

Mr. E. W. Buss, Western representative of the Chapman Valve Manufacturing Company, was a "heavy-pressure" representative for his concern.

Geo. Cutter, of Chicago, renewed his many acquaintances at the convention, and incidentally had a good word to say about Cutter's line of supplies.

The Varley Duplex Magnet Company, Jersey City, was kept in evidence by J. Mason Knox, who showed a line of samples of Varley magnets and coils.

The Yaryan System of heating residences, stores and public buildings from a central station, had an able representative in the person for A. J. Stahl, of Laporte, Ind.

Mr. F.S. Hunting, Mr. Thomas Duncan and **Mr. A. L. Draffen** kept the delegates well informed regarding the merits of the Ft. Wayne Electric Corporation's apparatus.

Mr. James F. Cummmings, president of the Armorite Interior Conduit Company, Pittsburgh, attended the convention; although a late arrival, he soon made up for lost time.

Mr. Chas. G. Guild, secretary and treasurer of the Jenney Electric Light & Power Company, Ft. Wayne, Ind., made his presence felt among the delegates in his usual courteous manner.

Mr. G. A. Hurd, of the Crane Company, Chicago, was very much in evidence and made many friends for his company. Mr. Hurd carried the Crane Company's exhibit on his watch chain.

The Northern Electric Manufacturing Company, of Madison, Wis., was one of the prominent factors in the success of the commercial side of the convention, making a fine display of exhibits.

The Northern Electric Company, of Madison, Wis., was represented in the person of President Fox, who kept the good features of the Northern motors prominently before the delegates.

The Crocker-Wheeler Electric Company was represented by Mr. Julian Roe. Mr. Roe did some active hustling and reports the business of the C. W. Company in a very prosperous condition.

Mr. James Wolff, Chicago manager of the New York Insulated Wire Company, was able to spend but a few hours at the convention; these few hours, however, were very much appreciated by "Jim's" friends.

The Siemens & Halske Company, in Mr. McGill had a representative who was much in demand, particularly to answer enquiries concerning 220-volt plants, which were so often referred to in the papers read.

Everybody was glad to see "Commodore" Col. Copeland, of the "Upper Mississippi River Squadron." This genial gentleman will be long remembered for his unbounded hospitality at La Crosse last summer.

There may be others but L. W. Burch, of the Electrical Supply Company, of Madison, was one of the most popular attendants at the convention. Mr. Burch has the honor of being the oldest electrical traveling salesman in the northwest.

McGill & Pomeroy, of Chicago, who sell railway supplies, porcelain, water motors, etc., arrived at the convention in detachments—that is, Pomeroy got there first and McGill came after. As one delegate expressed it, this couple make a "warm team."

Mr. W. M. Smith, of the Chicago Insulated Wire Company, spent Thursday at the convention. Mr. Smith reports the demand for insulated wire very satisfactory, and says he has every reason to believe the coming season will be one of the best in their history.

Prof. Dugald C. Jackson, of the University of Wisconsin, took in the convention. He states that the University has its full quota of electrical and engineering students, the University having at present about all that can be conveniently handled with satisfaction.

Mr. Thomas R. Mercein, in his usually pleasant manner, added to his list of friends many who before knew him only by reputation. He endeavored to assist every one in having a good time, and he succeeded in making the convention a meeting long to be remembered.

Mr. H. J. Gille, the St. Paul representative for Washburne & Moen Company, has a "wire" on a host of friends aside from the large number who purchase his trade wire. Mr. Gille is one of the enterprising, up-to-date men of the Northwest, and has the best wishes of a host of friends.

The Cloos Electrical Engineering Company, Milwaukee, exhibited a primary switch for a two-phase alternating system; also a line of alternating direct-current junction boxes, a single wire direct coupling box, a double wire alternating coupling box, and a house lamp-post direct series switch.

Mr. John S. Maurer, of the Crouse-Tremaine Carbon Company, Fostoria, O., had a kind word and a hearty hand-clasp for all of his many friends. The Fostoria Incandescent Lamp Company, Fostoria, O., are to be congratulated on having such an enthusiastic and capable representative as Mr. B. M. Myers proved himself to be.

Rohn & Meyer, Milwaukee, had on exhibition a line of Helios incandescent arc lamps, consisting of 5 and 3 ampere, 220-volt, single alternating 100-volt. These lamps are claimed to be the longest burning arc lamps on the market, and direct current lamps burning 175 to 200 hours and alternating lamps burning 100 hours.

Association Recruits. To no one is more credit due for their able efforts in keeping a watchful eye upon the membership rolls of the convention than Mr. Thomas R. Mercein, Mr. Joseph M. Hill and Mr. W. W. Low. Nearly 50 new members were brought into the convention through the efforts and recommendations of these gentleman.

Mr. W. L. Church, general manager of the lighting department of the Milwaukee Lighting & Railway Company, spared no effort in furthering the pleasure and entertainment of the delegates. Mr. Church had charge of the local theatre party, and through his efforts many acqaintances were made and many pleasant hours passed.

Mr. G. F. Whitfield, of Milwaukee, attended the convention. Mr. Whitfield has just received the appointment as state representative for the Columbia Incandescent Lamp Company, St. Louis. This gentleman also represents Pass & Seymour, of Syracuse; Queen & Company, Philadelphia, and the Simplex Electric Company, of Chicago.

"Uncle" Geo. Searing and "Papa" Ned Grier, the two great switch men of the Northwest; the former representing Hart & Hageman, of Hartford

Conn., and the latter of the Bryant Electric company, of Bridgeport, Conn., occupied Room 118, Hotel Pfister. This is another great illustration of the "Lion and the Lamb lying down together."

The Electrical Engineering Company, of Minneapolis, had its interests well looked after by President F. Morgan Brooks, aided by C. R. Gilman. Mr. Brooks reports the business of the Electrical Engineering Company as being in a very prosperous condition, and he was much elated over the splendid prospects in evidence for his company for the coming season.

George W. Patterson was present as representative of the Medbury railway supplies, American Circular Loom conduit, Gordon-Burnham and Law primary batteries and the Ohio storage battery. That Mr. Patterson made good use of his time in Milwaukee was evident from a large order that he secured from the Milwaukee police department for Gordon-Burnham batteries.

Mr. Chas. E. Gregory, of the Elliptical Carbon Company, of Chicago and Cleveland, attended the convention in all his pristine glory. Mr. Gregory did not attempt any elaborate exhibit, but the search light which he had mounted at the distant end of one of the corridors, beamed upon the convention in as brilliant and kindly a manner as did Mr. Gregory himself.

Genial Tom Ferris, Wisconsin representative for the General Electric Company, proved a host in himself. Everybody who knows Tom Ferris, knows something good about him, and it would be a disappointment indeed not to meet Mr. Ferris at the Northwestern convention. Mr. Ferris has, by his sterling ability and energy, acquired an enviable reputation as a salesman.

The Central Electric Company was represented by Mr. Chas. E. Brown, secretary, and by Mr. W. P. Upham. The exhibit consisted of an Edison Home Phonograph, an instrument especially designed for entertaining evening parties. This phonograph is remarkable for its distinct enunciation—in this respect it is unsurpassed. Room 6 was a centre of attraction, and the songs received many encores.

They say that "Tom" Grier "came up" to the convention on a boat. Mr. Grier arrived in a very spirituelle and generally "pale and interesting" condition. "Tom" says the night on the boat was worse than "a long and short man" hold-up in Chicago, because, when they hold up a man in Chicago all that he is required to do is to throw up his hands; this, however, did not seem to be the limit on the boat.

The Electrical Supply Company, of Madison, for the first time in the history of the convention did not make an exhibit. This is due to lack of time on account of the large amount of business this firm has been doing lately. However, they interested the members of the convention by distributing their new illustrated catalogue, which undoubtedly proved as attractive as an exhibit. Messrs. Burch & Stagg did the honors.

The McDermid Manufacturing Company was represented by Mr. C. L. Burlingham. Mr. Burlingham carried two tin boxes in his pocket; one box contained two sponges and a chamois skin; the other had some of his famous "cleanor." Mr. Burlingham demonstrated to the satisfaction of many of the central station delegates the fact that "cleanor" was a "good thing" for wood-work in cars, brass-work, etc. "Cleanor" is certainly a good article and was well represented by an able advocate.

"Billy" Lowe did not wait for anybody's old wagon to carry him, but waded right into the convention, after the genuine good time so characteristic with this gentleman. Mr. Lowe had a host of friends at Milwaukee who listened with interest and pleasure to his descriptions of the various good goods the Electric Appliance Company always has in stock. Unfortunately, Mr. Stacey, of the Electric Appliance Company, could not attend the convention, having been detained by the pressure of business.

The American Rheostat Company's exhibit consists of a ½-HP, 110-volt automatic starter, a 5-HP, 110-volt automatic starter, a 7½-HP, 110-volt automatic starter, and the front of a 100-HP, 110-volt automatic starter. Also a 5-HP, 220-volt automatic speed controller, a 40-KW, 110-volt rear of switchboard field rheostat, a 3-KW, 115-volt wall type field rheostat, a 10-HP, 220-volt reversible elevator controller, a 5-HP, 220-volt "Perfection" starter, a front for a 20-HP, 220-volt "Perfection" starter, and a controller for sewing machine work.

The Columbian Incandescent Lamp Company, St. Louis, Mo., had a full line of lamps, showing the regular lamps of their manufacture. An interestinfi feature was the exhibit of the materials showing the different stages of filament making; the liquid in its first stage, the threads before carbonization, the carbonized and treated filaments, etc. They also showed some of the original Goebel lamps, which attracted much attention. Mr. A. C. Garrison, secretary and treasurer; Mr. Geo. P. Rex, Chicago manager, and John E. Randall, factory superintendent, were present.

The Phœnix Glass Company, New York, Pittsburgh and Chicago, was represented by Western agent E. H. Fox, assisted by Chas. C. Frick. This company showed a full line of silver etched and cut-glass electric globes and shades of the most up-to-date patterns and styles of prevailing interior decorations. The "Glad hand" in the shape of a large opal glass hand was one of the most interesting features of the exhibit. This exhibit attracted considerable attention, especially as regarded the arrangement of the display, and many favorable comments were heard from the delegates over the representation tendered by the courteous gentlemen in R. 22.

The People's Electric Company, of Madison Wis. was ably represented by Mr. F. H. Ford and Mr. C. W. Bacon, who exhibited a Northern motor, which evoked considerable interest, and was especially admired because of its exquisite and handsome finish; this particular motor having been designed for the University of Wisconsin. They also had on exhibition the New Ritter "Time Saving Soldering Iron," an iron that is always hot, ready and reliable; Fagan combination cut-out and switch, and a regular line of electrical supplies comprised the balance of their exhibit. This exhibit was, perhaps, to central station delegates, about the most popular shown, and Messrs. Ford & Bacon are to be congratulated on the fine showing they made.

The General Electric Company, was represented by Messrs. F. N. Boyer, J. Scribner, R. A. Swain, from the Chicago office, and Thomas Ferris, of Milwaukee. The display of this company attracted much attention, and comprised all the latest types of electric lighting appliances and instruments. Among these were a direct current magnetic blow-out lightning arrester for use on circuits up to 850 volts, and also the Niagara type of Wirt lightning arrester. Several different types of arc lights were shown and also a new series arc cut-out and ceiling board. The new lamp inspectors' indicating wattmeter attracted marked attention, as well as the new electrostatic ground detector, and also a pocket case containing a complete set of repairing and adjusting tools for Thomson's recording wattmeter. Another feature that attracted attention was the display of the small direct-current motors ranging from ⅛ to 1 HP.

Mr. James C. Wormley exhibited a line of Wormley & Shelby lamps ranging from 200 to 250 volts and from ⅛ to 50 CP consisting of about 75 regular and 100 miniature lamps, no two of which were alike. Filaments were also shown in various stages of manufacture, and especial attention was called to the square cut filaments manufactured exclusively in this country by Professor A. A. Shaillet, technical manager of the Shelby Electric Company, and squirted cellulose filaments made by Jos. Hardwick, superintendent of the above company. The filaments were shown in a liquid form, before and after drying, carbonized, also mounted and treated The finished lamps were shown burning on a frame made expressly for the convention. The 3-watt, 220-volt lamps attracted a great deal of attention, as they were the first lamps ever shown in that efficiency of 220 volts.

The Dearborn Drug & Chemical Company, of Chicago, were most generous with souvenirs. They presented to the delegates a handsome silver-plated match-box, on the reverse of which was a very appropriate ad.; they also gave out a neat, serviceable paper-covered lead pencil; on each slip of the lead pencil cover being printed a separate and distinct advertisement of the Dearborn Company, so that every time the user sharpens his pencil, the merits of the Dearborn compounds will be kept prominently in mind. In addition to this, this company also presented a fancy letter opener and a neat blotting pad. Mr. W. H. Edgar was present and assisted by Mr. C. S. Kehler, the Milwaukee representative, made many friends among the central station men present. Mr. Edgar states that the sale of Dearborn compounds was never so large or prospects so bright as at present. The exceeedingly

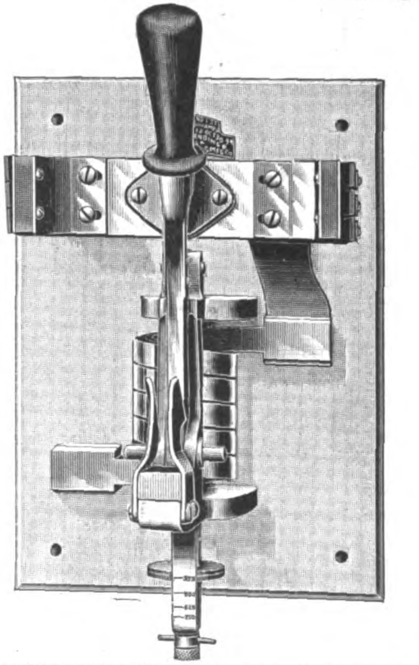
I-T-E Circuit Breakers



The above represents Instrument of from 100 to 1250 Amperes. Standard Switch-board Type, Single Pole, Direct Current.

Affording Protection against Grounds and Short Circuits.

A prominent English Engineer is quoted as saying he would not hesitate to short circuit any dynamo, provided it be safeguarded by an I-T-E Circuit Breaker. A large number of these safety devices are in use upon the switch-boards of the leading tramways and lighting stations in Great Britain.

The CUTTER ELECTRICAL & MFG. CO.

120 Liberty Street, New York.

large business, so rapidly built up by this company, seems marvelous to any one not fully acquainted with the sterling merit of the Dearborn compounds.

The Western Electric Company, New York and Chicago, was represented by Mr. A. L. Tucker, manager of the supply department, Mr. A. M. Little, M. W. Mixer and Thos. G. Grier. This company had a number of advanced sheets illustrating the new apparatus which it is putting on the market. The Western Electric Company is prepared to furnish for the coming year the most approved patterns and latest types of alternating current ceiling and desk motors, direct-current ceiling motors, wall bracket motors, desk and column fans and battery motors. It is unnecessary to remark that with the large representation they had present, nearly every delegate at the convention was informed regarding the new types of apparatus, as well as the line already carried in stock by the Western Electric Company. Manager of supplies, A. L. Tucker, in his quiet, courteous manner, added many new friends and customers to the already large list of the Western Electric Company, while that affable gentleman, Mr. A. McNab Little, did his share in his own peculiar style.

Heysenburg & Badt exhibited, in Parlor 7, samples of the H. & W. Company's supplies, in the shape of a hangerboard, spark arrester, commutator compound, and a composite dynamo brush. They also showed a lamp bank, containing a full assortment of the famous Hardy incandescent lamps, including 220-volt lamps. They also had on exhibition a line of the Weston Electrical Instrument Company's catalogues of all the Weston portable and switchboard instruments, including the famous Round Pattern switchboard, ammeters and voltmeters. These gentlemen also carried a full boxes, ventilating fans, speed regulators, theatre line of the Ward-Leonard Electric Company's circulars describing the well known Carpenter and the Ward-Leonard enamel rheostat starting boxes, ventilating fans, speed regulators, theatre dimmers, standard enamel resistance plates, etc., etc. Edison-Brown plastic rail bonds and elastic copper amalgam bond were also shown. Much interest was evinced by central station delegates in this company's exhibit of Helios lamps, which particular exhibit was looked after by Rohn & Meyer, of Milwaukee, the state agents for Wisconsin. The exhibit was in charge of Professor F. B. Badt and R. F. Schuchardt, of Chicago, assisted by Mr. Wm. Goltz, of Milwaukee.

The Fort Wayne Electric Corporation, of Fort Wayne, Ind., exhibited 110 and 220-volt D. C. arc lamps, and two alternating lamps, one of high and one of low frequency, enclosed type. This company operates alternating enclosed lamps in two different ways: one with an ordinary choke coil replacing the resistance used in D. C. lamps, and one in connection with a special constant-current transformer through which the lamp is operated direct from the primary mains, avoiding by this means all losses usually found in the resistance or choke coil of the lamp. The lamps shown were very ornamental in appearance, being made in several different finishes such as old iron, oxidized copper, oxidized brass, etc. This company also exhibited a line of meters embracing various sizes and voltages adapted for the variety of purposes to which meters are put

One of the nice features of one of the meters shown is the variable friction compensator with which it is equipped. This provides for the elimination of increasing friction brought about by constant use usually resulting from the jewels becoming rough. Another nice feature is its accuracy in voltages within a wide range from normal and still maintaining its straight line characteristic. These meters are dust and insect proof, and are provided with everything necessary to prevent tampering by meddlesome customers. The latest feature in the meter is the adoption of the new kilowatt hour reading dial. The exhibit was in charge of Messrs. F. S. Hunting, Thomas Duncan and A. L. Draffe.n

The Wagner Electric Company St. Louis, had its exhibit in charge of salesman manager, E. H. Abadie, assisted by Mr. J. H. Perkins. They exhibited a 15-HP alternating current, single-phase induction motor, belted to a 15-KW D. C. 110-volt generator. The 15-HP induction motor was operated from a standard 200-light, type G transformer. The Wagner Company connected in circuit 100-volt lamps and demonstrated the practicability of operating their single-phase induction motors on the same circuit and from the secondary of the same transformer, without detriment to the lighting service. This company also had in circuit on the secondary side, one of the illuminated dial, dead beat station voltmeters. Several of this company's new type of transformer were exhibited, and a 30-lt. type F.; an 80-lt. type G and a 40-lt. type F.; also a line of switches and tablet boards and special pole or line switch. They had in addition a number of photos showing the general construction of case and core of a 40,000-volt transformer of 330-KW capacity, constructed for a transmission plant in Utah, which plant proposes by means of this apparatus to transmit current 54 miles from the source of generation, to be utilized for lighting and motor work; also general views of the factory and of 3 D C. 110-volt slow-speed motors of 5-, 7½- and 15-HP capacity, which they recently sold to Messrs. Rohn & Meyer, Milwaukee, for installation in the Baltz Hotel, Milwaukee. A very handsome souvenir was also distributed in the form of a calendar comprising photos of the various specialties manufactured by the Wagner Company.

BUSINESS NOTICE.

A TECHNICAL EDUCATION 10 CENTS A WEEK

The new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary textbooks.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 48 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

THE ONLY WATER-WHEEL GOVERNOR THAT GOVERNS.

WATERVILLE AND FAIRFIELD RAILWAY AND LIGHT CO.,
Waterville, Me., January 18, 1896.

LOMBARD WATER-WHEEL GOVERNOR CO.,
Boston, Mass.

Gentlemen: In regard to your Type C Governor, which is regulating for us our two Hercules Wheels which give power to operate our light plant, street railroad and power generator, we are frank to admit that THE MACHINE DOES ITS WORK ADMIRABLY. We have no hesitancy in recommending it to those in want of a Governor.

Yours truly,
(Signed) I. C. LIBBY,
President Waterville and Fairfield Railway and Light Co.

LOMBARD WATER-WHEEL GOVERNOR CO., 61 HAMPSHIRE ST., **BOSTON, MASS.**

HELP WANTED.

WANTED—Competent man to take charge of Electrical Repair Shop in the West. Salary, $125.00 per month. None but thoroughly competent man need apply. Address, giving references, "M," care AMFRICAN ELECTRICIAN, New York.

WANTED—Armature and Field Winders acquainted with both bar and coil construction. Address "ARMATURE," care AMERICAN ELECTRICIAN, New York.

WANTED—Engineer in an Electric Light Plant. Must take moneyed interest. State age, experience and references. Address, EXPERIENCE, care of AMERICAN ELECTRICIAN, New York.

WANTED—A practical and experienced electrician to take charge of the Electric Light and Water Works plant of the City of Alexandria, La. Permanent situation. Address with references and amount of salary wanted to W. C. JOHNSON, Secty. City Elec. Light & Water Works, Alexandria, Rapides Parish, La.

SITUATIONS WANTED.

WANTED—A well known constructing engineer of electric light and power plants, desires position as superintendent or chief engineer. Understands all kinds of windings and repair work. Can furnish the best of references. Address "ENGINEER," care AMERICAN ELECTRICIAN, New York.

FORECLOSURE SALE.—An opportunity for investors is offered in a well-equipped electric lighting, power and street railway plant at Lynchburg, Va. The plant is offered at foreclosure, to be sold February 28. Information can be obtained from TYREE & WILKINS, Real Estate Agents, Lynchburg, Va.

"A COLLEGE EDUCATION BY MAIL."

ELECTRICAL ENGINEERING TAUGHT BY MAIL FOR LESS THAN 7 CENTS A DAY.

STUDY AT YOUR OWN HOME by enrolling in THE HOME SCHOOL OF ELECTRICAL ENGINEERING.

The tuition fee can be paid either in advance or in installments, by paying **$2** when enrolling and the balance at the rate of **$2 a month,** which is **less than 50 Cents** a week. This includes all Text Books and Drawing Plates, and a complete set of Electrical Experimental Apparatus.

The tuition fee for the course, once having been paid, in cash or in installments, entitles you to instruction until you have satisfactorily completed each subject in the course, even if it takes five years or more to finish it.

The following courses are taught in The Home School of Electrical Engineering:

Complete Electrical Engineering. **Electrical Station Engineering.** **Complete Station Engineering.** **Electric Lighting.** **Electric Railways.** **Telegraphy and Telephony.** **Electroplating.**

Besides these we teach courses in the Home Schools of Mechanical, Steam, Civil and Sanitary Engineering, and in the Home Schools of Art, Architecture and Trades. WRITE FOR CIRCULAR P and state in what subject you are interested. This circular contains sample Instruction and Question Papers, list and prices of courses, and a sample drawing plate.

CLASSIFIED LIST OF ELECTRICAL BOOKS.

Any book on this list (or any electrical book in print) will be sent, post paid, upon receipt of price.

DYNAMO TENDERS' HAND BOOKS.

Badt's New Dynamo Tender's Handbook. 226 pages. 140 illustrations. Price, $1.

Contains instruction for the management of dynamos, correction of troubles, etc,

Bottone's How to Manage a Dynamo. 66 pages, 9 illustrations. Price, 60 cents.

An English work intended by the author for the use of stationary and marine engineers who may find themselves suddenly called upon to undertake the management of a dynamo.

Crocker and Wheeler's Practical Management of Dynamos and Motors. Fourth edition. 206 pages, 99 illustrations. Price, $1.

A practical manual on the operation of dynamos and motors. the localization and remedy of faults, testing, etc. The opening chapters explain the principles and construction of dynamos and motors, methods of installation, etc. The final chapters are on machines requiring special directions for operation, such as the T.-H.

Desmond's Electricity for Engineers. 424 pages, 131 illustrations. Price, $2.50.

Contains descriptions of various types of continuous and alternating-current machinery, with simple explanations of principles.

Gibbing's Dynamo Attendants and Their Dynamos. 58 pages, 14 illustrations. Price, 50 cents.

A practical book on the management of dynamos, written by the electrical engineer of an English municipal lighting plant.

Guy's Electric Light and Power. 352 pages, 47 illustrations. Price, $2.50.

Gives the author's experience of several years in English central-station work, with practical explanations of elementary electrical principles.

Lummis-Patterson's Management of Dynamos. 214 pages, 81 illustrations. Price, $1.50.

An English book on the elementary principles of the dynamo, with practical directions for its management.

20

MacFadden and Ray's Practical Application of Dynamo-Electric Machinery. 167 pages, 38 illustrations. Price, $1.

Gives simple explanations of elementary electrical principles, and describes various types of commercial apparatus.

May's Electric Light Plant. Price, $1.

An English book of instructions for the operation of electric-lighting plants.

Paterson's Management of Dynamos. 214 pages, 81 illustrations. Price, $1.

A handbook, by an English author, intended for the use of those in charge of dynamos. Also contains simple explanations of electrical principles.

Regan's Handbook of the Brush Arc System. Price, $1.

Includes a revolving mica representation of a Brush commutator, whereby the principle of the Brush type of dynamo may be easily understood.

Stephen's Wrinkles in Electric Lighting. 45 pages, 23 illustrations. Price, $1.

An English book of practical information on the management of dynamos, etc.

The AMERICAN ELECTRICIAN contains in every number articles relating to the operation of central station, electric railway, and isolated electric lighting plants. One of its features consists of articles and notes on practical expedients, apparatus and line repairs, detection and remedy of faults, etc.

21

ELECTRICAL MEASUREMENTS.

Bottone's Electrical Instrument Making for Amateurs. 175 pages, 48 illustrations. Price, 50 cents.

Contains instructions for making simple electrical apparatus.

Carhart and Patterson's Electrical Measurements: A Laboratory Manual. 344 pages, 142 illustrations. Price, $2.

Intended for college use, but answers many of the purposes of an industrial treatise.

Crapper's Practical Electrical Measurements. 125 pages, 56 illustrations. Price, 75 cents.

An elementary text-book, intended more particularly for school instruction.

Everett's Units and Physical Constants. 200 pages. Price, $1.25.

An authoritative compilation of physical constants and systems of units used in physical science, including electricity and magnetism. For electricity the constants for specific resistance, specific inductive capacity, contact and thermo-electric differences of potential, electrochemical equivalents, etc., are given.

Frey's How to Use Electric Measuring Apparatus. Price, 50 cents.

A manual of practical information relating to electrical testing.

Haskin's Galvanometer and Its Uses. 74 pages, 8 illustrations. price, $1.50.

Describes apparatus and gives some information concerning principles and practice of electrical measurement.

Houston's Measurement of Electric Currents, and other Advanced Primers of Electricity. 429 pages, 169 illustrations. Price, $1.

Contains simple explanations of the various methods of measuring electrical currents, E. M. F., resistance, etc., with descriptions of apparatus. Intended for popular reading and for use by beginners in obtaining familiarity with the first conceptions of electrical science.

22

Kempe's Handbook of Electrical Testing. Fifth Edition. 576 pages, 200 illustrations. Price, $7.25.

The standard English treatise on electrical testing. Deals principally with telegraph, cable and laboratory testing.

Nichols' The Galvanometer. 112 pages, 77 illustrations. Price $1.

Gives the mathematical theory of the galvanometer and describes the construction and manipulation of various types.

Parker's Systematic Treatise on Electrical Measurements. 120 pages, 100 illustrations. Price, $1.10.

Treats more particularly of methods used in laboratory, telegraph and cable testing.

Price's Treatise on the Measurement of Electrical Resistance. 199 pages, 70 illustrations. Price, $3.50.

A treatise on refined methods of accurate measurement of resistances.

Swinbourne's Measurement of Electric Currents. 237 pages, illustrated. Price, 50 cents.

Reprints of English papers on the measurement of electric current and electrical energy, with descriptions of apparatus.

Webb's Testing of Insulated Wires and Cables. 118 pages, 38 illustrations. Price, $1.

Descriptions of testing instruments, with instructions for their use in testing the insulation, resistance and capacity of conductors.

Alternating Currents

are treated more fully, simply and practically in the columns of the AMERICAN ELECTRICIAN than in any other Electrical Journal published.

23

PRIMARY AND STORAGE BATTERIES.

Benjamin's Voltaic Cell. 562 pages, 200 illustrations. Price, $5.

A comprehensive treatise on the voltaic cell, both primary and secondary batteries being included under that term. The various accepted theories are explained and discussed, and the construction and action of all the more important cells described.

Carhart's Primary Batteries. 181 pages, 67 illustrations. Price, $1.50.

Gives the theory of primary battery in simple language and describes the various practical forms of cells. A very satisfactory treatise on the subject.

Le Blanc's Elements of Electro-Chemistry. 284 pages, 33 illustrations. Price, $1.50.

The best elementary treatise on the modern theory of voltaic cells and of electrolysis.

Plante's Storage of Electrical Energy. 268 pages, 89 illustrations Price, $4.

Account of investigations and experiments that led to the modern storage battery.

Salomon's Electric-Light Installations. Vol. I. The management of accumulators. Seventh edition. 104 pages, 33 illustrations. Price, $2.

An excellent book for those in charge of an isolated storage-battery plant. The information contained has been largely derived from direct experience with a very complete plant of this class.

Warwick's How to Make and Use the Storage Battery. 140 pages, 22 illustrations. Price, $1.50.

Describes several types of storage batteries and gives some information in regard to their use.

THE

American Electrician

has the Largest Paid Circulation of any electrical journal in the world.

24

ELECTRO-PLATING.—ELECTRO-CHEMISTRY.

Bonney's Electro Plater's Handbook. 208 pages, 60 illustrations. Price, $1.20.

An elementary manual for amateurs and young students.

Gore's Art of Electrolytic Separation of Metals. 301 pages, 106 illustrations. Price, $3.50.

Deals with the principles concerned in the electrolytic separation of metals and with their practical application on a commercial scale. An English work.

Gore's Theory and Practice of Electro-Deposition. 132 pages, 35 illustrations. Price, 80 cents.

Contains practical instructions for carrying out the various processes involved in electro-plating.

Langbein and Brannt's Electro-Deposition of Metals. 458 pages, 138 illustrations. Price, $4.

A full and practical treatise on electro-plating, the deposition and coloring of metals, with descriptions of the electrical apparatus employed. An American work.

Lupke's Elements of Electro-Chemistry Treated Experimentally. Price, $3.

A translation from the German.

McMillan's Treatise on Electro-Metallurgy. 387 pages, 101 illustrations. Price, $3.50.

A technical manual on electro-plating, electrotyping, electro-deposition, and electro-metallurgical extraction and refining processes. The treatment of the various subjects is practical and detailed, and in a glossary the various chemicals and substances used in the different processes are described and directions given whereby their purity may be tested.

Urquhart's Electro-Plating. 226 pages, 24 illustrations. Price, $2.

A compilation of practical information on the deposition of metals, with descriptions of apparatus.

Watt's Electro-Metallurgy Practically Treated. 225 pages. Price, $1.

A practical handbook on the electro-deposition of copper, silver, gold, brass, bronze, zinc, nickel and iron.

OTTO Gas and Gasoline **ENGINES**

IN

ELECTRIC LIGHT PLANTS.

IF LOW COST OF RUNNING INTERESTS YOU, WRITE US.
CAN REFER YOU TO PLANTS USING UP TO 300 H.P.

THE OTTO GAS ENGINE WORKS,
PHILADELPHIA.

245 Lake Street, CHICAGO. | 39 Cortlandt Street, NEW YORK. | 19 Pearl Street, BOSTON.

WHY IS THE SINTZ MARINE ENGINE THE BEST?

1. It gives more actual power for the cost of running than any other engine on the market. We know others claim this, but we develop it.
2. It occupies less space and weighs less per horse power.
3. It requires no boiler, coal, wood or fireman.
4. It does not require a flame to ignite the charge.
5. It is absolutely safe, because the gasoline is always confined, never being exposed to a flame.
6. It can be, and is, run at higher speeds and maintains regular explosions.
7. It is practically free from all valves, and has less than one-half as many parts as any other engine, and only three moving parts.
8. It is clean—no dust, no dirt, no offensive odor and nothing to soil the clothes.
9. It only requires half a minute to start, and runs equally as well in cold weather as in warm.
10. It requires no government inspection, no licensed engineer or pilot.

Transformer Economy

The Diagram shows part of the map of Conshohocken, Pa., where **25 Small Transformers** (●) were replaced by **2** of our **Type H** (■) Transformers.

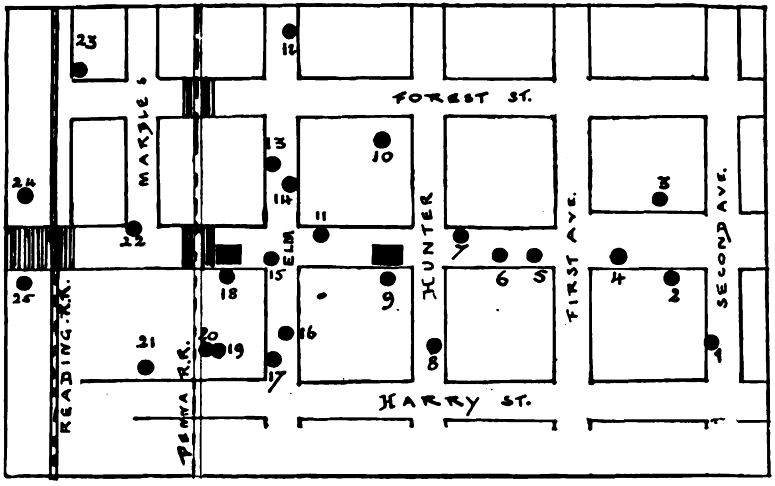
The table shows the actual performance of these Small Transformers.

The Result of the Change:

Core loss of 25 Small Transformers	1664
Core loss of the 2 Type H Transformers	238
Saving in Watts -	**1426**

You cannot afford to continue the use of old, small, individual Transformers, when a change to new methods will bring about such results.

It will pay you to use **Type H Transformers.** You can operate your plant with less Coal, with greater safety, with better regulation, and increase the station capacity by the amount saved in core losses.



THE CHANGE AT CONSHOHOCKEN, PA.

Location See Diagram	Transformer Capacity 16 C.-P. Lamps	16 C.-P. Lamps Connected	Watts Core Loss

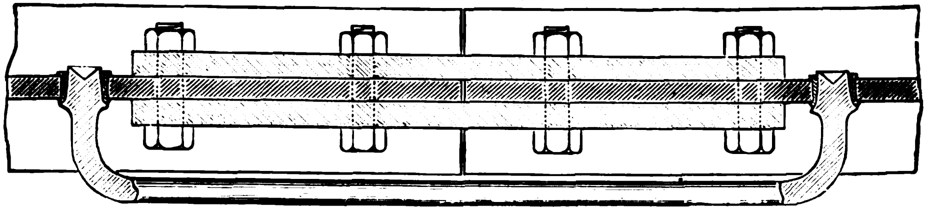
THRESHER ELECTRIC COMPANY,

DAYTON, OHIO, U. S. A.

The Columbia Bond Saves Coal.

It has a perfect contact of seven times the section of the road.
You can twist off the wire, but you cannot loosen the contact.
It consists of as few parts as any satisfactory bond can contain.



It has all the advantages which may be claimed for a one-piece bond, and at the same time be satisfactorily installed, as no riveted bond can be.

HIGH AND LOW WATER ALARM

Something New The Englehardt Safety Electric Water Column.

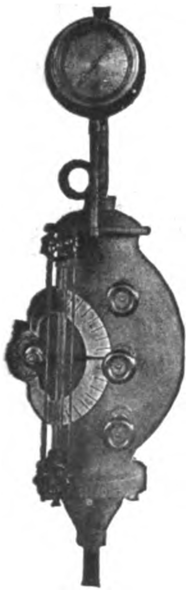

FIG. 1.

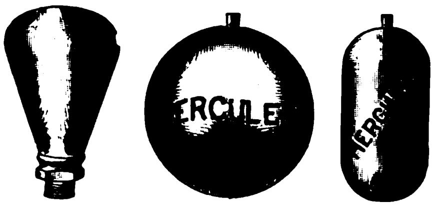

FIG. 2.

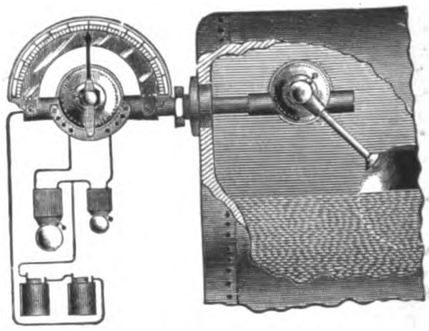

FIG. 3.

This safety electric water alarm is the best safeguard ever invented for the protection of human beings from steam boiler explosions. Can be placed on any boiler and takes up no more space than the ordinary column. The indicator shows at all times the height of the water and serves as a check on the gage glass. The alarm may be sounded in many different parts of a factory, or separate buildings. No public building is complete without one.

Fig. 3 shows our water alarm attached directly to a boiler, without the column. It cannot become clogged up with scale, as whistle alarms do. The very best materials used in all alarms, which are carefully tested before shipping, and warranted.

Hercules seamless copper floats and air chambers for all high pressures.
Floats of special shape made to order.

SAMSON TURBINE

WATER WHEELS

ADAPTED TO ALL HEADS FROM

3 FEET TO 2000 FEET.

ESPECIALLY ADAPTED TO ALL KINDS OF

Electric Power and Lighting Plants.

Recent tests at Holyoke enable us to guarantee:

The largest power ever obtained from a wheel of the same diameter. The highest speed ever obtained for the same power. The highest mean efficiency when running from half to full gate. We guarantee also: *A runner of the greatest possible strength. A gate unequalled in quickness and ease of opening and closing.*

Our experience of **36 years** building water wheels enables us to suit every requirement of water power plants. We guarantee satisfaction. Send for pamphlet of either wheel and state your **head** and full particulars.

AUTOMATIC STEAM ENGINES

WATER-POWER LIGHT AND POWER PLANT FOR A SMALL TOWN.

DELTA LIGHT AND POWER PLANT.

BY S. H. DAILEY.

While the water power electrical generating plant described herewith is not one of large power, it is notable for excellent design and the efficient manner in which all of the local conditions have been met, both with respect to generation and distribution.

The town of Delta, which the plant supplies with light and power, is located in the extreme southeast corner of York County, Pennsylvania. The stream—Muddy Creek—which supplies the power, drains the entire southeast section of York County, and even in the dryest season has a sufficient supply of water to furnish 1000 h.p. for a ten-hour daily run.

The power house is situated near what was at one time a natural waterfall of 20 ft., now covered by the dam.

Figs. 1 and 3 give a general view of the power house and dam. The location is an ideal one for the plant, having the advantage of bedrock for foundations of building and machinery, as also for an anchorage for the dam. At present, having only been in operation a few weeks, the power is being used in Delta for commercial and street lighting, running a pump for town water supply, furnishing power to a planing mill, printing office and other manufactures. As soon as the weather permits extension of the transmission lines, power will be furnished to the slate quarries in the vicinity, which are the largest roofing slate quarries in the country.

The dam is built on the crib pattern, being 35 ft. wide at the base, and 130 ft. at top, having a height of 41 ft. White and rock oak timber, 10 to 15 ins. square, securely pinned together with ⅞ in. square iron pins, is used for the cribbing, the foundation timbers being bolted to bedrock and those of the ends meeting solid rock, where they are firmly anchored. Fig. 3 shows the top of the dam.

The plan of the dam is that of a V of an angle of 160°, the apex of which points up stream. With the natural anchorage afforded it at the ends, there is, therefore, little fear of its ever giving any trouble. The down-stream section has a batter of 7 ft. The crib is closely packed with broken stone. The face is planked with 2½ in. white oak, and to further prevent leakage these planks are covered with 1 in. boards, while beyond this is a filling of stone, gravel and earth, extending 30 ft. up stream and rising 45 ft. on the face of the dam. The top is covered with 3½ in. oak plank, laid ½ in. apart to allow water to keep the cribbing wet.

In order that the water may be drawn off at any time, there is a steel discharge pipe 4 ft. in diameter, with gate, placed near the bottom, and running from back through the filling on the face. The storage capacity is estimated at 39,600,000 cubic ft. of water.

The power house is 22 ft. by 44 ft, and is built of stone laid in Portland cement, and faced with the same inside and out. It is two stories high, the first or ground floor being in one room, and occupied by the power machinery and generator. A general view of the interior is given in Fig. 4. The second story is divided into store room and living apartments for employees. The foundations are laid on bedrock.

The turbines, of which there are a pair, are of the McCormick type, as manufactured by S. Morgan Smith, of York, Pa.

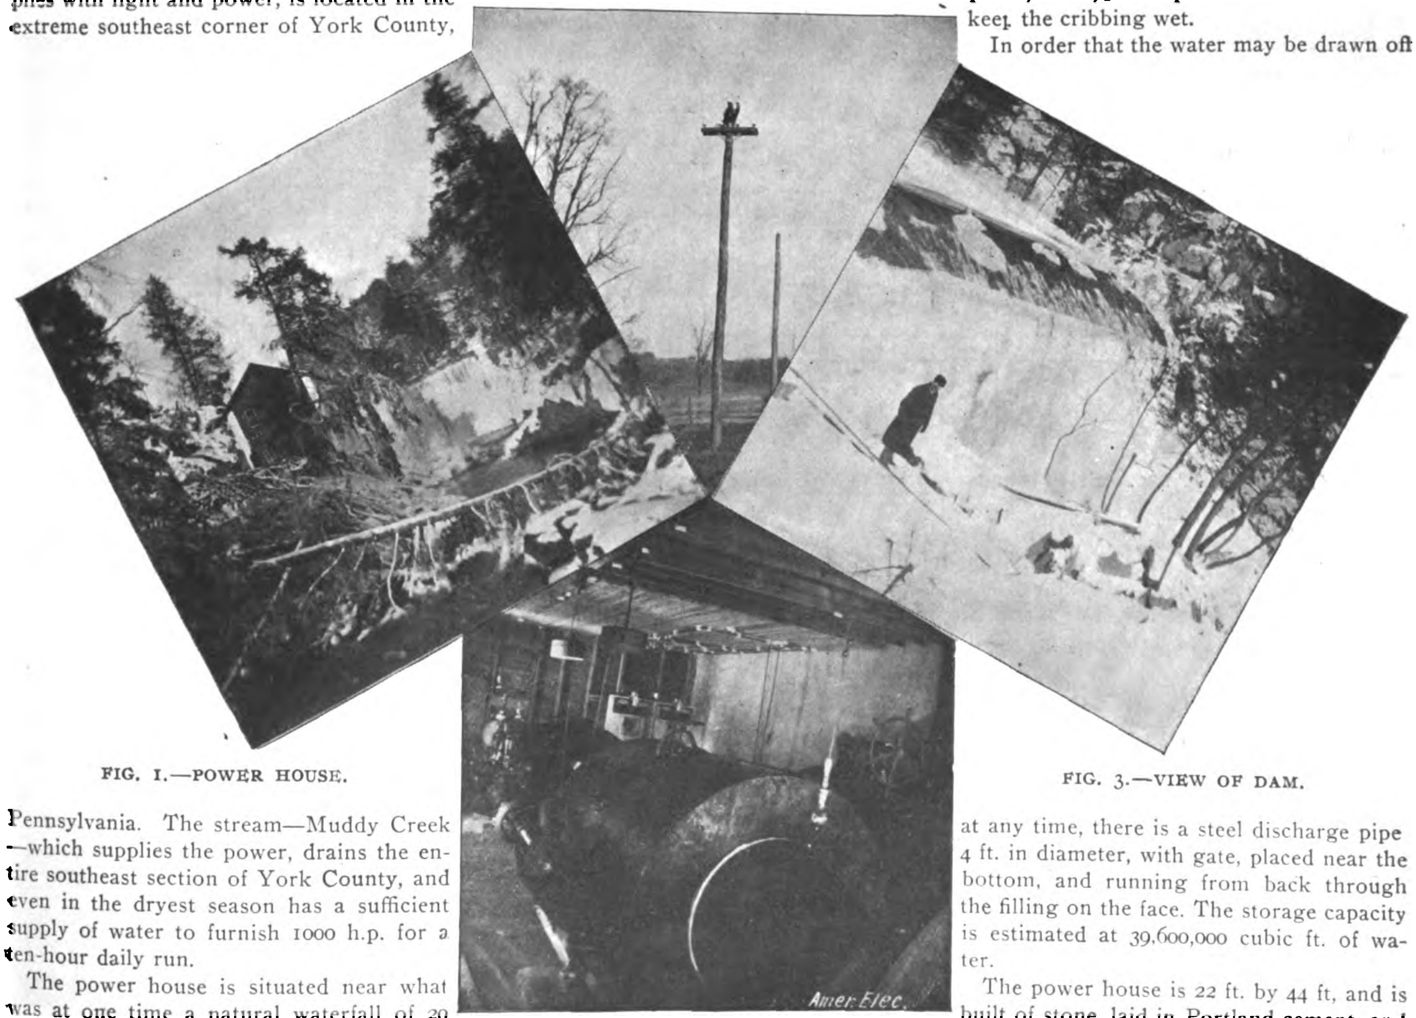

FIG. 1.—POWER HOUSE.

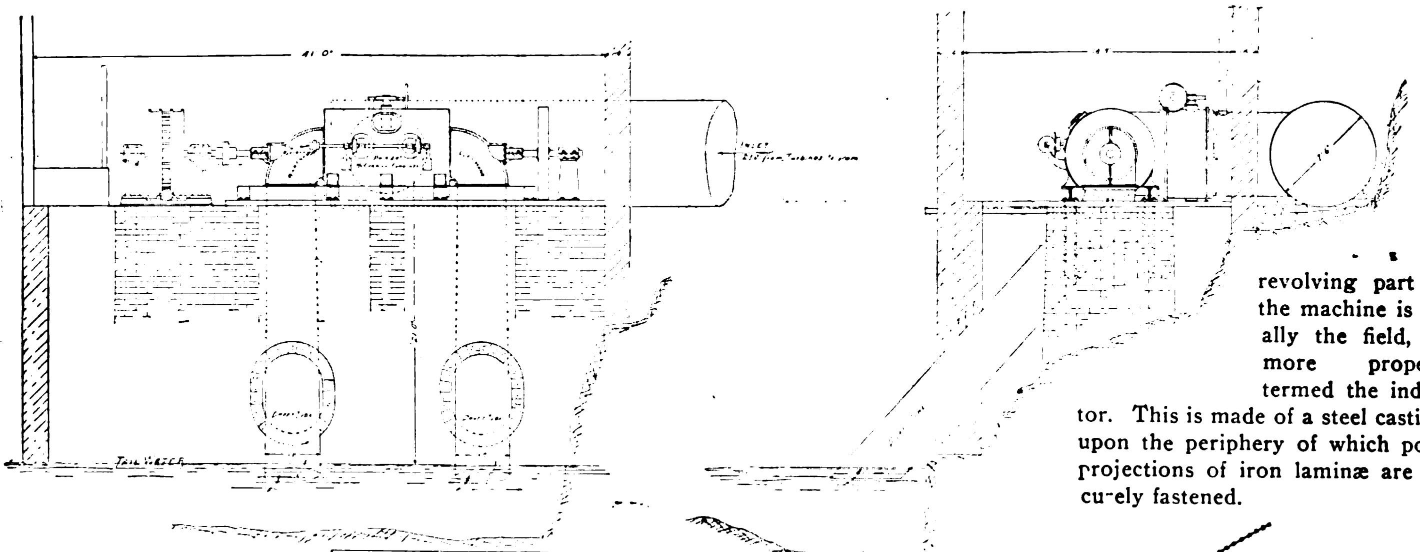
FIG. 2.—POLE LINE.
FIG. 4.—GENERATING ROOM.

FIG. 3.—VIEW OF DAM.

They are 24 ins. in diameter, and located one-half way between the surface of the water in the dam and the tail water, and with a 42 ft. head and 400 r.p.m., develop 575 h.p. As the general plan shows, the turbines are supplied with water from the dam, 250 ft. distant, by a steel tube 7 ft. 6 ins. in diameter, near the end of which, at right angle, is tapped a branch tube 6 ft. in diameter, leading direct to wheel casings. This 6 ft. tube is supplied with a gate valve in order that No. 1 wheel may be cut off from the supply pipe without affecting a second set of wheels, which will be installed at a later date. From the wheels the water is carried to the tail race by draft tubes 48 ins. in diameter. The efficiency of these wheels is rated by the makers at 85 per cent.



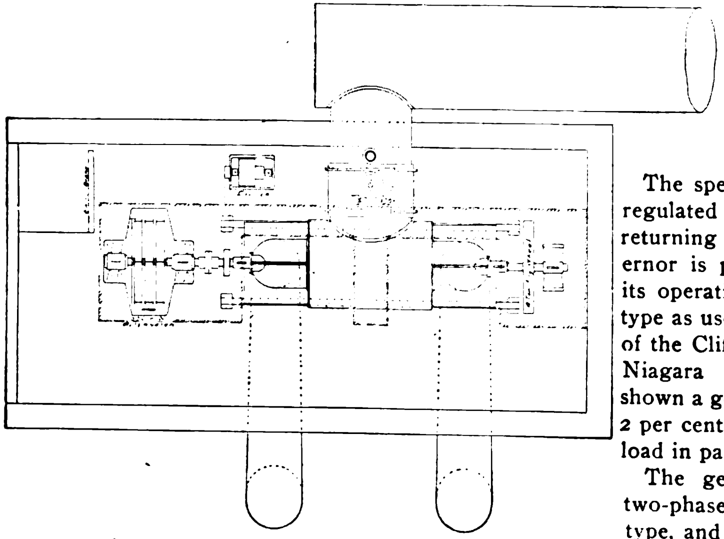


FIG. 6.—PLAN AND SECTIONS OF POWER HOUSE.

The speed of the turbines is regulated by a Replogle relay returning governor. This governor is purely mechanical in its operation and of the same type as used in the power house of the Cliff Paper Company at Niagara Falls, where it has shown a governing efficiency of 2 per cent from full load to no load in particularly severe tests.

The generator was of the two-phase alternating current type, and was furnished by the Stanley Manufacturing Company, of Pittsfield, Mass. It is designed to generate 350 k.w. at 5600 volts, with 800 alternations and a speed of 400 r.p.m. The generator is direct-connected to the shaft of the turbines by a flexible coupling. Fig. 10, showing the generator armature drawn out, gives a complete idea of the construction of the generator, showing, as it does, that simplicity and strength are striking characteristics—the wearing parts being only two journals. It has no moving wire, no collector rings and no commutator. The revolving part of the machine is really the field, but more properly termed the inductor. This is made of a steel casting, upon the periphery of which polar projections of iron laminæ are securely fastened.

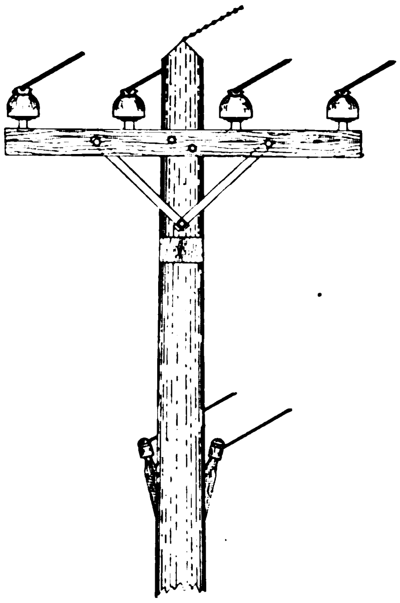

FIG. 5 —TRANSMISSION POLE.

The armature is made up of laminæ of iron, and the individual coils, wound separately on forms, are secured in grooves provided for them in the laminations.

The armature and field wires are brought out from the machine to a terminal board (Fig. 9), consisting of two heavy slabs of marble fastened to the machine. Owing to

the wide differences of loss in different lines and difficulty in balancing the load on different circuits, the E. M. F. of either of the two currents may be varied independently of each other by merely turning a handle at the terminal board one way or the other.

From this board the wires are led to the switchboard, which is of white marble and fitted with all the necessary switches, volt and ammeters, etc., a panel for each side of the machine.

The switches, current breakers, etc., are of a superior grade, and made absolutely safe for handling a current of such high voltage.

The static ground detector, Fig. 12, is used on this board, one on each side, and is fully described in AMERICAN ELECTRICIAN February, 1897. The exciter is of the multipolar type. From the power house to sub-station No. 1 is five miles, this being the length of the transmission line completed; it will, however, be extended 1.75 miles, to sub-station No. 2, as soon as the weather permits.

FIG. 9.—GENERATOR TERMINAL BOARD.

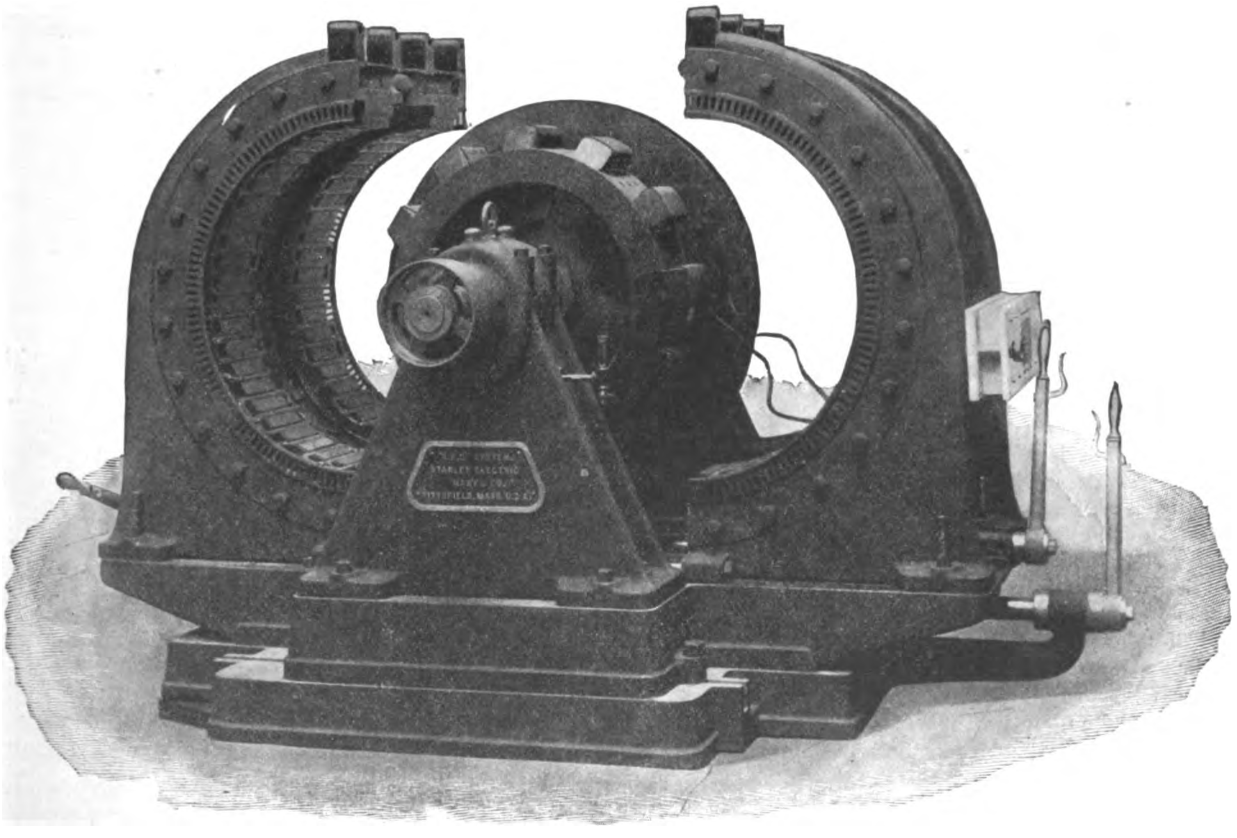

FIG. 10.—TWO-PHASE GENERATOR.

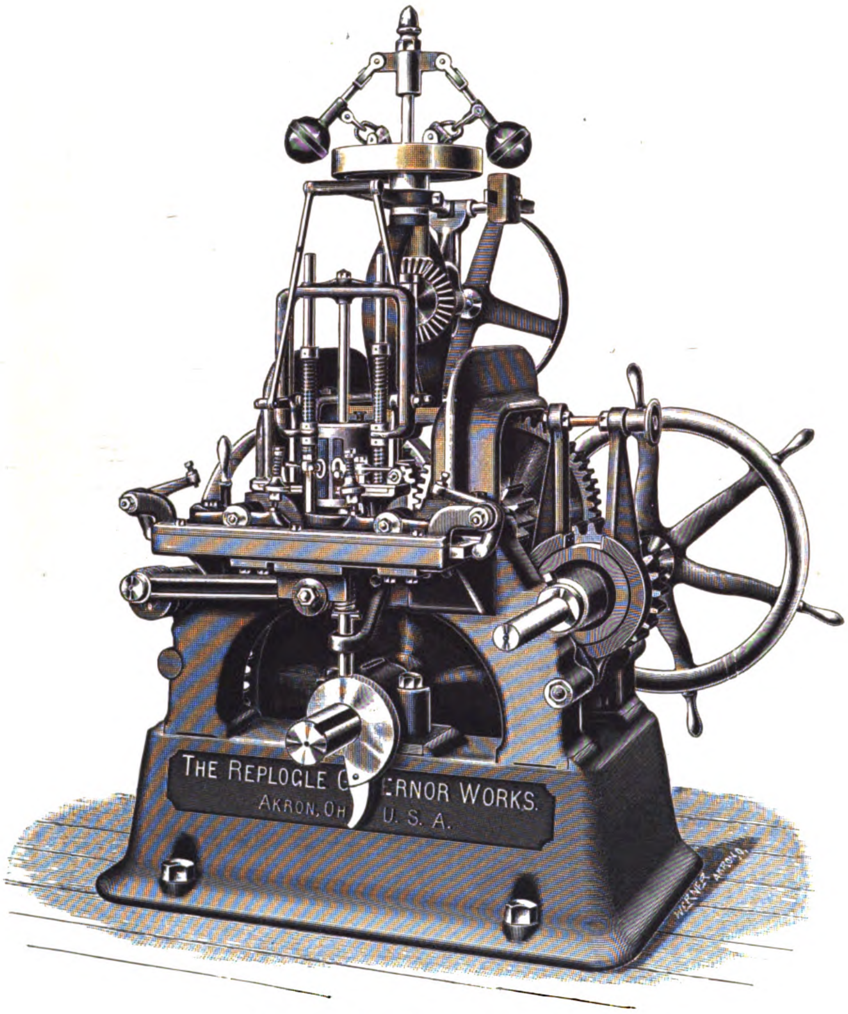
Chestnut poles are used, varying in length from 28 ft. to 40 ft., with a minimum diameter of 7 ins. at the top They are set 5 ft. in the ground, and all poles not in line are securely anchored or guyed with ¼ in. galvanized steel cable. The distance between poles in line is 100 ft., but at curves or at a turn, this distance is reduced, being 80 ft. in some cases and 90 ft. in others.

The cross-arms are of yellow pine, 5 ft. x 4¼ in. x 3¼ in., with locust pins, carrying four No. 4 B. & S. gage soft-drawn copper



THE REPLOGLE G
ERNOR WORKS.
AKRON, OH
U. S. A.

FIG. 11.—TURBINE REGULATOR.

wires, 18 ins. apart, one phase on each side of the pole. The cross-arm is let into a gain, 1 in. deep, and held there by two 7 in. x ½ in. galvanized lag bolts, the bolt being screwed in—not driven. To further support the arm, a pair of galvanized iron braces, 1½ in. x ¼ in. x 19 in., are bolted to it by ⅜ in. bolts, and toed to pole with one 3 in. x ½ in. lag bolt. The gain for a second cross-arm was cut at the time of construction, to be utilized when the plant is extended.

One transposition is made in the line about one-half way between the power house and the point of distribution.

The insulators, which were furnished by R. Thomas & Sons Company, East Liverpool, O., are of the triple petticoat type, 5 ins. in diameter, 5 ins. high, and weigh 5 lbs. each. The glazed surface between the pin and the wire is 11½ ins. All were subjected to a break-down test of 40,000 volts.

A barbed wire, strapped and stapled to the peak of the pole, is run the entire length of the line, and grounded at the butt of a pole every half-mile.

Six feet below the transmission line is run a private telephone line, connecting the sub-stations and power house. This line, which has a transposition every half mile, is also arranged to connect with the local telephone system when desired. The drop in the transmission line is 10 per cent.

Fig. 8 shows the manner in which power and light are distributed. At present there are in sub-station No. 1—located about the centre of Delta—three step-down transformers. Two are of 35 k.w., converting from 5000 volts to 450 volts, one on each phase, and supply power to manufacturers by four No. 2 B. & S. soft-drawn copper wires, constituting the main power line. From these feed wires are led two motors, of a size depending upon the power supplied. The other transformer is of 40 k.w., converting from 5000 to 1200 volts, and supplying current to a switchboard, which is in the same station, for the Delta Electric Light Company, a separate corporation, under whose supervision the commercial and street lights are managed.

It will be noticed that the 40 k.w. transformer is attached to one phase only. The danger of overbalancing the system by so doing is governed at the terminal board on the generator.

From the sub-station switchboard two No. 8 B. & S. insulated wires are run to four transformers of 100 lights capacity each, converting from 1200 to 220 and 110 volts, and placed upon the poles at such positions as to feed the main lighting circuit evenly.

The town line consists of six wires, and is run on two cross-arms, one two-pin arm on top carrying the primary circuit, and a four-pin arm below, which carries the secondary circuit of three wires for commercial service, and one for the street lights. The street lights, as shown in Fig. 8, are connected on the outside wire and one leg of the three-wire system, thus being on a 220-volt circuit, which is run to the switchboard and there controlled by an automatic switch, which shuts off the current at midnight.

In sub-station No. 2 will be placed, at first, two 60 k.w. step-down transformers, converting from 5000 volts to 450 volts, which will furnish power to slate quarries, each of which will use a 30 k.w. machine for hoisting, cutting and dressing slate.

This plant to-day is working in first-class order, and will prove, in a short time a good investment to the owners, the Delta Power Company. As soon as 400 h.p. of the present installment are contracted for, it is the company's intention to duplicate the present machines.

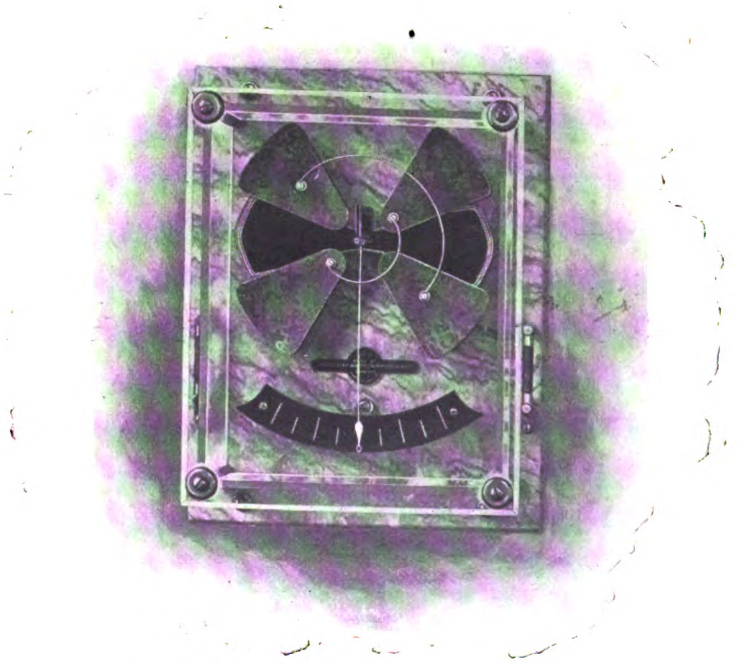


FIG. 12.—STATIC GROUND DETECTOR.

ARMATURE WINDINGS AND CONNECTIONS.

TWO LAYER AND MULTIPOLAR WINDINGS.

BY PROF. ARTHUR L. RICE.

In the first article were considered the conditions which must be fulfilled by a correct armature winding and the connections,

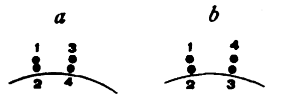

FIG. 1.—NUMBERING OF CONDUCTORS.

both lap and wave, for an armature with a single layer of wire. (It may be here noted that the caption of Fig. 7 should be "wave" instead of "lap" winding.) Few armatures are so made; it is generally necessary to use two layers of wire to get the E. M. F. required with a machine of reasonable size, and wire large enough to carry the current demanded. The process of connecting is the same, but requires some additional precautions.

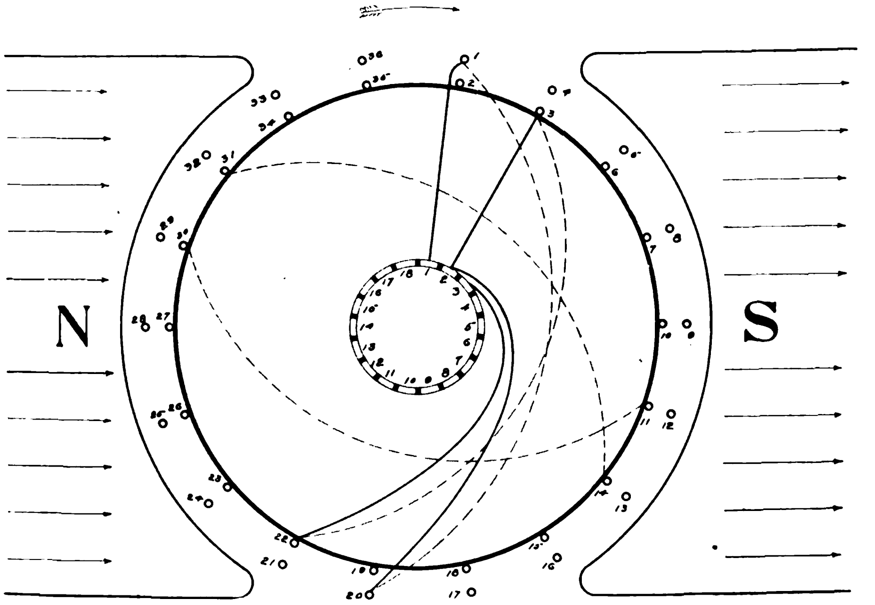

FIG. 2.—TWO-LAYER LAP WINDING.

Take the case of an armature for a dynamo having two layers of wire, 36 conductors, i. e., 18 coils and 18 commutator bars; the conductors will be placed two deep on the armature and standing opposite the bars. The winding may be on a smooth or a slotted core; in either case, the arrangement is the same. Either of the two methods of numbering, shown in Fig. 1, may be chosen. For the case under consideration it will be better to use (b), as the winding table is much more regular. It must be remembered that an inside conductor must connect on the back to an inside so as to make it possible to wind the coils, and the same for the outside conductors.

TABLE I.—LAP-WINDING CONNECTIONS.

"	18	"	"	35	"	"	18	"
"	1							

The winding to be considered is the lap form. Take a back pitch of 19 and a front pitch of 17, and suppose bar 1 to be connected to conductor 1, Fig. 2. Conductor 1 will connect to conductor 20, and both are outside conductors; the connection then goes to conductor 3 on the front. It would seem, at first sight, that the connections would be most symmetrical if conductor 20 is connected to bar 10; this would, however, give the full potential of the machine between bars 1 and 18, and is, therefore, unallowable. Conductor 3 is, therefore, connected to bar 2, and the connection from conductor 20 brought around by a long lead; the back connection is from 3 to 22, and so on, as given in Table I.

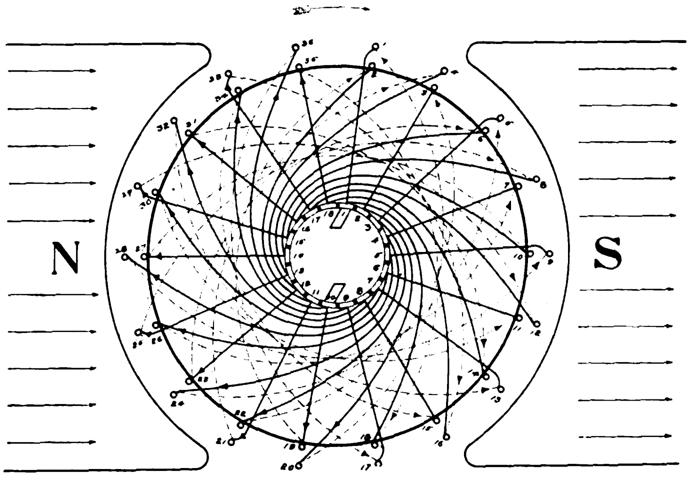

FIG. 3.—TWO-LAYER LAP WINDING.

The complete diagram is given in Fig. 3. By a consideration of the direction of current, as in the first article, it found that the brushes go on bars 1 and 10. This gives an equal number of conductors and coils by either path through the armature, and the two circuits will have the same E. M. F., because one of the two coils in the same slot is in one circuit, the other in the other. There is one objection; if Fig. 3 be inspected, it will be seen that the circuit leading from bar 1 through conductors 1, 20, 3, etc., has five outside coils and 4 inside; that leading through conductors 18, 35, 16, etc., has 4 outside coils and 5 inside. The former circuit will, therefore, have the greater resistance, but unless there be a great number of turns per coil, this will not be serious enough to need consideration.

In winding the armature, coil 3-22 should be wound first; next 2-19, next 14-31, and then 11-30 (the two latter being indicated).

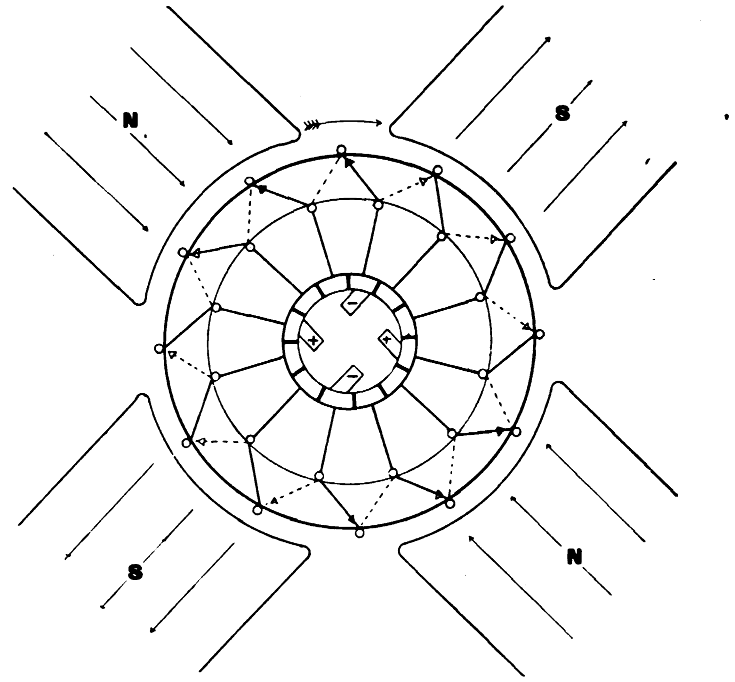

FIG. 4.—GRAMME RING FOUR-POLE WINDING.

then 11-30 (the two latter being indicated on Fig. 2), and so on, the back connections being carried on opposite sides of the shaft for successive coils, until all the inside coils are wound. Of the outside coils, 1-20 should go on first, next 4-21, next 12-29 and then 9-28, etc., until all the coils are in place. The long connecting leads should be soldered to the commutator first, and then the short ones. The object of winding and connecting in this order is to keep the same length of wire in each circuit, and to give mechanical symmetry and balance to the winding.

For a multipolar machine, the conditions which must be fulfilled are the same as for a bipolar. The Gramme ring form is the simplest in its connection. Consider Fig. 4; connections must be made, the same as in a two-pole machine, from the back end of one conductor to the front end of the one adjacent in order that the E. M. F.s generated may be joined in series. The inside conductors answer this purpose. If, however, the direction of the E. M. Fs. be traced out, it will be found that there are now four points instead of two where the currents from joined conductors tend to flow in opposition to each other; these points are nearly midway between the pole tips, as in the case of the bipolar machine; there will then be needed four brushes instead of two, and there will be four parallel paths for currents through the armature. Thus, a Gramme ring armature will answer for a two-pole or a four-pole machine without change, if the number of coils is divisible by four, the only condition being the addition of a second pair of brushes. Note that the positive brushes are opposite each other and the negative brushes the same, a positive being at 90 degrees from a negative. By analogy, a Gramme ring armature will run correctly in a machine with any number of poles, provided that the number of coils be divisible by the number of poles, and as many brushes be used as there are poles. The armature will also always have as many circuits in parallel as there are poles, and brushes of the same sign should be connected in parallel.

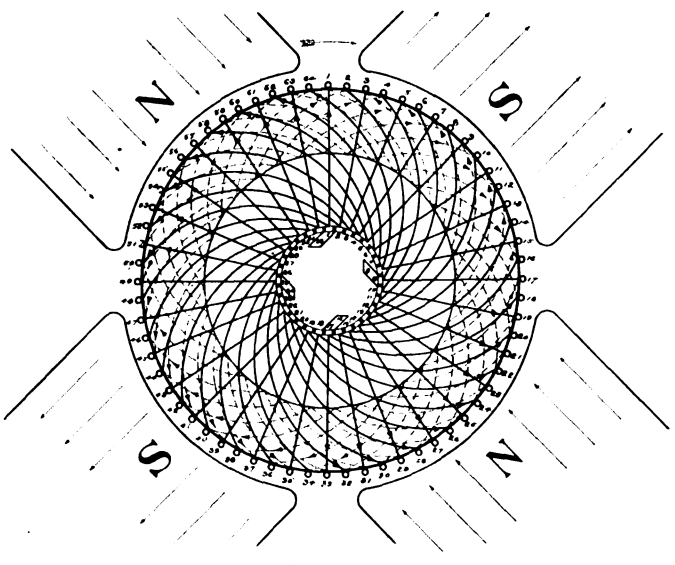

FIG. 5.—DRUM FOUR-POLE LAP WINDING.

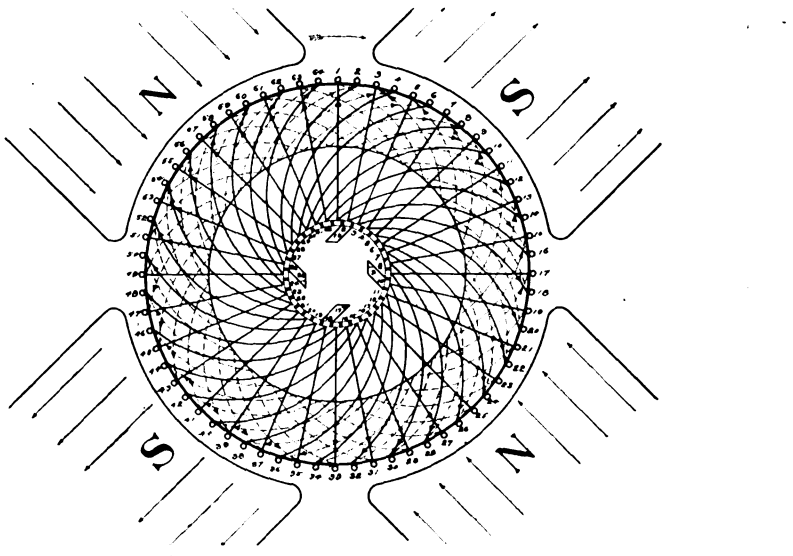

FIG. 6.—DRUM FOUR-POLE WAVE WINDING.

For a multipolar drum armature the end connections will be between conductors under poles of opposite sign, but not, as for a bipolar, at about 180 degrees apart. Take the case of a four-pole machine, to have 64 conductors in a single layer, the winding to be a lap connection and have a pitch of 15 back and 13 front; the odd number conductors being opposite the commutator bars, of which there are 32. Bar 1 will connect to conductor 1, thence to conductor 16, thence to bar 2, etc., Table II.

TABLE II.—MULTIPOLAR LAP-WINDING CONNECTIONS.

Bar		to conductor		back, to		front.
Bar	1	to conductor	1,	back, to	16,	front.
"	2	"	3	" "	18	"
"	3	"	5	" "	20	"

"	5	"	9	" "	24	"
"	6	"	11	" "	26	"
"	7	"	13	" "	28	"
"	8	"	15	" "	30	"
"	9	"	17	" "	32	"
	Etc.					

The complete diagram is given in Fig. 5. On consideration of the direction of current, the brushes would be placed on bars 2, 10, 18 and 26; brushes on bars 2 and 18 would be connected, and also those on 10 and 26. There would then be four parallel paths through the armature, and one-fourth the conductors would be connected in series in each path. If the armature is to be cable wound, having but a single turn per coil, the odd number conductors would all be laid in place with the end of the coil extending to the rear; these ends would then be bent around and laid in place, as the even number conductors, and each end connected to its proper bar. If there are to be several turns per coil, the winding would best be made of "formed" coils, that is, coils wound on a form so as to cover the space between 1 and 16, and laid on in order.

A machine of this character would almost always be made a two-layer machine, and could be more easily wound either in cable or formed winding. If a wave winding had been desired, the pitch would have been 15 front and back, and the connections would have been from bar 1 to conductor 1, to conductor 16, to bar 16, to conductor 31, etc., as shown in Fig. 6. The placing of the brushes will now be on bars 1, 9, 17 and 25, on account of the change of direction of currrent in conductor 1, due to change of pitch. There is one peculiarity to be noticed: in the case of the lap winding, the commutator bars are connected in successively—in the order of their position; in the wave winding, an odd numbered bar is connected up, then an even numbered bar nearly opposite; next an odd numbered bar nearest the first one, and so on. This is a peculiarity that will be noticed in all multipolar, multiple-circuit wave windings.

It is possible, by some combination of front and back pitch, to wind up any number of conductors which is divisible by the number of poles into a lap-wound armature. For a wave-wound drum armature, the following relations must always exist:

$$\text{Number of conductors} \begin{matrix}\text{plus}\\ \text{or}\\ \text{minus}\end{matrix} \text{number of circuits} = \begin{matrix}\text{number of poles*}\\ \text{times pitch.}\end{matrix}$$

From this condition is determined the average pitch, when the number of conductors and the number of circuits is given. Thus, for Fig. 7, February number:

---

* This may be expressed more briefly by the formula $C + K = ny$, where C = the number of conductors, n = the number of poles, y = the average pitch, K = the number of circuits in multiple.

$$24 + \text{or} - 2 = 2 \text{ times pitch.}$$
$$26 = 2 \times \text{pitch; pitch} = 13.$$
$$\text{or, } 22 = 2 \times \text{pitch; pitch} = 11.$$

In the case of Fig. 7, 11 was used. For Fig. 5,

$$64 + 4 = 4 \times \text{pitch}$$
$$\text{or } 64 - 4 = 4 \times \text{pitch,}$$
$$68 = 4 \times \text{pitch; pitch} = 17,$$
$$\text{or, } 60 = 4 \times \text{pitch; pitch} = 15,$$

and 15 was chosen.

The pitch thus determined is the average, and may be gotten by the use of any numbers for front and back pitch; thus, for Fig. 5, instead of using 15 front and back, 16 front and 14 back would have given an average of 15, and would have connected correctly.

◆

DESIGNING DYNAMOS AND MOTORS.

SMALL MOTORS.—II.

BY CECIL P. POOLE.

For the convenience of amateurs who are unaccustomed to such calculations as those presented in the preceding article, and who would, therefore, find the revision of the originally assumed figures burdensome, the writer has prepared tables showing economical fundamental measurements for motors of 1-16 to ½ h.p. to work on 110-volt, constant potential circuits. For machines to run on circuits of any other E. M. F. the slot measurements may require modification to suit the change in the size of armature wire, and in the case of very low voltages the length of the armature core may be reduced appreciably, because with larger wires the ratio of copper to insulation is much greater, and the slots contain a correspondingly large proportion of active material.

DATA FOR 110-VOLT MACHINES.

½	3.8	" 20	3⅞	2½	24	17/32	9/32	1450	3	7	2	3½	4 1/16

This increase in economy with increase in wire sizes is shown plainly in the tables above mentioned. In the case of ¼ and ½ h.p. armatures with 18 slots, for example, the diameter of the cores being the same, the length of the ½ h.p. core is only one-third greater than that of the ¼ h.p. core, and the speed is lower, which would tend to increase the armature length. This is due to the fact that the core will only accommodate 40 per cent more of No. 22 wire than of No. 20.

The greater economy of material obtainable in low voltage machines may be illustrated by comparing the 110-volt motor described in the February issue of this paper, with a machine of the same dimensions wound for battery current. The diameter of the armature is 2 ins., the length 1½ ins., and the number of slots 8. The lines of force passing through the armature were figured to be 89,743, and if the counter e. m. f. of the armature be put at 6 volts the number of wires required will be

$$\frac{6 \times 10^8}{89{,}743 \times \frac{2000}{60}} = 134 -.$$

There being 8 slots, 16 wires may be wound in each, making the total number 128 instead of 134; the slots are 0.4 in. wide, and deducting the space occupied by insulating troughs, 0.35 in. remains for wire. Four wires, side by side, and four in depth give the required 16, and each wire must be not more than $\frac{0.35}{4} = 0.0875$ in. in diameter over the insulation; the nearest commercial size is No. 13, which measures 0.082 in. Four of these side by side measure 0.324 in., and with the slot insulation require a slot 0.375 in. wide instead of 0.4, as previously used; the depth also need be only 0.375 in. The resistance of the armature winding will be approximately 0.025 ohm, and the winding will pass 25 amperes easily; if worked up to that limit the drop in voltage will be ⅝ volt; including brushes and connections it may reach a volt, and this reduces the counter e. m. f. to 5 volts, and the requisite number of magnetic lines to 78,000.

Allowing a magnet core density of 78,000 lines and a leakage of 40 per cent, the area of the magnet cores will be

$$\frac{1.4 \times 78{,}000}{78{,}000} = 1.4 \text{ sq. ins.,}$$

or a diameter of 1 11-32 ins. This being a non-commercial size, 1⅜ ins. diameter will be better, giving an area of 1.48 sq. in., and density of 74,000 lines, scant. This was the size specified in the previous article, and the width of the yoke was 2 ins. For wrought iron the density in the yoke should be not over 60,000 to 65,000 lines. The flux through the yoke is usually from 5 to 15 per cent less than that through the cores, owing to the leakage at each end of each coil; the maximum flux being 109,200, that in the yoke will be about 98,000. A wrought iron yoke, at 65,000 density, would have a cross-section of

$$\frac{98{,}000}{65{,}000} = 1.507 + \text{ins.}$$

say 1½, or a thickness of ¾ in.

The length of the cores depends largely upon the C^2R loss in the field coils, as with constant potential at the terminals and a fixed size of wire and depth of winding, the exciting power of a coil is the same for any length within reasonable limits, the only effect of lengthening a coil being to reduce the heat loss. The length of cores for the 110-volt motor was 3 ins.

TABLE OF AMPERE-TURNS PER INCH OF LENGTH FOR VARIOUS MATERIALS AT DIFFERENT DENSITIES.

Lines per sq. cm.	Lines per sq. in.	Cast Iron	Cast Steel	Wr'ght Iron	Sheet Iron
2000	12 900	4	......	......	....
3000	19,350	7	......	......	1.5
4000	25,800	12	......	4	2 5
5000	32,250	22	......	5	3.2
6000	38,700	50	8	6	4.2
7000	45,150	85	9	7	5.2
8000	51,600	162	10	8	6.4
9000	58,050	......	12	10	8.1
10000	64,500	......	14	12	10.2
12000	77,400	......	20	19	17.5
13000	83,850	......	26	25	24.0
14000	90,300	......	38	36	32.0
15000	96,750	......	60	58	50.0

The densities, etc., in the various parts of the circuit may be summed up as follows.

	Density.	Total Length of Path.	Amp. turns.
Armature body	41,600	1.875 ins.	9
Armature teeth	97,000	0.75 "	38
Air-gap	$\frac{78\,000}{5 \text{ ins.}} = 15{,}600$	⅛ "	611
Pole-pieces (cast,	$\frac{97{,}000}{5 \text{ ins.}} = 19{,}400$	3 ins.	21
Field-cores	$\frac{109{,}200}{1.48} = 74{,}000$	6 "	102
Yoke (wrought)	$\frac{98\,000}{1.5} = 65{,}333$	3¾ "	45
Total ampere-turns			826

For shunt field windings the size of wire may be roughly approximated by the formula

$$\frac{At \times l}{v} = d^2,$$

in which At represents ampère turns; l the average length in inches of each turn; v the voltage across the terminals of the winding, and d^2 the size of wire in circular mils. Assuming a depth of ¼ in. for the winding, the average length of one turn is

$$(1\tfrac{3}{8} + \tfrac{1}{4})\,\pi = 5.1 \text{ in.}$$

the ampère turns being 826, and the voltage 6, the formula gives 702 as the value of d^2. The next larger size is No. 21 wire with 810 circ. mils. Seven layers of this give a depth of .2625 in., and each limb of the magnet will take 73 turns in length, giving a total number of turns of 1,022 and a total length of wire of

$$\frac{1022 \times 5.1}{12} = 434\tfrac{1}{3}$$

ft. on the cores, or 435 ft., including connections. The warm resistance of this will be about 6½ ohms, and the exciting current, therefore, not quite 0.925 ampère. This gives an almost absurdly high efficiency for such a small motor, the field current being less than 4 per cent of the total, if the maximum armature current be placed at 25 ampères. As battery energy is pretty expensive, however, it might be better to let the foregoing data remain unchanged in order to economize in battery expense, than to cut down the length of the cores and economize in material.

A comparison of this frame with the two windings will show the striking advantage presented by low-voltage machines. It should be remembered, however, that this advantage decreases as the size of the machine increases. For more just comparison, the machine described in the February issue will be considered as a 75-volt motor, with the dead resistance eliminated.

	6-VOLT MOTOR.	75 VOLT MOTOR.
Watts applied at terminals	155.56	75.
Watts wasted by copper losses	21.2	13.
Watts wasted by iron losses	0.76	0.76
Watts available for work and friction	134.4	61.24
Electrical and magnetic efficiency	86 per cent.	81.6 per cent.

It will be seen that the 6-volt motor is more than twice as powerful as the 75-volt motor, and a little more efficient, although the mechanical dimensions are identical.

In the previous article, referred to several times above, a number of confusing typographical errors occurred. The sentence beginning on the fifteenth line from the bottom of the second column should have read: "The iron loss would not exceed .0625 watt, making less than 1 watt for the entire core, or 1.36 per cent of the output," etc. The hysteresis loss in the teeth was given at 9 watts per cubic inch instead of .9 watt, and the length of armature referred to as 6.36 ins. instead of 1½.

Another error, due to hasty copying from original data by the writer, was a reference to the total flux of lines through the armature as 77,000 instead of 89,743.

◆

ELECTRIC RAILWAY FEEDERS.

BY GEORGE T. HANCHETT.

Heavy electric railroading over private rights of way has brought the third rail into prominence, and the problem of distributing current by means of suitably insulated rails bonded together has become a serious one, for it has been demonstrated that the cost of a steel feeder made after this fashion is about one-third that of an equivalent copper cable. In calculating such steel feeders the engineer will turn to his tables of relative conductivity and will devise a method for estimating their resistance, but as such calculations have not been extensively made, there have been devised no easy and conveniently remembered formulas for making such calculations of which the writer is aware. Therefore a few suggestions along this line may not be unwelcome.

There are two numbers which, if remembered, will wonderfully assist in the calculations of steel feeders. These are 55 and 58, both multiples of 11. Rails are usually designated by their weight in pounds per yard, and therefore it is convenient to refer everything to this as a starting premise, for that is all of electrical interest that the engineer usually knows about the rail he proposes to use. Let, *w*, represent this weight in pounds per yard, then it follows that the weight in tons per mile of a rail of weight, *w*, per yard, is $5280 \times w \div 3 \times 2000$, which is equal to .88, *w*.

Rails are now supplied in 60-ft. lengths, and such rails are almost always used for third rail systems for the reason that they divide the number of bonds required by two. There are 88 rails, and therefore 88 bonds to the mile. The accompanying table will assist in estimating for ordinary purposes the cost of bonding:

SIZE AND COST OF COPPER BONDS.

Weight of Rail, Pounds per Yard.	Equivalent Copper Bond Circular Mils.	Cost of Equivalent Bond.
5	90909	$.39
10	181800	.59
15	272700	.83
20	363600	1.04
25	454500	1.27
30	545400	1.51
35	636300	1.73
40	72/200	1.97
45	818100	2.20
50	910000	2.43
55	1000000	2.65
60	1091000	2.88
65	1182000	3.12
70	1275000	3.36
75	1364000	3.59
80	1455000	3.82
85	1546000	4.05
90	1637000	4.28
95	1727000	4.54
100	1819000	4.79
105	1909000	4.92
110	2000000	5.19

Rails are seldom bonded to their full carrying capacity, though when used for feeders there is no reason why this should not be. In using this table we may take, for instance, a 60-lb. rail, and if we desired to bond it for ¼ of its carrying capacity, we would use a bond equivalent to a 15-lb. rail, or one of 272,700 circular mils, and similarly in other cases.

Eighty-eight, which has twice occurred in the foregoing, may be considered as the mechanical constant in calculating feeders, for it relates entirely to weights and numbers; 55 is the electrical one, and by properly incorporating into it the calculations, we may calculate the circular milage of an equivalent copper cable and the resistance of a rail per foot. A 55-lb. rail is electrically equivalent to one million circular mils. Therefore, if we have a rail of weight, *w*, and divide this weight by 55, multiplying the result by one million will give the equivalent copper cable for that rail. Those who are fond of their own formulas can, therefore, calculate their copper cable in the usual way, dividing the resulting circular milage by one million and multiplying the quotient by 55, thus obtaining the weight of rail in pounds per yard which will replace the copper cable.

For those who prefer to calculate the resistance of the rail directly, the following is convenient. If we divide .00055 by the weight of the rail in pounds per yard, we shall have its resistance in ohms per foot; and conversely, if we have the resistance of the required feeder in ohms per foot, we may divide that into .00055 and get the necessary rail in pounds per yard.

From the foregoing it is easy to see that a foot of rail will carry an amperage equal to one hundred thousand times its weight per yard, with a drop of 55 volts, and if we divide this current by the number of feet the rail is to transmit, we shall have the current the rail can carry for that distance at a drop of 55 volts. Inasmuch as 50 or 55 volts is a common line loss on heavy railroad systems, this formula is quite convenient; and the converse is equally so, consisting merely of a case where we have a given number of feet and a specified 55-volt drop, and a given rail and desire to know the number of amperes that can be successfully transmitted under those conditions. Obviously, we simply divide one hundred thousand times the weight of the rail by the distance in feet. This formula cannot be applied to return feeders consisting of the service rails. It should be remembered, however, that there are four times as many bonds in a set of return service rails, which are usually 30-ft. lengths, than in the outgoing feeder rails. A few examples will better illustrate the application of the foregoing formulas:

Suppose we are to transmit 2000 amperes a distance of 1000 yards, and that we have a 60-lb. rail for the purpose, what will the drop be? Dividing .00055 by 60 we at once get the resistance per foot. If we multiply that by the number of feet in the line, 3000, we get the entire resistance of the line, and if we multiply that by the current to be transmitted we get the drop. Therefore,

$$\frac{.00055 \times 3000 \times 2000}{60} = 55 \text{ volts.}$$

The converse of the problem is even easier. Suppose we have a 60-lb. rail, how much current will it transmit 1000 yards at 55 volts drop? Applying our formula, we multiply 60, the weight of the rail, by 100,000 and divide by the distance in feet, when we get

$$\frac{60 \times 100000}{3000} = 2000 \text{ amperes.}$$

Again, suppose that we have calculated a line and find that its resistance per foot must equal .000009167 ohms, what weight of rail will fill these conditions? Following our formula, we divide the resistance per foot into the quantity .00055, whence we get

$$\frac{.00055}{.000009167} = 60, \text{ nearly.}$$

If we have a rail weighing 60 lbs. to the yard and wish to find the equivalent cable, or the size of a copper bond which will have equal conductivity per unit of length, we divide 55 into the weight of the rail and multiply by 100,000, which gives the following:

$$\frac{60 \times 100000}{55} = 1091000 \text{ circular mils;}$$

and vice versa, if we have calculated by ordinary methods, that a cable of 1,091,000 circular mils is necessary to transmit a certain amount of power, we point off six places and multiply the result by 55, which gives us

$$1.091000 \times 55 = 60, \text{ nearly,}$$

the weight of the equivalent steel rail.

Lastly, if we wish to determine the weight of a 60-lb. rail in tons per mile, we multipy by .88, which gives us

$$60 \times .88 = 52.8 \text{ tons.}$$

These formulas are based on the follow-

LII. RY

ing facts: First, that a 55-lb. rail is equivalent to 1,000,000 circular mils, and second, that a foot mil of copper has a resistance of 10 ohms. Neither of these assumptions is absolutely accurate; 10 ohms is high for a foot mile of pure copper, but is more accurate where commercial copper is considered than the value given for pure metal. Steel rails, it is to be added, are apt to vary considerably in their resistance. According to the formula, the ratio of the section of the steel and copper feeders of equal conductivity is nearer 7 than 6, but it has been stated by some that steel rails have run as high as 12 times the resistance of copper feeders of equal section. For this reason it is very advisable in ordering steel rails for electric railway purposes to test samples, because their electrical resistance in such cases is almost if not fully as important as their mechanical qualities.

STORAGE BATTERIES IN ISOLATED ELECTRIC PLANTS.

BY CHAS. BLIZARD.

The advantages of accumulators as auxiliaries in central and power stations are now so well recognized as to require no comment. The service that a battery can perform in connection with an isolated lighting plant is no less valuable, and the following may be pointed out as some of its applications in this capacity.

A battery of accumulators, operated as an auxiliary to an isolated electric plant, will assist the dynamo during the hours of heavy load, and also in the case of sudden momentary overloads. It will permit of the operation of a smaller generator than could otherwise be used.

By the addition of a battery to an existing dynamo plant the total capacity of the plant may be increased without enlarging the generators; the battery charged during the hours of light load will assist the dynamo in meeting the demands during the periods of heavy load. In this system the dynamo is run under a practically full, steady load, and at its most economical point.

A battery will furnish current for the night service or during the hours of the day when the load is too light for the economical operation of the dynamo. In this service it will generally effect a very marked saving in the fuel and labor accounts; in the former by running the engine at its most efficient point, and in the latter by dispensing with one or two shifts of men.

A battery will act as a regulator of potential, permitting lighting and electric elevator services to be taken from one generator, which is run at full, steady load, while without the battery two generators are required, one of which, at least, is run under a widely fluctuating and very uneconomical load.

A battery increases the reliability of the service, as by protecting the generator and engine from the strains of sudden overloads it removes a fruitful cause of breakdowns. In case of a temporary stoppage of the generator, a battery may be discharged at a very high rate and will carry the entire load up to the limit of its capacity.

By the use of a battery a 24-hour electric service may be obtained, with but a day run of the generating plant, and a battery will also furnish the current required during Sundays and holidays.

The only expense connected with the operation of a battery in an isolated plant is the maintenance and the interest on the first cost. Any intelligent man who will follow instructions can take proper care of a battery, and the attention required is so limited that no increase in the engine room force is necessary.

In office buildings, apartment houses, hotels and buildings of a similar class operating electric elevators, a battery will act as a regulator during the day, permitting the power for the lamps and elevators to be taken from one dynamo; it will assist the dynamo during periods of heavy load; it will furnish the current required by lamps and elevators during the night and over Sundays and holidays. If it be included in the original installation the capacity of the generators may be reduced and the first cost of the entire plant, with or without the battery, will be practically the same.

Batteries operated in the service outlined above are showing an annual net saving of from 25 per cent to 40 per cent on their cost.

In office buildings, mills, factories and hospitals and other similar institutions without electric elevators and a night lighting service, a battery charged during the day, with the surplus current from the dynamo, will assist the generator during the heavy loads and will furnish currrent for the lamps required after the dynamo has been shut down, saving all expense for gas or street current.

Batteries operated under these conditions are effecting a saving on their cost of from 20 per cent to 35 per cent per annum.

In residences a battery is an essential part of the electric plant. By a few hours' run of the dynamo to charge the battery, current for lamps, fan motors, etc., may be had at all hours of the day and night.

If operated in connection with a gas or gasoline engine, a battery will act as a regulator, producing an absolutely steady light.

INCANDESCENT LAMP FILAMENTS.

BY JNO. C. SHEDD, M. S.

The main elements that enter into the success or failure of the incandescent lamp are three. First and foremost stands the filament; second, the securing of a good vacuum, and third, the leading-in wires.

In the earlier lamps the first factor was chiefly considered and thousands of dollars were spent in trying to discover a substance that would neither oxidize in air, nor melt at the high temperature of incandescence. It being found that all substances that conduct electricity also oxidize, the vacuum pump was resorted to, to remove the air, and thus the first difficulty was surmounted. The second requirement was not so soon secured, and for a time platinum seemed to be the only available material.

It was very soon learned by experience, however, that platinum could not be depended upon to withstand the high temperature of incandescence, but that it inevitably fused at the critical moment.

In the meantime many other substances were experimented upon, and success was met in another direction with material both plentiful and cheap.

It had long been known that carbon was infusible at the highest temperatures, and that it possessed the requisitely high resistance. Indeed, some of the earliest experimental lamps had filaments of this material. The difficulty in the way of its use was twofold. First, the lack of a cheap and rapid method of manufacture, and second, the fact that while carbon is infusible, it is very rapidly oxidized when brought to a high temperature in the presence of even a trace of oxygen.

The latter of these difficulties may be met in either of two ways, first by means of the vacuum pump which is designed to remove all air; or second, by the introduction of a so-called inert atmosphere. The latter method presents the advantage of being the easier, as it is only necessary to displace the air in the globe by nitrogen or CO_2, or other gas that will not act chemically upon the filament. This method had its short-lived day, and now the vacuum method is alone used, for reasons independent of the chemical action. The presence of the gas is detrimental in that it absorbs the light and, what is more serious, produces convection currents which carry the heat from the filament to the glass. This can be observed even by the hand, for the globe of such a lamp is hotter than that of a vacuum lamp.

The early methods of carbon filament manufacture were cumbersome and unsatisfactory, producing a heavy filament, that had to be used at low voltage or else with several in series. The Edison bamboo filament was perhaps the first that was a commercial success. In this the fibre from the inside of the bamboo cane is taken and dressed into a round straw three or four inches long. These strips are then bent into a loop as they appear in the lamp, and are closely packed with powdered charcoal in iron retorts. The retorts are placed in a furnace and brought to a red heat. The result of this firing is to drive out all the chemical constituents of the filaments save the carbon, which is saved from oxidation by the charcoal packing. When removed they present a dark porous structure relatively strong and of high resistance.

The earlier lamps were supplied with filaments of this type, but they were frequently found not to be of uniform section throughout, and hence of greater resistance at these points. The result was that the points of smaller section rose to a higher temperature, thus endangering the life of the filament.

The remedy for this defect was soon found and is very ingenious. The filaments are placed in air-tight receptacles, which are then filled with one of the lighter of the hydrocarbon gases—such as that from gasoline—and the current is turned on the filament. The gas is now decomposed by the heat, the hydrogen being set free and the carbon deposited upon the filament. This deposit takes place most rapidly when the temperature is highest, so that the points of least section are built up the most rapidly, until finally the filament presents a uniform appearance throughout. This process of treating, or flashing, as it is called, also changes the color from a dead black to a steel gray.

Another material much used in filament making is cotton; which is first spun into a cord of a size determined upon by experiment and is then treated to a bath of sulphuric acid in water, which obliterates all structure, and renders it homogeneous throughout. Proper lengths are then cut off, laid in the proper loop, dried and fired. The resulting filament is not porous like the bamboo, and requires less flashing. The bamboo filament may now be considered as of the past, having been displaced by various secret formulæ used in the preparation of cotton or squirted filaments. The difference in color between the treated and untreated filament also involves a difference in their optical properties, the lighter colored surface being considered the better radiator. This advantage, however, is frequently offset by a deficiency in the vacuum, which is a factor frequently overlooked in considering incandescent lamps.

We have now secured a durable filament in a vacuum. The third requirement, while of minor consideration, is still essential. Its importance lies in the fact that when the lamp is burning, the glass globe of necessity expands with the rise of temperature, and again contracts when cooled. Were it possible to have an all-glass envelope, the matter could be dismissed, but since the filament must be in metallic connection with the base of the lamp it is necessary to take into account the expansion of the leading-in wires. The requirement to be fulfilled is that they shall have the same co-efficient of expansion as the glass; for, suppose the wires to have the larger co-efficient, it is evident that as the temperature rose they would expand more than the glass and break it; on the other hand, were the reverse the case the glass would expand away from the wire and cause a leak.

The substance that is found to agree most nearly with glass in this respect is platinum, and it is a significant fact that it was this feature of the Edison patent that alone withstood the efforts of infringing companies. Another variation from the usual all-glass envelope was the so-called stopper lamp, devised partly to avoid patents, and partly to facilitate the replacing of broken filaments. In this lamp the base, supporting the filament, is joined to the globe by a ground-glass joint, which is also cemented to render it air-tight. This feature, while in itself commendable, is nevertheless probably as expensive as the globe whose life it saves.

Having thus solved the main problem in connection with the incandescent lamp, the attention of the manufacturing companies is now turned to the details of construction. Thus, it is found that the air clings to the sides of the globes, so that it is by no means easy to get a satisfactory vacuum in a short time. The filaments also show a tendency to distintegrate with age, and to throw a cloud onto the globe, thus seriously reducing the candle power. This aging is also accompanied by a rise in the resistance of the filament, still further reducing the candle power when the voltage remains constant.

One company has even taken up the question of the shape of the filament, and has adopted one of square section, claiming that the added radiating surface raises the efficiency of the lamp. The argument is as follows: The current-carrying capacity of the filament depends upon the cross section, while the candle power depends, in a measure, upon the amount of radiating surface. If two filaments be taken, one with a circular, and the other with a square section, but of equal area and equal length, both will carry the same current, but the square filament will have the larger surface in the ratio of 100 : 86. Whether this advantage is important, careful experiment can alone decide.

ELECTRICITY.*

BY W. D. WEAVER.

Electricity is popularly considered the transcendent mystery among the forces of nature—a mystery which has defied all the powers of science, and the lack of a solution to which is a reproach to the human intellect. Moreover, it is generally believed that marvelous developments await the reply to the question, What is electricity?

This view is entirely unjustified. We know no more of heat, light and gravity than we do of electricity, yet lack of knowledge with respect to these gives rise to no lamentations, and startling discoveries are not confidently anticipated in the near future which will revolutionize the sciences of thermodynamics, optics and mechanics.

In point of fact, gravity, the most familiar of the forces of nature, is the one of which we know the least. Why does a stone when dropped from the hand seek the earth? To say that it is attracted by the mass of the earth merely involves reasoning in a circle, and gives no clue to the mechanism whereby it is constrained to take a course toward the centre of the earth. Of this mechanism, unlike that of electrical action, we have no satisfactory explanation; but, nevertheless, we never hear of a contractor hesitating to invest in a pile-driver for fear that at any moment some new discovery concerning gravity may result in the production of pile-drivers immensely superior to those in present use.

On the other hand, the theory of electrical action—based upon the work of Faraday, developed by Maxwell, Helmholtz and Kelvin, and experimentally demonstrated by Hertz—is as firmly established as are the theories of light and heat, with which it is, indeed, identical. This theory, however, may well be left to the savants—first, because its proper understanding requires a comprehensive knowledge of mathematics and years of study; and second, because its perfect understanding would not enable one to add a single watt to the output of any of the electrical apparatus now in commercial use.

The popular cry for a solution to the great mystery of electricity usually arises from the misconception that electricity is a substance—a "juice"—while in reality it is a mere word representing nothing definite, corresponding, in fact, to the algebraic *x*. As in the case of heat and light, we know certain effects and, following the human instinct, we are impelled to assign a direct cause, even though this consists of but the use of a name. All that we really do know is that we can transform into what we call electrical energy several other forms of energy known as mechanical energy, heat, and chemical or molecular energy. As electricity, so-called, can only be known to us from its effects, and is only useful to us as a form of energy, the mechanism of the transformation is really a matter of indifference so far as practical working is concerned, though, of course, of interest to other than savants in the same manner that it would be of interest to know the daily habits of the people of Mars, should that planet be inhabited.

In the dynamo, mechanical energy is transformed into electrical energy at an efficiency attaining 95 per cent. and over in large machines. We know the exact nature of all the losses accounting for the small deficit between 95 per cent and perfect efficiency, and know that none of these could be nullified were a complete answer given to the question, What is electricity?

A primary battery transforms into electrical energy as high as 50 per cent or more of the chemical energy supplied to it, and the nature of the wastes, as in the case of the dynamo, are known and their amount accounts for the difference.

Processes for the transformation of thermal into electrical energy by means of thermo-piles, thermo-electric batteries, magnetic heat engines, etc., or other similar processes that may in the future be discovered, are no less thoroughly understood so far as principles affecting efficiency enter, and higher efficiencies would not be obtained by any additions of knowledge concerning the electrical mechanism of the respective transformations involved.

In other words, with one exception to be noted later, in order that electricity may be produced at less cost than by present means, the discovery is necessary of a new form of energy whose transformation into electrical energy will be commercially effected more cheaply than by present methods. The discovery of such a new form of energy, however, is a matter no more related to the electrical than to any other branch of science. It may be added that electrical energy is the only entirely new form of energy with which man has become acquainted within historic times—though Mr. Keeley might dispute this assertion.

The exception above noted relates to the direct conversion into electrical energy of the energy set free by the oxidation of carbon. When carbon unites with oxygen, a definite quantity of energy becomes available for transformation into other kinds of energy. At present such transformation cannot be made direct into electrical energy, the state of heat having first to be passed through, and this involves a great loss, owing to the action of a law of nature known as the second law of thermodynamics. The problem of "Electricity Direct from Carbon" is, in fact, the most important now presented in electrical science.

---

* Reprinted from the *Annual Journal* of the Brotherhood of Electrical Workers.

"Light Without Heat" is another problem to which it has been thought electricity might furnish a solution, but thus far the work done in this direction has been without practical result. The effect of light is produced by vibrations in the ether of a frequency expressed in numbers by multiplying 5 by the 14th power of 10. It has been hoped that the ether might be "whipped up" to this frequency by electrical means, but three formidable difficulties have interposed.

In the first place, the frequency that may be obtained in the direct transformation of mechanical into electrical energy is limited; for example, a generator with 1,000 poles running at 10,000 revolutions per minute would generate a current of less than 100,000 periods per second. Secondly, with very high frequencies electrical energy cannot be transmitted by means of wires, owing to the increase in the apparent resistance of conductors at high frequencies. A No. 0 conductor, for instance, at a frequency of 100,000 periods per second would act as if its resistance were increased more than ten times, and with a frequency in the millions would become practically a non-conductor. Finally, in the only method known of obtaining very high frequencies, which is by means of the disruptive discharge, the losses are very great, a large part of the energy being dissipated in heat. The smallest electrical wave length that has been obtained even by the latter method is eight inches, corresponding to a frequency exceeding two billion periods per second—a frequency, however, more than 200,000 times less than that of light. The above considerations give an indication of the difficulty—if not the hopelessness—of the commercial problem of producing light by electrical means except through the intermediary of heat, either directly, as in the arc and incandescent lamp, or by molecular impact, as in the vacuum tube.

Recently the subject of the transmission of electrical energy without wires has been brought forward in a practical manner in the Marconi telegraph. This application is of peculiar interest, as it confronts us with the identity of electricity, heat and light. A source of heat or light sets up vibrations in the ether, which are propagated through space and give up their energy, in whole or in part, when something responsive is encountered—the eye, for example, in the case of light, or a thermal absorbent, such as a black surface, in the case of heat. Similarly, an electric discharge disturbs the ether, setting up vibrations in it which produce an electrical or magnetic effect when the waves encounter a responsive object—this object, in the case under consideration, being a very special arrangement known as the "Branly tube." The only difference between the several vibrations above mentioned is in the length of the ether wave, which is least for light, intermediate for heat, and longest for electricity.

In the Marconi system, an electrical discharge between the knobs of an induction coil sets up a disturbance in the ether, the discharge of the coil being controlled by an ordinary telegraphic key. This disturbance is transmitted through space in the form of ether waves, which, upon striking a certain powder normally nonconductive, causes it to become conductive, thereby closing a local circuit through the tube in which the powder is contained. In circuit with the tube is a battery and a telegraphic receiving instrument, and every time the sending key actuates the induction coil, the local circuit at the receiving end becomes conductive, thereby permitting a flow of current from the battery to operate the receiver, which latter registers or sounds a signal corresponding to that made with the key at the transmitting end.

As will be seen, the vibrational energy absorbed by the tube must be infinitesimal in amount, as the powder can have but very little work performed upon it. Nevertheless, is there not a probability that electrical energy for power purposes may in the future be transmitted by this process?

The answer to this question cannot be favorable. To start with, we must first transform, as at present, some form of energy, such as mechanical energy, into electrical energy. Next, the electrical energy must be transformed into a particular kind of ether vibrational energy. Finally, a receiver must be invented that will respond to the ether waves sent through space, and transform their energy into useful work. That is, we would have a generator at one end and a motor at the other, as at present; in addition, there would be a secondary transforming apparatus, against which, however, would be balanced the gain from utilizing the ether of space instead of metallic conductors in the transmission. Aside from the loss in the secondary transforming apparatus—and in such devices at present known the loss is great, much of the electrical energy being wasted in heat—we are confronted with the question, Can the vibrations thus set up be so directed that all the energy imparted to the ether will be utilized at the receiver? As ordinarily generated, the waves would radiate in every direction, and while such waves may be reflected and refracted like heat and light waves, and thus may be gathered into a beam, to do so would entail a loss, even were it at all practicable, which is extremely doubtful.

To resume, electricity is but a name, and electrical energy is alone a reality. The mechanism by which one form of energy is transformed into another—that is, the nature of electrical action in the present case—is to us a matter of commercial indifference so long as a knowledge of it will not result in increasing the efficiency of transformation. Finally, the only direction from which at present there appears any definite promise of increasing the efficiency of any of the several kinds of electrical transformation, is from the oxidation of carbon without heat—a problem which, it may be added, is now occupying the attention of the great electro-chemists of the world.

BLINDESS FROM THE ELECTIC ARC.

BY PROF. ARTHUR J. ROWLAND.

The danger to one's sight from the light of an electric arc, no matter whether produced for a useful purpose, or the result of some chance short circuit, should be clearly understood by every one. This is especially true, in view of the many uses of electric arcs, besides those so familiar in the common 1200 and 2000 candle power arc lamps.

If one's line of vision takes in such an arc as that in the ordinary arc lamp, or that due to an accidental short circuit, or one at the break of a large current at high potential, the eyes suffer a sort of paralysis, and on looking away one sees as through a fog. This effect soon passes away, and at worst requires a sojourn of a day or two in a dark room to produce a cure.

With arcs taking large currents, and especially if one electrode is metal, the effects are quite different and much more serious. At night one notices the intense brilliance and is on his guard. In daylight the contrast is not so great, and so one is more likely to suffer because of lack of care. After working with such arcs the eye does not immediately feel the effect; but after a time, perhaps hours afterward, a slight scratching is felt in the eye, as though there were some fine dust or cinders there. As time goes on this is followed by a feeling of dryness on the eyeball, accompanied by a very profuse shedding of tears, and all the symptoms of a heavy cold in the head are felt. If the attack is a bad one, the pain becomes a very intense aching and may be accompanied by a twitching of the eyelids. In these worse attacks the afflicted one can bear no light on the eyeball, and if the eyes are opened finds he is blinded.

In case of slight attack a simple eyewash is all that is necessary for a cure. Use one made of six grains of borax in a fluid ounce of infusion of sassafras pith, or one of ten grains of boric acid in an ounce of camphor water. I can vouch for the first and have almost equal confidence in the second. In a very bad case a physician will apply cocaine, that local anæsthetic so commonly used in the eye. No one but a physician should do this.

After a few hours the pain passes away, and by keeping in a darkened room and then wearing smoked glasses for a couple of days, the eye wash being kept in use, all ill effects pass away, leaving the patient with a firm resolve to avoid further experience in this direction.

It is found that the effect of the arc has been to produce an external burn—like a sunburn—on the conjunctiva, or outer membrane covering the front of the eyeball. If one protects the eyes, this "sunburn" from the arc affects the skin; and results precisely like those after a day's out-ing at the seashore in midsummer are experienced.

In protecting the eyes against the burning power of such arcs it is not sufficient to simply wear such glasses as are made for those who adjust and repair common arc lights. Far too much of the light gets around them. It is necessary to use a mask covering the whole face. Even if one thinks to protects himself from all direct rays, by holding his hand before his eyes for example, there will still be likelihood of his suffering to some extent. In this way one who stops to look on may suffer from an eye trouble, the cause for which he has quite overlooked.

Drexel Institute, Philadelphia.

Electrical Inspection.

To the Editor of American Electrician:

I have read with much interest what you say in the February issue about municipal inspection boards and their advisability.

If the inspection department of all boards of underwriters were conducted on the plan of the New Hampshire board, municipal boards would not only be advisable but an actual necessity if proper protection against fire hazards is to be obtained.

This State has been for two months without any inspector whatever, while during that time building has been progressing rapidly and house after house has been wired, the reports sent in, and no inspection has taken place on any of the buildings.

The buildings which are put up in this city are usually of a fire-trap order, in that they are cheaply constructed, of wood mostly, and all wiring is lathed in, the plastering is on, and in nearly all cases the house finished and connections made by the electric light company before the inspector gets around to examine the building. What he can at that time discover in regard to faulty electrical construction may be easily surmised.

A case recently came to my knowledge in a town not a dozen miles from this city where a church, wired five years ago and lighted during that entire period, was never inspected until some time during the past summer, when the society owning the same erected a parsonage on the adjoining lot.

Inspection was requested on the wiring of the parsonage, and shortly after the contractor received a bill of complaint, with instructions to immediately fix up the faulty work on the church, wired five years before by another firm.

With sharp competition, unprincipled contractors and careless workmen, a premium is placed on "sloppy" work, to say nothing about dangerous wiring, by this method of State inspection.

I went into a house not long ago which had been wired and was in process of lathing, and found ten or twelve unsoldered bare joints, at least half of which had been lathed in and the rest would shortly have been. That is only one instance, of which there are many. It seems as if the underwriters should embody in their rules one forbidding the covering up in any way the wiring until the same had the approval of the inspectors, and positively refuse any risks where this rule was violated. In the larger cities, where municipal inspectors are employed and buildings are constructed on a fire-proof plan, such annoyances may not be common, but in a city of the size of Manchester it is a common occurrence.

In many a case I have seen a gang of lathers following the wiremen and covering up the wires before the electrician had time to leave the room to go to another. In many other cases the plumbers, gas and steam fitters have laid their pipes upon and across the wires, and frequently I have heard the remark from them "that won't do any harm; they are only electric light wires, and will be covered up before the inspector sees it."

With a municipal system of inspection, every job could be thoroughly inspected before it was covered in, and any faulty work detected and eliminated. Until we get something of this kind dangerous work and incompetent workmen will be the order of the day, and the public will pay the bills some day when a first-class conflagration takes place as a result.

Let us have a competent inspector, let the inspector get around and inspect the work, let him see that every rule is complied with to the very letter, and then this "cheap John" wiring will become a thing of the past.

It would be entirely desirable to compel every electrician to pass an examination in the fundamental principles of his trade before entrusting to his charge any job of electrical work, no matter how small. The inspector might be chairman of a board of examiners of several members, chosen from among the practical electricians of the State, and until a candidate has passed a satisfactory examination he should not be allowed to take charge of any job.

A similar method is pursued in regard to steam engineers in many places, and are more lives and property at stake in the case of steam engineers than of careless or ignorant electricians?

Let us have, then, thoroughly competent workmen, proven so by some sure method, and a rigid inspection of the work done. The contractor, the workmen and the public in general will receive benefit from such a system.

Manchester, N. H. S. E. Sanborn.

[Assuming that the underwriters have sufficient business sagacity to properly look out for the vast money interest they have at stake, municipal electrical indoor inspection is superfluous. A double inspection—by municipal and underwriters' agents—can only result in annoyance and expense to the contractor, though, naturally, it will be welcomed by the insurance interest as an extra assurance of safety. Such municipal bureaus as proposed by Mr. Sanborn would inevitably become the prey of politicians, and the positions be filled through political favoritism and not merit. What may be expected in extreme cases was recently illustrated in New York City, where several of the officers of the bureau for the examination of stationary engineers were arrested on charges of bribery and blackmail on the complaint of engineers.—Ed]

The Hunter Alternating Current Patents.

To the Editor of American Electrician:

While you were kind enough to publish in your February number my criticism of your article appearing in the January number relative to my generic transformer patents, your editorial, in my judgment, is most unfair and misleading.

Your reference to the suit of Thomson-Houston Electric Company vs. East Reading Railway Company as evidence that the reasons I advanced for my assignees not suing on the Hunter railway patents are not true, is another example of making statements without a knowledge of the facts. Permit me to say that suit was brought under an agreement with me on my broad trolley patents, and the Thomson-Houston Electric Company had no intention of dropping it, and further could not have done so without *my* consent. For the reason that the Edison Company had joined issues with the Thomson-Houston Electric Company just prior to the time for arguing the case, I consented to drop it, and it was due wholly to myself and not the Thomson-Houston Electric Company that it was dropped. May be I made a mistake in dropping it, but that is another question.

Your reference to the prior art proves absolutely nothing. Neither Faraday, Ruhmkorff, Varley or Gaulard & Gibbs disclose in any sense the reduction of potential in a system of transmission due to the special construction of the induction coil itself. The Berliner and Rosetti patents do not show the invention, and have been held by the Patent Office is not anticipatory. You say that Gaulard & Gibbs demonstrated the reduction of potential in 1882. By their own writings, over their signatures, published in the Telegraphic Journal and Electric Review, Vol. 8, No. 408, page 293, they do not themselves claim any date prior to 1883, and that, too, after the date of my application of February, 1883. However, it is well known by those familiar with the facts that my invention dates as of August, 1881, which is anterior to these parties. A knowledge of this was known at that time to the Jablochkoff Company in Paris. Your reference to the Zipernowski and Deri patents needs no comment, as they are long after my reduction to practice. I might remind you that the court in the suit of the Westinghouse Electric Company vs. The Sun Electric Company decided in 1888 that the Gaulard & Gibbs patent did not embody the construction of a reducing transformer, but was limited to a series system, which might have a reduction of potential in the local circuits while employing a higher resistance secondary than primary, which is inconsistent with the methods in vogue, in which the ratio is 20 to 1, the former being the primary and the latter the secondary. Your reference to suspicion being attached to the issue of my broad patent is, therefore, without foundation and very objectionable.

You also make unjustifiable insinuations as to the acts of the Patent Office, built upon imaginary meanings placed upon my words relative to the fact that the public has yet considerable to learn on the transformer matters. The facts are neither warranted nor excusable on your part. Your entire editorial indicated an inate desire to detract. I do not object to honest, open criticisms, but misrepresentation and ungenerous attacks upon the Patent Office through me upon a false basis is not what we should expect at the hands of such a paper as yours. My objection is that you publish my statement of the facts and then falsify the basis of them.

R. M. Hunter.

Philadelphia, Pa.

[If Mr. Hunter believes that his electric railway patents are broader in scope than those of any one else, why does he not assert his claims under them? When in the Reading Railway suit an opportunity presented itself that would have enabled him to do so, he acknowledges that by his own act the issue was withdrawn.

As to the transformation of alternating current E. M. F., if Mr. Hunter will refer to Hall's "Manual of Magnetism," printed in 1849, he will find both step-up and step-down transformation there treated as a matter of common knowledge. Varley later described the closed magnetic circuit transformer, so that when the coming of the incandescent lamp opened up the field, the principles of the present commercial alternating current system were ready for application without further assistance from the inventive faculty than in the perfection of working details. Yet Mr. Hunter claims that by a patent issued in 1897 on an invention dating from 1881, he "covers the entire art" of alternating current operation and "all the apparatus employing transformers for reducing potential, now in use or likely to be used."

We do not understand Mr. Hunter's references to "insinuations as to the acts of the Patent Office" and "ungenerous attacks upon the Patent Office," for which assertions there is absolutely no basis in our remarks. We have dealt with facts, while Mr. Hunter, apparently, considers that his personality is the factor at issue.—Ed.]

The Jacques Cell.

To the Editor of American Electrician:

In reply to Prof. Anthony's letter, appearing in the February issue, there seems to be no reason to doubt the correctness of all the statements made by him in regard to his experimental observations, both on the Jacques cell and on the various forms of zinc battery which he has described. They seem to be in accord with previous observations made under similar circumstances. Nor is there anything in those observations to indicate that the oxygen used by him acts directly as a depolarizer, or does anything more than generate a depolarizer, which subsequently takes part in the electro-chemical reaction.

Prof. Anthony seems to have entirely missed the question at issue, so far as the Jacques cell is concerned, and in his experiments with the zinc cell he has failed to follow the directions and eliminate other influences. Consequently his experiments were not germane to the question.

That oxygen in the Jacques cell performs a function in the maintenance of current, there has never been any question. That function has been stated very clearly by Prof. Ostwald in the January issue of the American Electrician to be the re-oxidation of the iron, which becomes reduced by the electro-chemical reaction. He says the energy of the combination of this oxygen with the iron "is lost as far as the electrical process is concerned," and "the activity of the cell depends entirely upon the renewal of the exhausted ferric oxide, i. e., the amount of air or oxygen which is conveyed to the iron cathode." By the "activity of the cell" Dr. Ostwald evidently does not mean electromotive force, but the ability of the cell to maintain a currrent through a closed circuit, which is the only process that would exhaust material or necessitate a renewal of anything.

The experiments of Prof. Anthony simply corroborate these statements, and show that the maintenance of current depends upon the continuous renewal of the exhausted depolarizer. But what has this to do with the cause or source of the electromotive force? It is the cause of this electromotive force that is the question at issue, not the capacity of the cell in coulombs or ampere-hours. The electromotive force must exist before any current can flow, before any material can be exhausted or require renewal, and it does exist and is maintained before any oxygen is introduced, and even while the caustic alkali is saturated with illuminating gas. The electromotive force certainly cannot be caused by the renewal or regeneration of anything, especially of a by-product that results from the operation of the electromotive force itself. Neither can the cause of the electromotive force be dependent in any way upon the number of ampere-hours that may be taken from the cell before it requires a renewal of its depolarizer. The electromotive force of this cell remains unchanged as long as the composition of the electrolyte remains unchanged, and the temperatures of the iron pot and the inner electrode (whether it be of iron or carbon) remain constant and different.

In the February issue Dr. Thomsen states:

1. That the direct combination of two elements cannot evolve electrical energy.
2. That if the oxygen combines chemically with the iron none of the energy of that combination can be evolved as electrical energy.

He concludes, therefore, that the Jacques cell can evolve electrical energy as a galvanic battery, only on the hypothesis that iron at the temperature of the cell occludes oxygen without combining with it chemically. That is, the galvanic theory of this cell rests entirely on the hypothesis that oxygen at 500 deg. C. combines with iron without evolving its energy of combination or any considerable portion of it. But this hypothesis in regard to iron is entirely untenable. Dr. Thomsen offers no evidence in support of it, simply because there is no such evidence. Iron does not under any known condition occlude oxygen and does not combine with oxygen in any way except by the production of an oxide of iron and the evolution of more energy than the same oxygen would evolve in combining with carbon. The statements of Dr. Thomsen (aside from this entirely unsupported and incredible hypothesis in regard to the occlusion of oxygen by iron) leave no escape from the conclusion that the electrical energy of the Jacques cell originates in heat and in heat only.

Returning to the experiments of Prof. Anthony with zinc and sulphuric acid, we find from his own statements that he did not perform the experiments which I suggested, but introduced another depolarizing agent, that produced the effects which he attributed to oxygen. By allowing his copper tube to stand for ten or twelve hours in the dilute acid he produced a considerable quantity of copper sulphate in the electrolyte. This gave him a Daniell cell, with copper sulphate as a depolarizer, which on closed circuit deposited finely divided copper on the copper tube or carbon rod. Oxygen and sulphuric acid coming in contact with this finely divided copper, or even in contact with the unamalgamated copper tube, would rapidly convert it into copper sulphate. In other words, his electrode, like the platinum electrode, was capable of being rapidly oxidized by contact with the air.

I should perhaps have given more explicit directions and stated the precaution necessary to guard against other reactions than the one under consideration. Prof. Anthony claimed that in a cell consisting of zinc and platinum electrodes and an electrolyte of dilute sulphuric acid, oxygen gas forced into the cell acts directly as a depolarizer, without first combining chemically with some other substance; or, that the depolarizing effect would be produced by oxygen, if any inert conductor were substituted for the platinum. My suggestion was to substitute for the platinum in this cell either carbon or "a well amalgamated sheet of silver, lead or copper." It is essential that the metal shall be entirely free from oxide, thoroughly clean and thoroughly amalgamated. No impurities capable of alternate oxidation and reduction, such as salts of copper, should be present even in minute quantities. Such salts act as depolarizers on closed circuit, and are again regenerated by bringing the reduced metal in contact with air. All such bodies must evidently be excluded, if we wish to observe the effect of oxygen alone.

Instead of excluding these bodies, it is evident that Prof. Anthony introduced a large quantity of copper sulphate by allowing the copper tube (the condition of its interior being probably unknown to him) to stand ten or twelve hours in the acid. In such a solution, carbon also would act in the manner he has described. There is no necessity or advantage in using porous cups in this experiment, there being only one electrolyte and nothing to separate. In

Prof. Anthony's experiments the porous cups used only aggravated the effect of the copper sulphate by confining it to the immediate neighborhood of the copper or carbon electrode, and producing a Daniell cell of the typical form—an admirable arrangement for exhibiting the 1.04 volts which he obtained.

I have repeatedly performed the experiment under proper conditions, and found that the oxygen has no effect whatever, if it has no chance to first combine with something else. The amalgamated copper must be thoroughly washed in very dilute sulphuric acid, quickly dipped in pure water, thence into the cell and entirely submerged in the electrolyte. The circuit must be closed through a resistance of a few hundred ohms, allowing a small current to pass, in order to prevent as far as possible any oxidation of the plate. The potential difference should be measured as soon as possible, first without the current of air, but while the electrode is being rapidly shaken to prevent the collection of hydrogen gas. The air should then be introduced and the potential difference again measured. If the experiment is rapidly and properly performed to prevent the formation of copper sulphate, no effect is produced by the introduction of the air.

The same is true if we use mercury, carbon or amalgamated silver or lead instead of copper. I have obtained the same result also with dilute hydrochloric and even with dilute nitric acid. With dilute sulphuric acid as electrolyte and mercury as the electrode there is no danger of oxidation, and the only precautions necessary are that the mercury shall be agitated and the platinum or other wire used to make contact with the mercury shall be insulated from contact with the electrolyte and the air. It is understood that the zinc used in these experiments must be clean and thoroughly amalgamated.

The difference between the behavior of these metals and that of platinum under the same conditions shows that the depolarizing effect is due to the action of the oxygen on the platinum and not to the direct action of the oxygen itself.

I believe if Prof. Anthony will repeat these experiments, observing the precautions necessary to exclude all depolarizing influences except the one he alleges, he will find good reason for changing his opinion, though it may have been fixed, as he says, for twenty years.

In "effectually" disposing of my statements, Prof. Anthony again declines to explain how an electromotive force of 1.2 volts is produced without thermo-electric action betwen the iron rod and the iron cup. He adroitly shifts the burden of this explanation to the shoulders of "the German experimenter," to whom he has referred. If he refers to the work of Liebenow and Strasser, I will state that I am familiar with the experiments described by those investigators, but know of nothing in them to justify the statement of Prof. Anthony. They made no measurements of either electromotive force or difference of temperature between the iron cup and the iron rod. Their measurements were confined to determining the electromotive force between two electrodes inserted into fused alkali, one being a pipestem containing potassium chloride and the other a rod of carbon, iron, nickel or silver. Their results, as far as they go, show that the cause of the electromotive force is thermo-electric, though they failed to correctly interpret their own results. They found, for instance, that a difference of one volt may be obtained between two iron pipes inserted into the fused alkali and maintained at different temperatures. But they did nothing to show the cause of this electromotive force, if it is not thermo-electric, and they did not even hazard a guess as to its cause. The explanation they suggested of my experiments was a mere conjecture, not founded on nor supported by any of their results, but based purely on analogy and a theory of "passivity."

The only theory of oxidation or chemical action that can account for this phenomenon is the theory that the simultaneous oxidation and reduction of equal quantities of the same substance constitutes a source of energy—a theory, according to which two iron electrodes immersed in an electrolyte constitute not only a galvanic battery, but an inexhaustible source of energy.

If Prof. Anthony knows of any facts or results obtained by any experimenter which prove that the electromotive force between the iron rod and the iron cup is caused by oxidation and not by heat, why does he not give a statement of those facts, instead of a mere reference to a conjecture in a foreign language? The language in which these facts are said to be described must be capable of translation. Let the readers of the AMERICAN ELECTRICIAN have the facts and they can make their own conjectures.

Philadelphia, Pa. C. J. REED.

EXPLORING THE POTENTIAL AROUND THE COMMUTATOR.

BY PROF. A. F. MCKISSICK.

The method here described, due to Mordey and given in S. P. Thompson's "Dynamo-Electric Machinery," is perhaps the most covenient for exploring the potentials around a commutator, and is as follows, reference being made to Fig. 1:

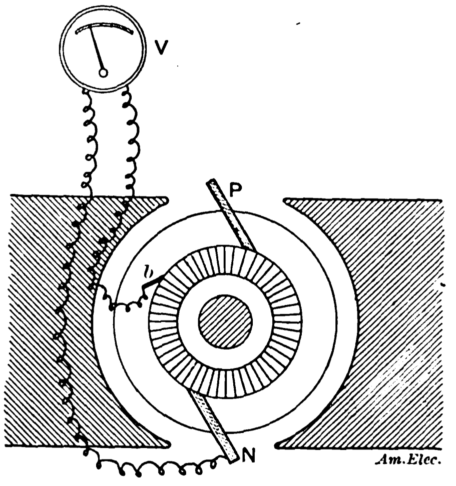

FIG. 1.—DIAGRAM OF ARRANGEMENT.

One terminal of the voltmeter, *V*, is connected to one of the brushes of the dynamo, and the other terminal is joined by a wire to a small pilot brush, *b*, which can be pressed against the rotating commutator at any desired part of its circumference.

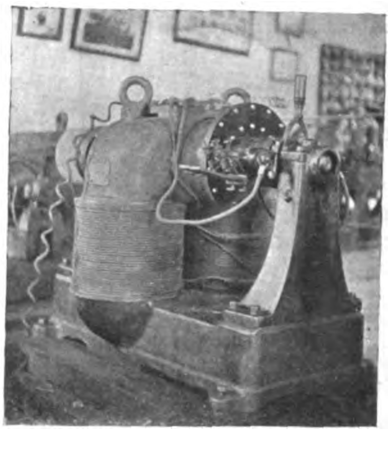

FIG. 2.—APPARATUS FOR EXPLORING POTENTIAL.

By plotting the results obtained, using potentials for ordinates and positions of pilot brush for abscissæ, we obtain the totalized or integrated curve of potentials. We can determine, by the aid of these curves, the relative value of different parts of the field and see whether there is a proper distribution of the lines of force.

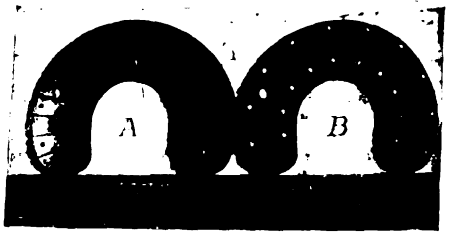

FIG. 3.—DETAILS OF APPARATUS.

The following simple piece of apparatus was constructed for the application of this method, Fig. 2 showing the apparatus attached to a machine, and Fig. 3, the parts of the apparatus.

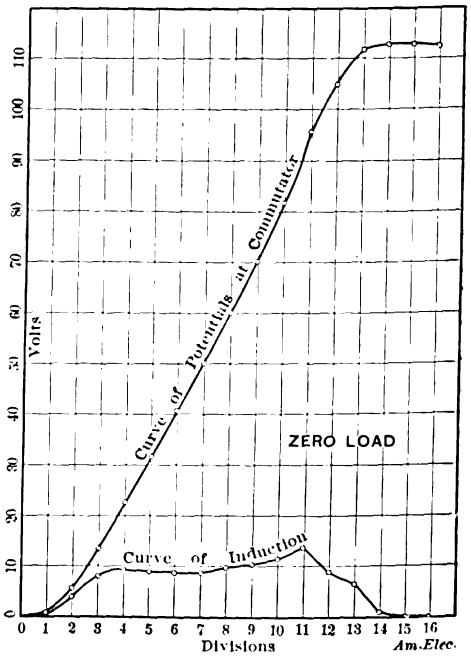

FIG. 4.—CURVE OF POTENTIALS, NO LOAD.

In Fig. 3 *A* is a piece of hard rubber ½ in. thick, slotted, as shown, at equal angular distances, and made to fit on the brush-holder rods of the machine to be experimented with. *B* is a cover of hard rubber, ¼ in. thick, attached to the piece, *A*, with screws. A brush of thin brass or copper, ¼ in. wide, is attached to one terminal of the voltmeter, the other terminal of the voltmeter being connected to one of the brushes (see Fig. 1); by pushing this brush in each slot until a firm contact is made with the commutator, we get the successive readings.

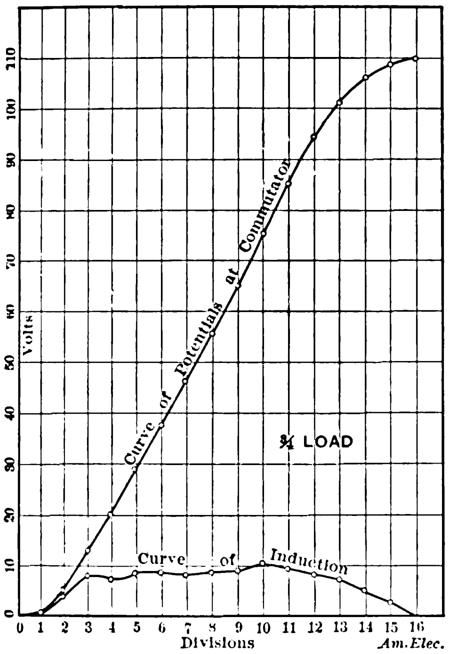

FIG. 5.—POTENTIAL CURVE FOR THREE-QUARTERS' LOAD.

In Fig. 4, the curve of potentials at the commutator was obtained with the apparatus, the dynamo working at no load. The curve of induction, shown on same sheet, was plotted by taking the differences of successive readings. The ordinates of this curve of induction do not give us the potentials of a single coil in successive positions, but the potentials of equal successive divisions of the commutator.

In Fig. 5 the same curves are plotted for three-quarter load.

◆

NOTES.

Electrical Equipment of Third Avenue Street Railway, New York.—The Third Avenue Railway will soon begin to change from cable to electrical equipment. The services of Dr. Louis Duncan, of Johns Hopkins University, have been secured as consulting engineer.

The Omaha Exposition.—The Omaha Exposition Company has ordered 2155 k.w. of General Electric dynamos and transformers for illuminating purposes alone. Among the apparatus are four 125-light arc dynamos of the Brush multi-circuit type; four 120-k.w. and two 180-k.w. alternators and a 225-k.w. direct current generator for power purposes. The exposition promises to be the most extensive ever held in this country, excepting the two, Philadelphia and Chicago, World's Fairs.

Economy of Steam Pumps.—Elaborate tests were recently made on board the U. S. S. "Minneapolis" on the consumption of steam per h.p. per hour by the auxiliary machinery, the exhaust being condensed and weighed. Of six steam pumps tested, No. 1 (1 h.p.) consumed 204 lbs. of steam per 1 h.p. hour; No. 2 (.78 h.p.), 318 lbs.; No. 3 (6.4 h.p.) 155 lbs.; No. 4 (2.5 h.p.), 170 lbs.; No. 5 (8.8 h.p.), 91 lbs.; No. 6 (1.5 h.p.), 242 lbs. Of three dynamo engines, the consumption of No. 1 (33 h.p.) was 68 lbs. per 1 h.p.; No. 2 (35 h.p.), 56 lbs.; No. 3 (27 h.p.), 72 lbs. All of the above were working condensing when being tested.

A Confidence Man.—We are advised by a subscriber in the City of Mexico that he was recently victimized to the extent of over $1,000 by an electrician calling himself Paul Freeman, and that he learns this same man is now using his name in similar transactions in the United States. In Mexico Freeman represented that by going to New York he could arrange for consignments of goods on very favorable terms. When sent there for that purpose, he succeeded, by means of drafts on his Mexican employer in obtaining a large sum of money, and then for a time disappeared from sight. Our informant states that recently, however, he has learned that Freeman is using his name with American merchants, to whom he represents that he has large orders for electrical supplies from Mexico.

Municipal Ownership.—Mr. M. J. Francisco has issued a fifth edition, with statistics to date, of his well-known book on "Municipal Ownership vs. Private Corporations." As the author has personally examined nearly all of the municipal plants in the United States and Europe, he is well equipped to write on the subject, and makes a vigorous presentation of the case against municipal government, well supported by statistics. Under the head of "Municipal Plants and Their Records," the towns owning plants are taken up alphabetically and the history of the plant given, together with data as to cost of lighting from the same. Another list is of municipal plants sold or abandoned, of which thirty are enumerated. The pamphlet, which will be found interesting reading by both opponents and advocates of municipal ownership, may be procured from the author, at Rutland, Vt.

A Boston Central Station.—The Boston Electric Light Company, which up to the present has obtained current for its lines from a number of stations scattered throughout the city, recently decided to concentrate all generating machinery in a single building, to be erected in South Boston. The three-phased alternating current system will be used and four General Electric machines, each of 1,500-k.w. capacity, are to be installed, with a reserve of 50 per cent., making a total capacity of 12,000 h.p. The dynamos are to be of the revolving field type, and will generate current at 2,200 volts. There will be two synchronous motors of 100 h.p. each for driving exciters, and no less than 18 synchronous motors of 200 h.p. each, which will drive arc-lighting machines. There will also be two rotary converters of 500 k.w. each to supply power circuits with direct current at 550 volts. For incandescent lighting the present circuits will be supplied from the three-phase wires, using the transformers now in place.

Testing Insulators.—In the article on the Butte, Mont., electric power transmission plant in the February issue, an error—not due to the writer of the article—occurred in the description of the method of high voltage insulators. The arcs are established, not between projecting pins and the surface of the water in the insulators, as stated, but between quarter-inch gaps in series in the testing circuit and between the insulators. Twenty pins are mounted in a frame, the lower ends dripping into water contained within the same number of inverted insulators. When the testing circuit is closed, sparks jump across the gaps in series, and the character of the spark determines the condition of the corresponding insulator. As twenty insulators are tested at a time, this corresponds to a total spark-length of 5 inches. The transformer employed will support a spark 6½ inches long.

Under-Running Trolley Decision.—Judge Lacombe of the United States Circuit Court of the Southern District of New York has rendered a very important decision affecting the Van Depoele fundamental patent on the trolley arm, which in effect reverses a previous decision by Judge Wallace, and sustains the patent. It is claimed by those interested that the decision of Judge Lacombe gives to the owners of the Van Depoele patent an exclusive right to the use of the overhead trolley. On the other hand, it is asserted by the opposite side that the decision, while it sustains the claim as to the use of a pivoted arm connecting a trolley wire with the car, this claim mentions no springs or other means for holding the arm in continuous contact with the overhead wire; consequently, the device as described is inoperative, and the spring supported trolley pole does not come within the range of the decision.

Electrolytic Chlorine.—In a recent paper Mr. C. F. Scott described the electrolytic process employed at the works of the Matheson Alkali Company, at Niagara Falls. The raw material, common salt, (chloride of sodium) dissolved in water, is fed into a cell built up of slate slabs, and the current entering at one carbon terminal, or anode, carries the metallic sodium with it to the mercury cathode, where it unites with the mercury, forming an amalgam. The chlorine, the other element of the salt, is liberated at the other carbon terminal, where it is drawn off by means of an electrically driven exhauster. The cell is divided into three compartments, and is arranged to rock back and forth. The two outside compartments are alike, while the central compartment is somewhat different. Here the mercury and amalgam form the anode and an iron grid the cathode. Water is fed into this compartment, the current causing it to unite with the sodium of the amalgam, forming sodium hydrate of caustic soda. The hydrogen liberated passes oft into the air. There are now two useful products from the cell—chlorine gas and caustic soda. The caustic liquor is conveyed to huge kettles, where the water is driven off by heat, the finished caustic being a solid substance of almost snow whiteness. The chlorine gas is conveyed to lead chambers, the bottoms of which are covered with layers of slacked lime to the depth of about four inches. This lime being finely powdered, acts as a sponge, absorbing the chlorine gas. The lime contains from 35 to 38 per cent. of chlorine.

Electrical Exhibition.—The list of exhibitors who have contracted for space at the electrical exhibition to be held in Madison Square Garden in May, already numbers more than one hundred, being no less than five times as many as were booked at the corresponding period preceding the 1896 show. As many have taken a much larger space for the present exhibition, the proportion on that basis is even greater. One of the features of the exhibition that will be much appreciated is an operative exhibit consisting of a complete reproduction of a section of the under running trolley in use on Madison avenue, in New York. The section will be complete in every respect with the yokes, tracks, etc., blocked up above the floor, that the method of making contact may be clearly seen. On the track will be a car fully equipped and capable of actual operation. A telegraph tournament will be held in connection with the exhibition, when a contest will take place for a prize for high speed of transmittal; there will also be a typewriter receiving contest. Mr. James D. Reid, the historian of the telegraph, a friend of Morse, and a worldwide known telegraphic pioneer, will be one of the judges.

Electric Heating— In a paper read before the recent annual meeting of the American Paper and Pulp Association, Dr. Bell said that the question of electric heat for the drying rolls, and generally for freeing the pulp from water, has been several times broached to him recently, and added: "It is only fair to say right now to those interested that the amount of power required to furnish heat for drying the daily product of a modern paper mill is enough to stagger the wildest-eyed and longest-haired electrical crank who ever claimed that electricity was in its infancy. That drying by steam is expensive is painfully evident to anyone in the business, but if you are minded to seek for improvements do not take up electrical heating until you have exhausted the possibilities of producer gas." Mr. C. F. Scott at the same meeting said that some time ago he was written to by a mill owner regarding the heating of rolls in his paper mill by electricity. He stated a 100-h.p. boiler did the work, but he would like to use electrical apparatus, as he had a water power which would give 100 or 200 h.p. "A 100-h.p. boiler," Mr. Scott said, "is one which will supply steam to an engine which will give 100 h.p. output; the actual energy which is in the steam and which is effective for heating is about 1,000 h.p.—a 1,000-h.p. electric plant would be required to replace a 100-h.p. boiler. The steam plant has an actual efficiency of about 10 per cent. for supplying mechanical power, or an apparent efficiency of about 1000 per cent, when used for heating."

Electrical Equipment of Brooklyn Elevated Railways.—The Brooklyn Elevated Railway Company awarded a number of important contracts on Feb. 23 for the equipment of its lines with electric power. The first order called for twelve motor cars, each to be equipped with four Walker 80-h.p. motors, and later other cars will be ordered until the road is entirely equipped. The Sprague multipolar unit system will be used, and the third rail method of taking currrent, as applied on the Chicago roads, will be employed. The motors were designed by Prof. Short, of the Walker Company, especially for elevated railway service, and will be built upon the lines of generators. The frame will be circular in form, and contain four laminated field magnets with pole shoes. The armature is hollow and provided with air ducts running laterally through the laminations to insure perfect ventilation. Both the magnets and armature will be wound with bar copper, with only one turn on the armature for each commutator bar. The modern practice of very few slots in the armature is followed, with four conductors in each slot. The insulation of the magnet coils will be of asbestos, while mica will be entirely used in the insulation of the armature.

Aluminum as an Electrical Conductor.—Mr. Alfred E. Hunt, president of the Pittsburgh Reduction Company, in a recently published pamphlet calls attention to the advantages of aluminum as an electrical conductor. The electrical conductivity of commercially pure aluminum is 63 per cent that of copper, and its tensile strength is 26,000 lbs. per sq. in. for pure soft iron, and 40,000 lbs. for hard drawn wire. The specific gravity is 2.16, and as that of copper is 8.93, the latter, therefore, is 3.33 times heavier than an equal volume of aluminum. Comparing cost, the weight of one mile of No. 10 copper wire is 162.32 lbs, and its cost at 14 cents per lb. would be $22.72; the weight of aluminum wire of the same conductivity would be 77.91 lbs., and the cost $22.58 at 29 cents a pound, at which price aluminum electrical wire can be procured on the market at the present time for large orders. A great advantage is that the strength of aluminum wire is 60 per cent greater than that of copper wire of the same conductivity, and consequently it can be used in much longer spans, thus reducing the number of poles and insulators. Experiments are now being made by the Pittsburgh Reduction Company to show that a wire of aluminum alloy can be furnished with a tensile strength of at least 65,000 lbs. per sq. in., and an electrical conductivity of more than 50 per cent that of copper. The tensile strength of copper wire, it may be added, is 65,000 lbs. per sq. in. when hard drawn. As an instance of the advantages of aluminum for electrical conductors, it is stated that in the Chicago Stock Yards a mile of aluminum wire of No. 11 gage replaced a telephone line of copper wire that had become badly corroded on account of its being frequently subjected to sulphur gases from passing locomotives. The aluminum wire is giving good satisfaction, and withstanding the corrosion much better than the copper. Since aluminum has a very much higher conductivity than brass, its superiority to that material is pointed out for use in electrical apparatus. Aluminum parts can be furnished at a price 10 per cent cheaper than brass, section for section, its weight, of course, being very much less.

Niagara Power.—In our January issue appeared a notice of the apparatus to be installed by the Buffalo Railway Company in order to utilize electric power from Niagara. The Buffalo General Electric Company has since then completed its plans for the utilization of Niagara power, and it is expected that within six months the city of Buffalo will be entirely lighted by electricity transmitted from the Falls. The first contract covers eleven 250 k.w. air blast transformers, wound for 11,000 and 22,000 volts, and stepping down to 352 volts, secondary. The transformers will be fed by two independent sets of cables, so that light and power service will not be interrupted in case of break-down of one set of cables. Owing to the low frequency of generation at Niagara—25 periods—the current for lighting will be raised to 60 periods by motor generators, each of which will be of 400 k.w. capacity. For generating direct current for arc lighting, there will be thirty 125-light Brush machines, direct coupled in pairs to fifteen 250-h.p. synchronous motors; 500-volt direct current for ordinary power service will be obtained from two 200-h.p. rotary converters. The total capacity of the plant, all of which is to be supplied by the General Electric Company, will be 5900 h.p., furnishing current for 3750 arc lamps, 24,000 incandescent lamps and about 600 small motors.

Cost of an Electric Transmission Plant.—In a paper read before the recent annual meeting of the American Paper and Pulp Association, Dr. Bell gave an estimate for an electric transmission plant to deliver 1,000 h.p. at a distance of ten miles from a water power. Allowing 1000-k.w. capacity in the power house, with a generator in reserve, there will be three 500-k.w. machines direct connected, if the speed of wheels will allow. The market price of such machines, complete with station equipments, and wound for 5,000 or 6,000 volts, will, including installation, not exceed $10,000 each. The present tendency is toward high-voltage generators, connected directly to the line for such cases, although low-voltage generators with raising transformers can be obtained not far from the same price. In any event, reducing transformers for 1,000 h.p. would have to be installed in the mill, of which the aggregate cost in large units would not exceed $5000 to $6000. The 1000 h.p. in motors would be needed for driving the various parts of the mill, and assuming units of 100 h.p. or more, the probable cost of these motors would be $15,000 to $20,000, depending somewhat on the size and speed of the various units. This completes the necessary electrical machinery. The line, assuming, say, 6,000 volts delivered and 10 or 12 per cent. drop, could be erected with all copper up for less than $20,000. Altogether, the machines at both ends of the line could be installed, including a suitable station, for about $80,000; under favorable conditions for somewhat less. The cost of the water privilege and the necessary hydraulic work is the most uncertain factor in working out any assumed case of power transmission. It may fall even to $25 or $30 per horse-power, and it may rise to $150 or $200. Taking the general average of powers in regions where they have not yet acquired an artificial value by proximity to towns, one may say without being widely astray that $75 per horse-power will cover the necessary expense. With a considerable head this figure will be somewhat reduced. For a rough estimate of the hydraulic cost in the case in hand, it will be fairly near the mark to double the cost of the electrical part of the equipment, making $160,000 as the total investment in the power plant for furnishing 1,000 h.p. day and night. This figure is stated to be a conservative one, as a certain plant with a generating station of 1000 h.p. was installed complete, including distribution lines to the amount of $15,000, but no motors, for less than $25,000, and this at a time when electrical machinery was considerably more costly than at present. As to operating expense, the figures are not difficult to secure. In the first place, there will be for interest on the investment at 6 per cent., and an annual charge of 4 per cent. to the credit of a sinking fund, for depreciation of replacement. Then adding 2 per cent. for insurance and taxes, the total annual charge due to these items becomes $21,600. The regular operating charges can be made up about as follows: Labor, eight men and team, $6,500; supplies and general maintenance, $5,000. These figures are more than ample for any ordinary case. Summing them, $33,100 is the total annual cost of 1,000-h.p. for twenty-four hours per day, which brings the charge per horse-power per year down to $33.10. This power generated by steam, with coal at say $3 per ton, using the non-condensing engines too often employed, would cost at least double the amount mentioned, and even with a first-class steam plant the cost would fall little, if any, below $50 per year. In other words, the net yearly saving by employing electrical transmission in such a case as assumed amounts to from $15,000 to $30,000 per year, which figure could often be exceeded under the conditions actually existing in paper-mill work.

The Diesel Motor.—For some time our foreign exchanges have devoted much space to the recently invented Diesel motor, which is claimed to embody principles that insure an extremely high efficiency of the apparatus as a heat engine. This motor is, like the gas engine, an internal combustion heat engine, the fuel being gas, petroleum or powdered coal. The peculiar features of the motor are an initial compression of the air in a separate cylinder, and the utilization of the compounding principle. There are three cylinders, one of which is considerably larger in diameter than the other two. The air undergoes an initial compression in one side of the larger cylinder, from which it is discharged into a reservoir. It is then admitted into one or the other of the smaller cylinders, where it is finally compressed to a very high temperature—about 1000 degs. Fahr. At the end of the compression stroke the fuel is injected, and a gradual combustion ensues, which completely consumes all of the fuel and without the usual explosion. The gases are then exhausted from the smaller into the other side of the large cylinder, where they do work through expansion, being exhausted into the air on the return stroke. The injection and combustion of the fuel can be regulated automatically according to the power required, and thus the speed retained constant at all loads. It is claimed that in practical operation during the past nine months the Diesel motor has shown that it can turn into mechanical work 26 per cent of the heat units of the fuel consumed, which gives it a commercial efficiency about twice that of the best steam engine. Another advantage claimed for the motor is that it can be set to work without loss of time, as it is started by simply opening a valve admitting stored compressed air into the cylinder. In operation it runs almost noiselessly and without shock or jar, in this respect differing materially from the usual gas and oil engine.

Electricity in Paper Making.—At the annual meeting of the American Paper and Pulp Association, held in New York last month, Dr. Louis Bell and Mr. C. P. Scott read interesting papers on the application of electricity to paper making. Mr. Scott prepared his paper with a simple account of the characteristics of electricity and electrical apparatus, and then proceeded to show in what way and under what conditions they may be made profitable in the paper making industry. Both the direct and the alternating current systems were described, and the conclusion arrived at that the requirements of pulp and paper mill service are such that the polyphase alternating current system is in general better adapted than the direct current, owing largely to its flexibility, the simplicity of the alternating current motor and its ability to stand acid fumes, dampness, the severe strains of sudden stoppage, and long continued service. As to the advantage of electricity in general, it will enable the power to be brought to the mill, which can be located at the most convenient spot, instead of having to go to the power, while electric transmission enables the energy of separate water powers to be concentrated at one point. In distribution of power within it enables a great saving to be effected in shafting, greatly reduces the loss from friction, introduces great flexibility, and is desirable from considerations of convenience. Mr. Scott doubts the advisability of the application of electric motors attached directly to each part of a paper machine, owing to the expense that would be entailed by the necessary regulating and adjusting apparatus. Dr. Bell in summing up his paper said the best field for the use of electric motors in paper manufacture is in reducing the cost of power by utilizing the now well-tried methods of power transmission. By this means a mill can be located so as to obtain its materials and ship its product economically, without foregoing the advantages of cheap water-power. With the transmitted energy at hand, power can be economized by the skillful use of motors in its distribution. There is no cut and dried rule or formula by which the best equipment can be at once determined. Each case has to be considered on its merits, and by the light of common sense, for in the last resort the best equipment is the one which enables a given grade of paper to be turned out at the lowest price. Concerning the distribution of power in the various parts of a mill, Dr. Bell does not think the saving is enough to justify the use of an electrical system for distributing the power except in connection with a transmission plant. It is quite as important to know when to let well enough alone, he says, as to have a prophetic instinct for improvements.

Sensational Newspaper Science.—A recent number of *Science* has an article entitled "Time Wasted," protesting against the evil results of the exploitation of science for sensational purposes. "During the century which is now approaching its end," it says, "scientific discoveries and their applications have been so numerous and so far reaching as to practically revolutionize conditions of material existence, and they have often been so wonderful in character that it ought not to excite surprise to find intelligent people ready to accept without question announcements of inventions and discoveries of the most improbable and absurd character. Along this line the evil influence of a sensational press is enormous." "Unfortunately," it adds, "some men, who may be said to inhabit the fringe of genuine scientific activity, lend themselves to this sort of thing and are made much of accordingly. Whole pages of this modern journalism are filled with accounts of discoveries that *are going to be made*, for writers of this class are shrewd in taking advantage of the fact that human interest and human memory are now practically restricted to about twenty-four hours' time." An unfortunate result of this is that there are many very intelligent and thoughtful people, who ought to constitute the best support of scientific work to whom "the line separating the genuine accomplishments of honest scholarship are the output of sensationalism, which ought to be clear and sharp, is becoming very nebulous, and there is imminent danger of a revolt against the whole thing." The writer of the article had evidently in view some of our electrical wizards.

ESTABLISHED 1889.

American Electrician,

WITH WHICH IS INCORPORATED

Electrical Industries.

W. D. WEAVER, Editor.

Published on the first of each month by the

American Electrician Company,

NEW YORK: Havemeyer Building.
CHICAGO: Monadnock Block.

JAMES H. MCGRAW, President.
W. H. TAYLOR, Vice-President.
C. E. WHITTLESEY, Treasurer.

Diagrams of Electrical Connections.

In the present issue the supplement, "Diagrams of Electrical Connections," is bound in the body of the paper, retaining its own paging, and perforated so that it may be easily separated. This will insure even margins, and obviate complaints we have received that the separate sheet was omitted by the binder. A portfolio for the sheets may be obtained from the publisher for 30 cents, postage included.

The Diesel Motor.

In another column we give a brief description of the Diesel motor, which has recently been attracting so much attention abroad. It is said that fuel in the form of a powder may be fed to this motor, but we doubt if it will be used otherwise than as a gas or gasoline engine. As such, however, it possesses two important features—both conducive to economy— high compression and secondary expansion. The air is compressed in two stages to a temperature in the neighborhood of 1000 degs. Fahr., and the graduated gas or oil charge admitted at the end of the second stage, when it is at once ignited. The mixture of air and gas produces a high temperature, and therefore pressure, without explosive action, and after expansion to the end of the stroke, passes into a larger cylinder, where it does further work, finally exhausting into the atmosphere. The two smaller cylinders each work on the Otto cycle, as in the case of the ordinary gas engine. One half of the large cylinder is used for initial air compression, and the other half, during alternate revolutions, works expansively the exhaust from one or the other small cylinders. The motor is thus a combination of two single cylinder gas engines, with a single acting expansion cylinder in common.

The Cost of Steam Power.

At the December meeting of the American Society of Mechanical Engineers, Mr. F. W. Dean gave figures to show that the very best steam generating plant of 1000 h.p. can be installed to-day complete—including buildings, chimney, compound engines using 12.5 lbs. of steam per h.p.-hour, boilers evaporating 9 lbs. of water per lb. of coal, economizers and all accessories—for $57 per indicated h.p. Such a plant can be run on 1.4 lbs. of coal per indicated h.p.-hour, and on this basis it is shown that the cost of a yearly h.p. of 10 hours per day will be $17.84 with coal at $3.85 a ton. This includes an allowance of 5 per cent for interest, 3½ per cent for depreciation, 2 per cent for repairs and 1 per cent for insurance and taxes.

For comparison with the cost of water power, it is desirable to know the estimated cost of an annual steam h.p. on the basis of 24 hours per day. If in Mr. Dean's estimate the items of depreciation, cost of repairs, oil, waste and supplies are doubled, and allowance made for two shifts of men, such yearly cost would amount in round numbers to $35 with coal at $3.85 a ton. In the bituminous mining regions coal can be purchased at the mines at the rate of 50 cents per ton, and on this basis the cost of an annual 24-hour h.p. is reduced to $19.

As stated before, these estimates are made on the basis of 1000 h.p., and while for plants of a larger size there would, of course, be a reduction, such reduction would be at a comparatively low rate in the case of steam plants. On the other hand, the reduction in cost for water power plants where the quantity of power is large, will usually be quite considerable. Nevertheless, the low cost at which steam power may be generated should not be lost sight of in considering a water-power electrical generating scheme.

Condensation in Steam Engines.

As has been shown in these pages, the working efficiency of steam engines may be as high as 70 per cent—by working efficiency being meant the ratio of the useful work of an engine to the entire amount of the heat energy supplied it that is available for transformation into work. In many engines, however, this efficiency is 50 per cent or even below, and the difference is largely or entirely due to internal condensation, which source of loss, it should be added, is usually not entirely absent from the most efficient types of engines. It is therefore of interest to take a glance at the conditions which cause this condensation, and see what remedy suggests itself.

During exhaust, the condenser side of the cylinder of an engine is cooled, the tendency being for the temperature to drop to that of the condenser—say 110 degs. F. When the steam valve is opened on the return stroke, by contact with the cooled surfaces part of the entering steam, if not considerably superheated, is condensed, thus doing no useful work. During admission the walls of the cylinder are also heated up to nearly the temperature of the entering steam.

When expansion begins, the pressure in the cylinder falls, part of the water condensed is re-evaporated, and the cylinder walls are again cooled. On the other hand, expansion under work is itself accompanied by condensation. At the end of the stroke there are left in the cylinder part of the water condensed at admission, and water condensed during expansion, while the cylinder walls have been cooled by re-evaporation. As soon as the exhaust begins, the great reduction of pressure causes, in most cases, complete re-evaporation, which increases the back pressure and further cools the cylinder walls.

That is to say, part of the heat received at admission is on the return stroke delivered to the condenser without doing work. The result is thus somewhat as if in a perfect engine the efficiency were lowered by having a by-pass from the admission side of the cylinder to the condenser, through which at each stroke a certain amount of steam passed. Or the condensation is equivalent to a leakage past the piston into the exhaust. The amount of re-evaporation at the end of stroke is sometimes as high as 50 per cent of the weight of the total steam condensation, and in single cylinder engines is rarely below 15 per cent.

The obvious remedy is superheating, and multiple expansion engines present an ideal case for its application. Superheating the steam initially is attended with difficulties, but in the case of engines having receivers the matter is a simple one, as it is then merely necessary to introduce into tubes in the receivers steam direct from the boilers. There can be no doubt but that great economy may be thus obtained, and it is notable that recent engines which have shown extremely low steam consumptions were fitted with receiver heaters. It should be added that there is a limit to superheating, beyond which it becomes a disadvantage. This limit would appear to be reached when all the steam at release is just saturated, though considerations relating to the normal condensation due to the performance of work may still further reduce the limit. As to the employment of steam jackets for the prevention of condensation, if on the high pressure cylinders, they will do some good, but owing to the thickness of the cylinder walls, the amount of heat passed through will be much less than can be imparted through thin reheater tubes, against which, moreover, the steam impinges in its passage. If on the low pressure cylinder, the jacket is little less than "a furnace for the condenser."

Charge for Telephone Service.

Judge Cox, of the District of Columbia, has decided that a telephone subscriber cannot allow his telephone to be used by outsiders, such use being pronounced an abuse of the time of the telephone operator, an infringement of the rights of the telephone company, and an infringement of the rights of other subscribers. This decision appears to have aroused considerable indignation in Washington, but it is difficult to see that any other view of the question could have been taken. A telephone company maintains a special plant for a certain service, and it would seem that it is entitled to charge for every use of that plant. The charge for service, it must be assumed, is based upon the cost—direct and indirect—to the company, and if a subscriber permits unauthorized persons to use his telephone, he increases that cost, or causes additional labor to the employees, for which neither employees nor company receives compensation, such use being also apt to interfere with the service of other subscribers.

Judging from the statements of the subscriber who instituted the suit, the trouble in Washington arose, not so much from a denial of the above principles as through what appears to have been lack of judgment on the part of the telephone company. This subscriber, who paid for two telephones, one in a warehouse and another in a hotel owned by him, states he was informed that he could not use the hotel telephone to talk to the warehouse without extra charge, unless the conversation related to hotel business. Should this be a correct statement of fact, it is yet another illustration of the too frequent lack of diplomacy on the part of those who, as servants of the public, should cater to its prejudices instead of assuming an attitude inviting conflict.

Idle Current.

In our last issue we pointed out a rational method of viewing the power factor, and defined it as a fraction expressing the part of the impressed E. M. F. usefully employed, the remaining portion of the impressed E. M. F. being "held up" in a circuit containg inductance, by the inductive E. M. F. generated in the circuit by the current flowing. Another term often very vaguely understood is "idle current," but this admits also of rational explanation.

Suppose we have an alternating current motor connected to a 100-volt circuit, and that at a certain load 10 amperes of current flow. Now connect up a condenser with the motor, either in series or in parallel, and of such a capacity that the motor's inductance will be neutralized. The alternating current will now pass through the motor as if its circuits were non-inductive—that is, the alternating current will meet with no more hindrance than would a direct current flowing through the same circuit. Owing, however, to this latter fact, the power of the motor would, under the conditions assumed, be increased by an increased flow of current, and to keep the machine down to the same brake power as before, suppose we insert a non-inductive resistance in circuit. Now, if by means of a voltmeter we find the resistance between the terminals of the motor 80 volts, then with 10 amperes of current flowing, the power factor of the motor at the assumed load will be .8. That is 80 volts represent the useful E. M. F. of both cases, and 20 volts the amount that had been "held up" by inductance in the first case.

Now, if we remove the resistance it will be necessary to reduce the flow of current to 8 amperes in order that the motor shall run under the same conditions—that is, consume 800 watts—as the impressed E. M. F. has again become 100 volts. That is to say, the motor when working at the same load requires 10 amperes of current when it is inductive, and 8 amperes when it is non-inductive. It is usual to say that the extra current required in the first case is idle current, but it will be seen that more current is required because in the first case part of the impressed E. M. F. is idle, and this is the more correct way of looking at the matter.

In other words, instead of assuming the excess of the product of the volts and amperes over the true watts to be due to idle current, it should be considered due to an idle E. M. F.—an E. M. F. "held up" by the inductive E. M. F., to repeat a somewhat inelegant term. Current is never idle, and in receivers is the primary factor, E. M. F. being secondary to it. In the case of a motor—direct currrent or alternating—there is a counter E. M. F., and if the impressed E. M. F. that balances this counter E. M. F. is cut down, more current must be sent through the machine if it is to continue to work at the same rate. Or to state it more directly, if a direct current motor has its E. M. F. reduced from 100 to 80 volts, the current sent through it must be increased in the inverse ratio in order that the motor may develop the same power; and similarly, when inductance balances part of the E. M. F. supplied to an alternating current motor, the current must be increased to maintain the power. In both cases all of the current does work; in the first case, the 20 volts are actually lacking, while in the second case they are present but neutralized—that is, idle, so far as the power of the machine is concerned.

A CHEAP TESTING SET.

The Wheatstone bridge is one of the most valuable instruments that can be devised, not only for its primary office of measuring resistances, but for testing faults of any kind. Most beginners are not aware that a convenient substitute can be made that will answer in many cases, and the expense of which need not exceed two or three dollars. Following, a description of such an easily made apparatus is given, and it may be of interest to those anxious to possess a testing set and do not feel that they can afford the large sum usually asked for such an outfit.

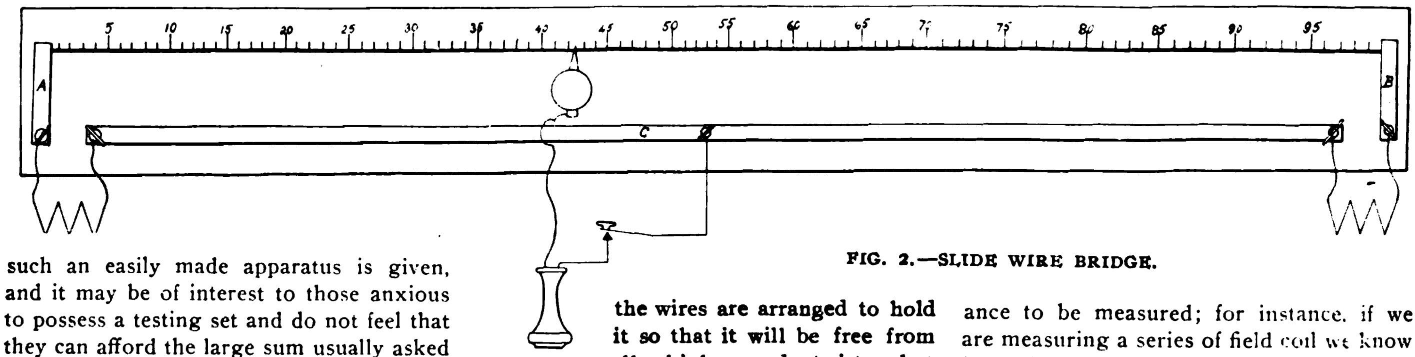

FIG. 2.—SLIDE WIRE BRIDGE.

Select a board of some dry wood and shape it nicely to the dimensions of 42 ins. long by 8 ins. wide. Procure some flat copper rod which is at least ½ by ¼ of an inch in sectional area. Of this there should be one continuous bar 36 ins. long, and two shorter pieces about 3 ins. long. Then secure a good straight piece of German silver wire, about No. 14, Brown & Sharpe gauge. Go over this with a micrometer, testing it at every inch in its length, and be sure that the piece selected is of uniform diameter and has no nicks or marks of any kind.

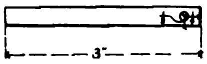

FIG. 1.—COPPER BAR.

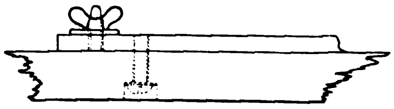

FIG. 3.—METHOD OF FASTENING TERMINAL BLOCKS.

With a suitable size of drill, bore holes ¼ of an inch from the ends of the short pieces of copper rod, and ⅛ of an inch from the flat sides, as shown in Fig. 1. The wire should now be soldered into the copper block, care being taken that it comes exactly flush with the block, no drops or beads of solder appearing around the joint. To do this, the better way is to heat the copper block very hot and thoroughly tin the inside of the hole and fill it with solder, which, if the block is hot enough, will remain melted. Having previously tinned the outside of the wire, insert it in the hole thus prepared, pushing it straight in until the proper distance has been reached. Be very careful not to pull it outward unless the solder does not fill well around the hole where it enters, because any outward pull of the wire would draw a meniscus of solder around it, which would be undesirable. The length of wire between the two connecting blocks, as shown in Fig. 2, should be exactly one meter long. This should be most carefully adjusted for accuracy.

The copper blocks are provided with binding screws at their terminals for the convenient insertion of known and unknown resistances, and are secured to the board, as shown in Fig. 3, by screws passing up from beneath. The blocks carrying the wires are arranged to hold it so that it will be free from all kinks and twists, but not to put any mechanical strain upon it, which might change its resistance; in other words, the wire should be straight, not stretched. A little platform of thin wood or pasteboard should now be built up underneath the wire so that it will support it throughout its length, and on the top of this strip of pasteboard should be pasted a meter scale; if the wire has been accurately adjusted, it will exactly fit between the terminal blocks. If these directions and the drawings are carefully followed, the result will be a bridge of considerable range.

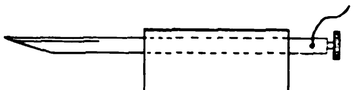

FIG. 4.—WEIGHTED INDEX.

To use this instrument, a source of E. M. F. is connected to the end blocks and a galvanometer, or, as shown, a telephone receiver, is connected to the long middle block, and its other terminal to a weighted index, which can be moved along the board between the wire and the long copper rod and make contact with the former at any point desired. This index is preferably made of a brass rod, one end of which has been filed up to a V-shape and drawn out to a sharp point, as shown in Fig. 4. The other end of the brass rod is conveniently shaped up into a binding post, to which the detector terminal may be attached; the weight may be a piece of lead cast about it and suitably shaped. The sharp edge of the brass should be very soft in order not to mar the wire at the point where it rests upon it, and for that purpose should be annealed by heating it in a flame and allowing it to cool slowly. A few standard resistances should be provided; one, ten and one hundred ohms will be sufficient. These may be conveniently made by measuring off the proper amount of insulated wire with a testing set, coiling it about a small wooden block and inserting it in a short piece of large brass tubing, which is then filled with paraffine. These coils may be made of moderately fine wire and stout, projecting terminals of as nearly no resistance as may be, lead out through the paraffine for purposes of connection. Fig. 5 shows a section of such a coil prepared for use.

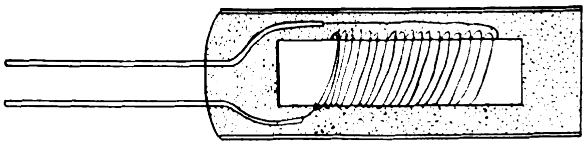

FIG. 5.—RESISTANCE COIL.

The known resistance is selected as nearly as possible equal to the unknown resistance to be measured; for instance, if we are measuring a series of field coil we know its resistance to be at most but a fraction of an ohm, consequently we should use the lowest resistance coil that we have, which in this case would be one ohm. Similarly, in measuring a shunt field coil whose resistance may be 16 or 20 ohms, we should use the ten ohm coil, and so on. The known resistance is connected across the binding posts at one end of the bridge, and the unknown resistance is similarly connected at the other. A source of e. m. f., two or three dry cells will answer, should be connected from *A* to *B*, The weight index is adjusted along the wire for a position where no deflection of the galvanometer occurs, and the point is read on the meter scale.

If a telephone is used instead of a galvanometer, it is best to interpose a key in the circuit, as shown in Fig. 2. The procedure is to then seek a point on the scale where the opening and closing of the key produces no click in the receiver.

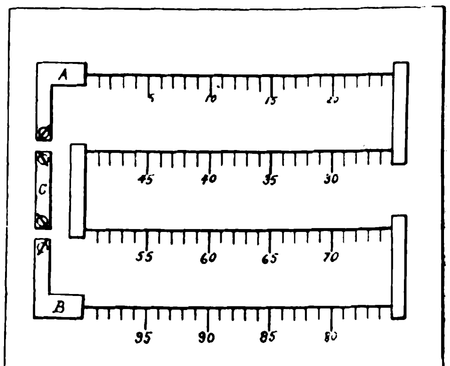

FIG. 6.—IMPROVED BRIDGE.

Multiply the known resistance by the length of the wire on the unknown side and divide it by the length of wire on the known side, and the result will be the value of the unknown resistance.

The bridge that has just been described is rather a clumsy construction, being nearly 4 ft. long, but it can be modified as follows, and the result will be more convenient:

A board 12 ft. x 14 ins. is provided with blocks of copper, as shown in Fig. 6. Four wires, each 25 centimeters long (about 10 ins.), should be soldered into them, as shown in the diagram, the blocks at the end being shaped as shown so as to be brought up conveniently near a third one. Assuming the blocks to be of negligible resistance, the wire must then be divided into four lengths of 25 scale divisions (one meter) each, and thus a more compact and satisfactory instrument will be obtained.

◆

LECTRICAL APPARATUS FOR AMUSEMENT—III.

THE SPIRITUALISTIC CASH BOX.

BY NEVIL MONROE HOPKINS.

Those familiar with the literature devoted to magic will doubtless recall the valuable experiments in the Black Art, conducted in Algeria by Robert Houdin, acting under a commission of the French Government. Charged with the suppression of the objectionable feats of magic and hypnotism, as carried on by the Marabout priests and Mohammedan miracle workers, the great French conjurer and magician set out, carrying such magical apparatus of his own invention best suited, in his keen forethought and judgment, to convince the Marabouts that a European could not only surpass their miraculous exhibitions, but expose their fraudulent occult demonstrations, with which they continually awed the more ignorant Arabs, and excited others to discontent and rebellion.

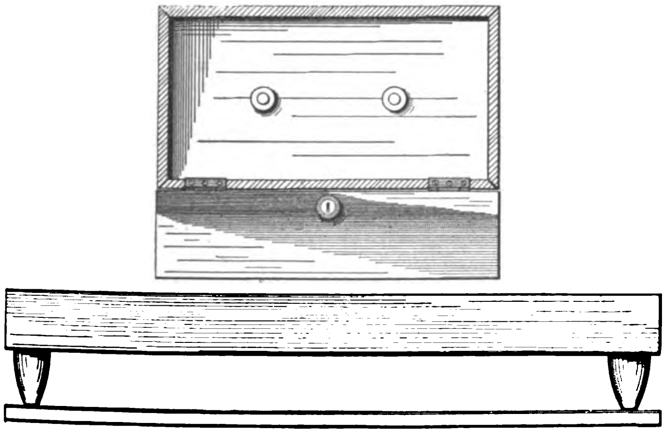

FIG. 1.—ELEVATION OF BOX AND PLATFORM.

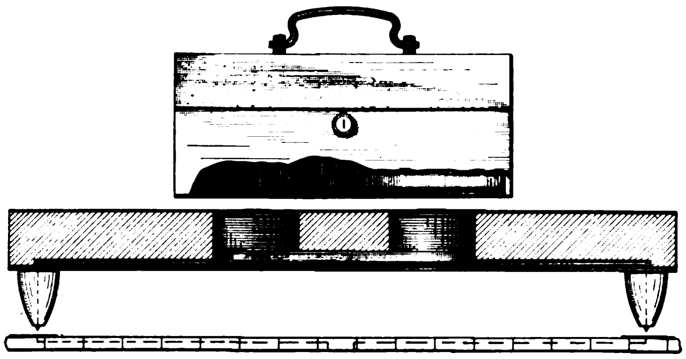

FIG. 3.—SECTION SHOWING ONE PAIR OF ELECTROMAGNETS.

Probably no other experiment had such success or such humiliating effect on the great priests as that performed by the aid of Houdin's greatest electrical trick, "The Light and Heavy Chest." Although this trick is referred to in a number of magical works the writer has never seen the mechanism of the box together with its secret pulleys and electro-magnets described, beyond a vague statement that the trick was dependent on electro-magnetism and trick pulleys. While the box designed and described by the writer probaby differs very radically from the historical one used in Algeria, it will be found extremely light, or extremely heavy, at the will of the operator.

Before describing the construction of the box and platform, the method of introducing and working the trick may not be altogether untimely. Fig. 1 shows the appearance of the writer's design of box, which includes a low "insulating" platform both of which may be closely observed by the spectators without the least fear of any telltale portion being discernible. After filling the box with beans, coin, cut paper or any handy objects or material asssociated with magical exhibitions, it is placed on the little platform and locked. A light rope is seen hanging from a couple of pulleys fixed to the ceiling, with which the box may be hauled up a few feet in the air. The performer having lifted the box a couple of feet or more from its platform, requests that some spectator take the end of the rope and hold the box in suspension. The performer now makes the usual mesmerical passes, and commands the box to increase gradually in weight, until it rests upon its little stand, or platform. The magician may have a couple of fingers under the handle of the box, and slowly lower his hand as the box descends, showing that he alone has the power of sustaining its weight and of arresting its rapid downfall.

The box once on the platform, the rope is untied or unhooked, and the person who was unable to resist its slow but sure descent is requested to stand on the platform and endeavor to lift it up independently of the rope and pulleys. He will be as unable to do this as he was to prevent the descent of the box, until equalizing mesmeric passes have been made by the performer, rendering the box as light as a small block of pine wood.

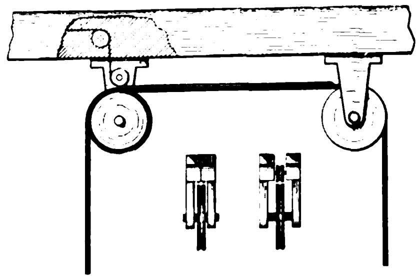

FIG. 2.—TRICK PULLEYS AND CORD.

By referring to Fig. 2, the pulleys, together with the secret wire, will be understood. The box is suspended from the left hand end of the hanging rope, and is pulled into the air from the end at the right. The fine, blackened steel wire passes through the supporting beam, over the small concealed pulleys, and is attached to the main rope as illustrated. To cause the box to increase in weight gradually, it is only necessary to suspend a large pail or other commodious receptacle from the end of the secret steel wire behind the scenes, and allow water or sand to slowly fill the same, when the pull, as will be seen, acts on the right-hand rope and taxes the strength of the person endeavoring to hold the box in suspension. Once on the platform, the double pair of electro-magnets are brought into play, making it next to impossible for the box to be lifted without the sanction of the performer.

Let us now take up the construction of the box and platform, together with the electromagnets, leaving the pulleys until the last. The present design represents the smallest box and magnets advisable to construct; in fact, the dimensions may be increased with advantage if the trick is to be shown to a number of persons on a stage. The box given here measures about 12 inches by 7 by 5, and is made from pine board ½ inch thick. An iron plate ⅜ inch in thickness is screwed on the bottom, and the whole given a coat of mahogany stain, making the whole appear as wood. The iron plate can to advantage be let into the bottom, in order that the sides of the box may cover the edges of the plate. A lock and key should be provided, as well as a neat brass handle. The base or platform is made from a piece of pine board 2 inches thick, and measuring about two feet by 12 inches. It must be provided with turned wooden legs, which raise the board about 2½ inches from the ground or stage upon which the trick is presented.

Fig. 3 shows the box partly cut away, allowing the iron bottom to be seen. The position of a pair of the magnets is also shown, together with the turned wooden legs, which are provided with sharp steel points, connected with the windings on the electro-magnets. These sharpened points prick through the carpeting on the stage and make contact with a couple of heavy copper plates, which have wires soldered to them, leading to the source of electrical energy and the controlling switch.

The electromagnets are fitted to the interior of this board or platform, by making four 3-in. augur holes or lathe cuttings, to receive the bobbins, with a couple of joining grooved channels chiseled out to receive the frame or bar of the magnets. Before doing this work, however, the magnets should be made and wound, the plan of construction being made clear by referring to Fig. 4. It will be seen trom the dimensions marked on the illustration that the 2-inch base-board will just take the magnets when they are carefully adjusted in the auger holes, with the grooved channels cut to the proper depth.

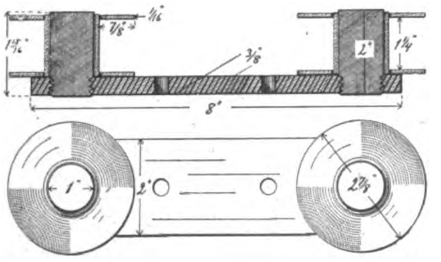

FIG. 4.—CORES, FRAME AND SPOOL SECTIONS OF A PAIR OF ELECTROMAGNETS.

Having made the magnet cores as shown the spools may be put together. These spools are made by soldering brass disks on thin brass tubing, which is slipped over the poles of the magnet core. These circular brass disks are quickly made by cutting out eight pieces of sheet brass 1-16 inch thick, to squares measuring a litttle over three inches. This can easily be accomplished by using tinner's shears, getting the squares as nearly equal as possible. They are now put together and soldered all around the edges in order to securely hold the lot from moving or slipping among themselves when the whole is chucked in the lathe, and the hole cut through the centre to receive the brass tubing. Having cut the hole through, the pack is removed from the lathe chuck and mounted on a lathe mandrel in order to cut the solder away and bring the plates down to true circles.

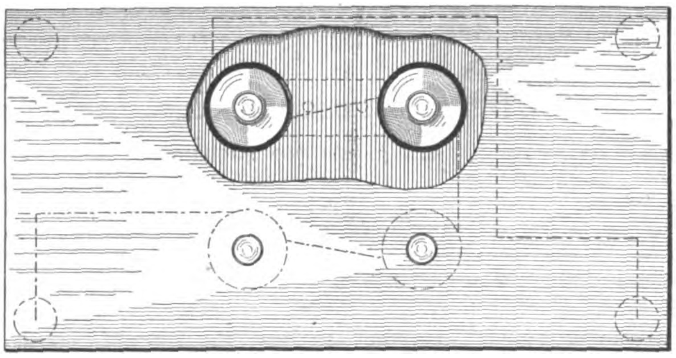

FIG. 5.—PLAN VIEW OF PLATFORM, SHOWING POSITION OF DOUBLE PAIR OF ELECTROMAGNETS.

Let us now wind these bobbins with double cotton-covered magnet wire of No. 18 guage after giving the inside of the brass spools six or eight coats of orange shellac, allowing each coat to thoroughly harden before the next coat is applied. Each spool must be wound full in even layers, a coat of shellac being applied to each layer as it is wound on. In order to wind the four spools full, and have a quantity of wire left for the electrical connections, four pounds of this No. 18 wire is required. Of course each pair of magnets must be wound for north and south poles, by reversing the convolutions of the wire on each bobbin, with the two pairs of magnets connected in series as shown by dotted lines in Fig. 5. This plan also shows clearly the position of the two pairs of magnets, designed to attract the iron bottom of the box on the four corners, each magnet pole taking one-fourth of the pull or strain put on the handle of the box. With this distribution of the magnet poles in relation to the handle of the box, which lies between them, it is impossible for a side strain or twist to concentrate its effect on any single pole, causing the bottom of the box to be disengaged from it.

Having completed the magnets they are pushed into the interior of the base-board or platform, and adjusted by shaving down the grooved channel, or by putting pieces of tin underneath, as the case may require, until the poles of the magnet project about 1-16 of an inch above the level of the platform. Having the adjustment perfect, the shank or bar of the magnet is screwed firmly in place by means of stout screws, and the holes shown in the bar illustrated in Fig. 4. The top of the base board is now covered with a piece of the thinnest wood, securely glued on, with circular holes accurately cut to allow the magnet poles to pass through. Walnut may be had of this extremely light weight, which may be planed down to meet the magnet poles after it is glued on, allowing them to protrude about 1-64 inch. The top is now completed, with the exception of paint or stain, a dark paint hiding absolutely the poles of the magnets if the work has been neatly done.

The bottom of the platform must have grooves cut with a gauge chisel to receive the wires from the magnet windings before a similar wooden bottom is glued on and painted to match the top. The turned legs are glued on the bottom and the proper wire connections made, preferably by soldering.

The magnets may be excited by a large plunge battery of eight or ten cells, or by connection with an incandescent electric lighting system through a bank of lamps arranged in multiple arc. If the service is of the usual 110-volt pressure, eight or ten lamps wired in multiple arc, and included in the circuit, allow sufficient current to pass for energetic excitation of the magnets.

The pulleys for carrying on the suspension part of the trick are too simple to require any detailed description. They may be turned from wood or metal, and be provided with either wood or metal blocks.

In exhibiting this box and stand, the performer elaborates on the fact that the little platform is purposely raised from the stage in order to allow a clear, unobstructed view under the box at all times, isolating it from all possible connection with devices under the stage. The spectator requested to lift the box, is, of course, made to stand on the platform after the running rope is united, his weight serving to press the points in the little legs to good contact with the copper plates under the carpeting.

Owing to the freedom with which it is possible to pick up the little platform at any stage of the trick and exhibit it as "an ordinary board," and the use of the pulleys and secret steel wire, theories as to the working of the trick are difficult to form, as in most tricks performed by bringing two methods into play differing in principle. Of course, a second pair of similar electromagnets can be set into the flooring of the stage to great advantage, in order to show that the little raised platform is merely an isolated stand, having nothing to do with the trick. By elaborating in this manner a most effective trick is sure to result.

DYNAMO TESTING.

TESTING FOR INDIVIDUAL LOSSES.

As mentioned in previous articles, the losses of the dynamo are separate and distinct, and each may be individually tested for and its magnitude determined. For convenience they are herewith re-enumerated. First, the wire losses consist of, *a*, field wire loss; *b*, armature losses; *c*, losses by eddy-currents. Second, iron losses, consisting of, *a*, hysteresis; *b*, eddy-current losses. Third, brush friction. Fourth, Bearing friction. Fifth, Wind resistance.

Some of these losses can be calculated at once, some vary with the load, some do not and some of them are almost inseparably combined together.

The C^2R losses can always better be calculated. The resistance of the armature and the field magnet should be measured when they are warm from continuous running. The currents in these parts at any particular load for which the value of these losses is desired should be measured, and the watt losses will be equal to the square of the current multiplied by the resistance it traverses. The resistance of the armature is usually very low, and can best be measured by means of what is known as the "fall of potential" method. To do this, disconnect the armature from the circuit and pass through it a strong current—the stronger the better—provided the carrying capacity of the armature is not exceeded. The armature should, of course, be at a standstill. Take the difference of potential at the brushes and divide it by the cur-

LII. RY

rent in amperes for the resistance of the armature. The advantage of this method is that both the current and potential can be measured with considerable accuracy, whereas there would be difficulty in measuring a resistance of so low a value.

The field coil, if it be a low resistance series field coil, can be measured in a similar way, and the shunt field coil, in which the resistance is comparatively a large quantity, can be measured with precision by ordinary bridge methods.

The eddy-currents in the armature wire are usually very small indeed, and cannot be conveniently separated from the eddy-current losses in the other members of the machine. The losses due to eddy-currents are usually measured in bulk, together with iron loss due to hysteresis. This is done by driving the armature on open circuit in a fully excited field by a calibrated motor or similar convenient method of measuring the power. The difference in the power necessary to drive the motor thus, and that necessary to drive it with the field unexcited, is the losses due to eddy-currents and hysteresis. These two losses may be separated by making two experiments at different speeds. The eddy-current loss is proportional to the square of the speed. and the loss by hysteresis varies directly as the speed.

It is necessary to determine the combined eddy-current and hysteresis losses at two separate speeds. Call these speeds s_1 and s, call the total watt losses, due to eddy-current and hysteresis at each of the speed w_1 and w, respectively, and call the eddy-current and hysteresis losses at one revolution per minute x and y, respectively, it follows that

$$x s + y s^2 = w.$$
$$x s_1 + y s_1^2 = w_1.$$

This is a simultaneous equation, and from it the value of x and y can be computed in terms of w, w_1, s and s_1, all of which are known quantities. Their value will be found to be equal to

$$x = \frac{w s_1^2 - w_1 s^2}{s s_1 (s_1 - s)}. \quad y = \frac{w s_1 - w_1 s}{s s_1 (s - s_1)}.$$

From these formulas we may readily calculate the value of $x\ s$ and $y\ s^2$; if s is the standard speed, these quantities are the eddy-current and hysteresis losses desired.

The wind resistance of an armature is very slight if it is of a smooth, symmetrical type, and so small that it can hardly be measured. If the armature has a fanning action, such as is the case with the Brush arc machine or the Stanley-Kelly alternator, it may be sewed up in canvas and run with the fields unexcited and afterwards stripped and run again, the difference in the power necessary being the wind resistance of the armature. If the armature is of a plain, smooth body type, without spokes or other projections, which would tend to make the wind resistance a measurable quantity, it will be so difficult to measure these losses that errors involved will often exceed the quantity to be measured.

Bearing friction can be measured by measuring the power necessary to drive the dynamo at the commercial speed with unexcited field and lifted brushes. Bearing friction varies with the load, being sometimes greater and sometimes less when the load comes on, according to the pull of the field magnets upon the armature. There is no convenient way to determine it directly at full load.

It may, however, be estimated by subtracting from the gross input at full load the output and all the losses, excepting that of bearing friction, the other losses being calculated by the methods of the preceding paragraphs. It will be found instructive to compare the bearing friction at full load and at no load. As previously mentioned, the result may be almost anything, and the discrepancy may be so great that it will pay to shape the field magnets a little differently, so as to reduce the pull on the armature.

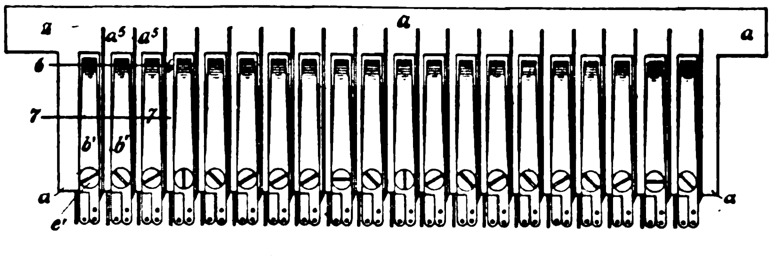

FIG. 1.—STRIP OF JACKS.

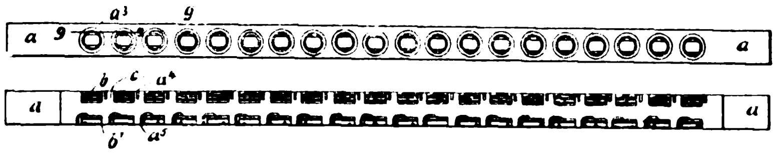
Brush friction may be conveniently determined by mounting the armature loosely in the centres of a lathe and mounting the brush holder with its supports upon a centre rest. Thus arranged, the armature is belted to a small calibrated motor, and the difference between the power necessary to drive it with the brushes lifted and that consumed when the brushes are down is the brush friction. Balancing the armature thus in the lathe centres makes the bearing friction almost nothing and very constant, thus enabling the brush friction to be measured with greater accuracy.



FIGS. 2 AND 3.—FRONT AND REAR VIEW OF JACKS.

AMERICAN TELEPHONE PRACTICE.

SWITCHBOARD DETAILS.

BY KEMPSTER B. MILLER.

As has been pointed out in previous articles, success in practical telephone working can only be attained by the greatest attention to matters of detail. Nowhere is this fact better illustrated than in the design of the various parts which go to make up a multiple board. In the construction of large boards of this type, the possible capacity of the board is limited by the number of spring jacks which can be placed within the reach of a single operator. It is evident, therefore, that space must be economized to the last degree, and yet the jacks must be substantial in order to resist the wear and tear of years of service; must be made easily removable so as to be accessible for repairs; must perform their electrical functions with absolute certainty, and at the same time be so arranged as to facilitate the orderly and systematic connection of the wire leading from the line cables.

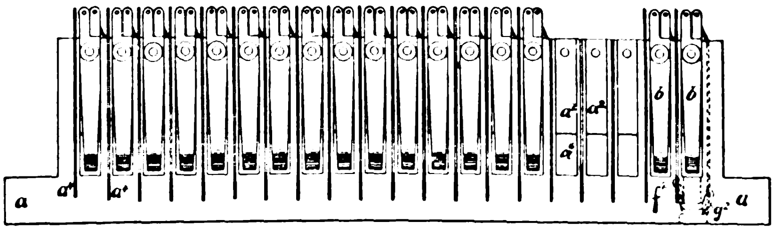

FIG. 4.—BOTTOM VIEW OF JACKS.

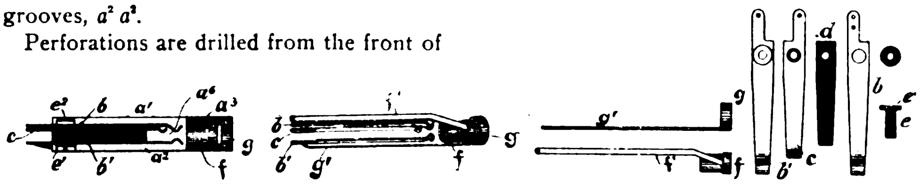
Moreover, when we consider that a multiple board and a capacity of 5000 subscribers will have in the neighborhood of 130,000 spring jacks, we can easily realize that the cost of producing these jacks must be seriously considered. It is well to state here, however, that any economy in the construction of a switchboard which will tend to decrease its durability and reliability of action is poor economy indeed.

As an illustration of modern spring jack construction, we will consider the spring jacks used in the branch terminal multiple board described in the preceding article. It has become common practice to mount the jacks in strips of twenty, and to so arrange each strip that it may be removed from the board by the removal of two screws, which bind it firmly to the frame work.

Fig. 1 shows a plan view of such a strip carrying twenty jacks. Fig. 2 is a front, and Fig. 3 a rear elevation of the same, while Fig. 4 is a bottom view. Fig. 5 is a vertical section through the centre of one of the jacks. Fig. 6 shows the metal portions of one jack assembled, and Fig. 7 shows the parts which, with the strip, *a*, go to make up a complete jack.

The hard rubber strip, *a*, forms the frame work for each strip of twenty jacks. The projections at its ends provide for attachment to the switchboard. In this strip are milled, on its upper side, the transverse grooves, a^1, a^1, and on its lower side similar grooves, a^2 a^2.

Perforations are drilled from the front of the strip, one perforation to each pair of grooves, having its axis centrally located and parallel with respect to the grooves. A small portion of the hard rubber is removed from between the grooves so as to leave a rectangular opening, a^6, shown in Figs. 4 and 5, through the strip connecting the two grooves at those ends which are nearer the front of the jack. In the grooves, a^1, upon the upper surface of the rubber strip are mounted springs, *b*, and *c*. The spring, *b*, is the longer of the two, so that its curved extremity is presented close to the end of the perforation through the front portion of the strip, *a*. The springs are insulated from each other by a strip or tongue, *d*, of hard rubber placed between them, thin and flexible enough to impede the flection of the two springs. In the under groove, a^2, is mounted another spring, b^1, similar to spring, *b*, and of equal length.



FIGS. 5, 6 AND 7.—DETAILS OF JACK.

The three springs, *b*, *c*, and b^1, are firmly secured to the strip, *a*, by a bolt, *e*, passing through them and the body of strip, *a*. The bolt is insulated from the springs, b^1, and, *c*, by rubber washers and bushings. In the perforations, a^8, in front of the strip, are inserted short tubes, *f*, of brass. Each tube or thimble, *f*, is provided with a shoulder, which bears against a corresponding ledge in the perforation, a^8, so as to prevent the tube from being thrust backward toward the rear of the jack by the insertion of the operators' plugs. The thimble, *f*, is provided with an extension, f^1, to afford electrical connection with it from the rear of the jack. This strip, f^1, extends through an oblique duct, f^2—shown in dotted lines in Fig. 4—and thence through a transverse slot or saw cut, a^4, to the rear of the strip.

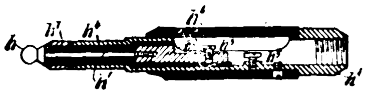


FIG. 8.—DETAIL OF PLUG.

In front of the thimbles, *f*, in the perforations, a^8, are placed the test rings, very short tubes of brass, *g*. These are forced into place against other ledges in the perforation. The ring, *g*, is also provided with an extension, g^1, projecting to the rear of the strip of spring jacks. These extensions, g^1, are of wire and pass through another duct, g^2, in the front portion of the strip, *a*, into a saw-cut, a^6, thence to the rear of the strip, where they are connected with the spring, *b*.

The springs in these jacks are of hard German silver, which has been found the most desirable material for this and similar purposes.

The detail of one of the plugs used with these jacks is shown in Fig. 8. The tip, *h*, of brass is secured by the rod, h^1, to the block, h^2, also of brass. Insulated from the tip portion by a rubber bushing is the sleeve contact, h^4, of the plug, which projects rearwardly and forms the main body of the plug. Over this portion is slipped a shell, h'', of hard rubber or fibre, which forms a handle for the plug. Between the tip and sleeve and insulated from each, is the ring, h^7, which, as was described before, is for short-circuiting the springs, *b*, and b^1, when the plug is inserted in the jack.

Screw connectors, h^3, and h^5, form convenient terminals for attaching the strands of the cord to the tip and sleeve, respectively, of the plug. These connectors are always readily accessible for inspection or repair by the removal of the sleeve, h^4.

This brings us to the subject of flexible cords for switchboard use. The matter seems at first thought to be a simple one, but much thought and time have been spent in perfecting this branch of the equipment. Even at this late day, the best cord is not good enough. As near a perfect cord as has up to the present time been made is constructed as follows: Each conductor in the cord is composed of strands of tinsel and a few fine copper wires, to add strength and conductivity. Around each of these conductors is wrapped tightly, in opposite directions, two layers of floss silk. These should be wrappings and not braids, as a wrapping serves to keep any broken ends of the tinsel or wire down in the bunch better than a braid. Around these wrappings of silk is a braid of linen, which adds strength to the conductor. If the cord be for a metallic circuit, the two conductors thus formed are then wrapped with two more layers of floss silk, and the whole is then encased in a strong spiral wrapping of hard spring brass wire. The wire in this spiral is stiff enough to retain its shape, but the spiral as a whole is so flexible as to allow free bending of the cord. An outer covering of polished linen is tightly braided over the spiral, and after the ends are tightly anchored to prevent the conductors sliding back and forth in the spiral, the cord is complete. An extra layer of outside linen braid is often put on the cord for a distance of about one foot back of the plug, to prevent the sharp bending or kinking of the cord by the operator in inserting the plugs into the jacks.

HANDY TOOLS IN POWER HOUSES.

A most frequent and annoying trouble in power houses is the cutting out of ordinary globe valves. If they are carelessly closed, the steam leaking through them, will cut the seats and the disks full of grooves, of which Fig. I is a fair representation. This renders them entirely useless unless they are again machined up true. Following is described a little machine which can be made at a small cost by any machinist and which will effectually reface grooved valve seats.

This, too, which is designed to operate in an ordinary bit stock, consists of a shank and is provided with the usual square shaped head adapted to be securely clasped by bit stock chucks. In the other end is drilled a rectangular hole, which will exactly fit two thicknesses of some standard tool steel, preferably 3-16 by 3-8. It is important that the sides of this hole toward the shank should be exactly flat and at right angles to the length of the tool, and that the hole should be very central.

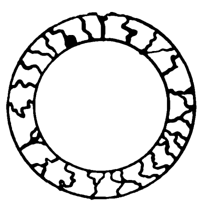

FIG. I.—SCORED VALVE SEAT.

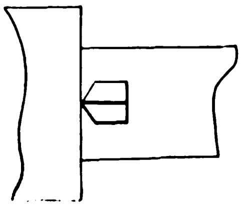

FIG. 2.—CUTTING TOOL.

The tool steel is prepared with a bevel edge, as shown to the right of the figure, and two such pieces are fitted into the hole so that they protrude at either end and form cutting edges. They are locked in position by means of a cup-shaped collar, which is secured to the end of the spindle, as shown, and is exactly the internal diameter of the valve seat to be refaced. It therefore follows that a number of these collars should be provided for various sizes of valves, but that the same spindle and cutting tools are adaptable to a number of sizes.

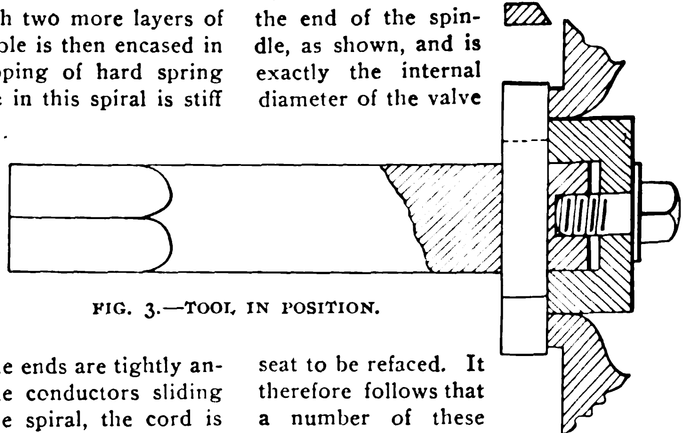

FIG. 3.—TOOL IN POSITION.

The method of procedure is obviously to fit tools into the shank, as shown in Fig.

2, when each of the two cutting edges will be central and opposite when viewed from one end of the hole, and therefore both of them will cut when the tool is turned. The tool is inserted into the valve seat as shown in Fig. 3, and rotated with considerable pressure by means of a bit stock. If skilfully done the valve seat will be bright, square and free from flaws after the operation is finished. Such a tool should not cost more than two or three dollars to build, and if the station attendant has a lathe at his disposal it is highly probable that with a little labor he can build the tool at even less cost. It will be found indispensable after it once has been tried.

◆

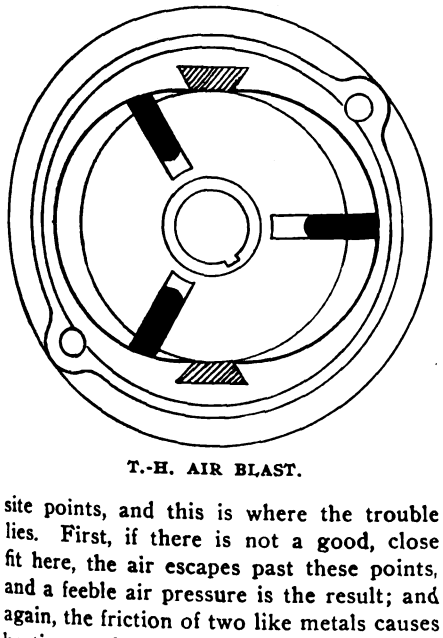
A REMEDY FOR TROUBLESOME ARC-MACHINE AIR BLASTS.

BY R. H. STERLING.

A weak feature of an otherwise excellent dynamo lies in the air blast of the Thomson-Houston arc machine. On the blast depends, more than all other causes, freedom from flashing; for, if there is not a powerful jet of air delivered to the brushes, flashing is almost sure to follow.

Then, again, a most fruitful source of heating lies in this selfsame piece of apparatus. These two defects—weak blast and heating—can be traced to one point, and the remedy is so simple and effective that I have found it advisable to apply the change in construction I am about to describe, to new air blasts that have not begun to show signs of wear.

It will be observed, on examining the interior of the blower, that the hub, or revolving part, touches the inner circumference of the case at two diametrically opposite points, and this is where the trouble lies. First, if there is not a good, close fit here, the air escapes past these points, and a feeble air pressure is the result; and again, the friction of two like metals causes heating and rapid wearing away of the parts. By referring to the accompanying diagram, showing the interior of the blower, there will be seen two dove-tailed pieces at the point of contact; these are segments of babbit metal, and are the simple devices that will relieve all the annoyance spoken of. The best way to insert them is as follows:



T.-H. AIR BLAST.

Remove both front and back plates, leaving nothing but the open ring of the case, and make two dove-tailed slots by filing, or better still, cutting in a planer (for the cast steel is difficult to file), and have them the same width as the space the hub revolves in and one-half inch thick. Now replace the back plate, lay the case face up, and place the hub in position and exactly in the centre, first pasting a piece of letter paper around the circumference of the hub. With some putty dam up any openings left at the edges of the slots, and place pieces of heavy cardboard, weighted down, on top of the slots, having two holes in each—one to pour the melted babbit through, and the other to allow the air to escape. The object of the cardboard is to form a level surface on the babbit.

It is best to have the blower case and hub warmed first, so that the babbit will not be chilled too quickly, which will allow it to flow at a thinner state and make a better cast. When cooled off, remove the hub and scrape smooth the surface of the babbit where the hub revolves. The thickness of the writing paper allows for enough clearance. See that the babbit has filled up flush with the face of the case under the cardboard, so no air can escape there.

After two years' trial of one of these remodeled blowers on an all-night machine, it has not been known to warm up, even in the warmest nights in summer, and the blast is as sharp as when first started. Furthermore, there seems to be no wear to the hard rubber wings, and a less amount of oil is required.

◆

INTERIOR WIRING.

SYSTEMS AND METHODS OF WIRING.

BY CHARLES E. KNOX.

In adopting the system and selecting the method of wiring, we are generally aided or (in some cases) hindered by the existing conditions. If current is obtained from an outside source, and there be little probability of an isolated plant being installed in the building, it simply remains to have the wiring comply with the requirements of that system. In some cases there may be two outside sources of supply; in this case it is frequently desirable to have the wiring adapted for use with either system, in the interest of the consumer.

If, on the other hand, a dynamo plant is to form a part of the installation, the problem becomes somewhat more complicated. In some cases (usually in large plants) it is reasonably certain that the plant in the building will be the sole source of current. As alternating current machines are rarely employed in isolated plants in buildings, the wiring in these cases would be the two-wire system for direct current. If, however, it is desired to supplement the plant with, or to have as an extra precaution in case of break-down, an outside source of supply, the wiring must be adapted for use with either or both systems.

If the outside source is the three-wire system, it is usually the practice to run three-wire mains and feeders, making the middle conductor of twice the cross-section of the two outside conductors, and having a triple-pole "breakdown" switch on the switchboard, so connected that, when the switch is thrown one way, the current is supplied from the plant in the house, the two outside conductors being connected together; when the switch is thrown the other way, the current is obtained from the outside source, the middle conductor becoming the neutral wire, one outside becoming positive and the other negative.

Another way of accomplishing the same result is to run two-wire feeders and mains, using double-throw feeder switches, so connected that when the current is obtained from the outside service, the load may be distributed equally (or nearly so) on the two "legs" of the system, by throwing the various switches one way or the other until a balance is obtained. We will discuss the comparative merits of these two methods later on in the series.

If the outside supply be alternating current, and it be used in conjunction with the plant, or if it is the sole source of supply, no radical change need be made in the wiring unless iron or steel armored conduit be used. In this event it is absolutely imperative that the two wires constituting any given branch circuit feeder or main be placed in one tube. For, if the two wires of any circuit were placed in separate tubes, we would have practically a single turn of conductor around an iron core (the core being the walls of the iron pipe), the result of which would be that a counter E. M. F. of self-induction would be created, and eddy-currents would be set up in the iron. The disturbance thus produced is proportional to the frequency of the alternations and the current flowing through the conductor.

The writer knows of one instance where this fact was overlooked by all parties concerned in quite a good-sized office building, where alternating current was to be used, and in every case the two conductors, constituting a feeder or main, were run in separate tubes. When the current was turned on, the E. M. F. was cut down to such an extent that it was barely sufficient to make the lamps red. The result was that the feeder and main circuit wire had to be pulled out of the tubes and run exposed on the walls and ceiling in moulding. Even if iron or steel tubes be not used, it is necessary to keep the wires as close together as possible, as the inductive E. M. F. depends upon the number of line of force inclosed by the loop, the area of which increases, of course, with the distance apart of the two conductors.

If a plant is to be installed as a part of the equipment, the voltage of the installation may be made to fit the requirements. At the present time, for incandescent lighting, the choice of voltage lies between the 110 and 220 volt systems, the selection of one or the other being dependent on whether 110 or 220 volt lamps be used.

While it is doubtless true that the latter voltage will in time largely, if not entirely, supersede the former, the selection and use of the higher system should be attended with the utmost care. The reason that this precaution is necessary is due to the small factor of safety usually allowed in the manufacture of electrical specialties. All the standard sockets, rosettes, receptacles, panel boards and switches are designed for 110 volts, and they have "troubles of their own" even at that voltage. To increase the voltage with these same appliances is simply increasing the possibility of defects in the installation. Of course, there may be existing appliances here and there which may have been designed with a sufficient margin for using them on 220-volt circuits, but each socket, rosette, etc., should be examined with regard to its availability for that voltage. Then, too, the wiremen will have to become accustomed to the higher voltage, so that they will exercise greater care in making connections at the outlets, fixtures and panel boards.

As to the method of running the circuit work, this is also usually determined by attending circumstances. If the building is a new one, it is rarely either desirable or necessary to expose the work. If the circuit work is concealed, it is necessary to place the wires in conduits. It is poor economy nowadays to use any conduit other than an iron or steel tube with a suitable insulating lining. The "best is none too good" and this best is neither too good nor too expensive, so there is really no excuse for not using it. Brass conduit is still largely used in installations outside of the great cities, but with this tube so many precautions must be taken to prevent its destruction by the traffic incident to the construction of a building of any size, by the nails of the carpenter in laying the floor, and also by the action of the cement on the copper in the tube, that it is questionable whether there is any actual saving between the cost of it and of the iron tube. The estimated difference in cost between the use of brass and iron-armored tube is probably between 10 and 20 per cent. To use any existing conduit other than those having iron, steel or brass armor, where it is possible to use these, would be a short-sighted policy.

In buildings already built, and, indeed, sometimes in new buildings, it is both preferable and essential to run the work "exposed." There are three ways of insulating the wiring generally employed in this class of work. The wires may be run: first, in moulding; second, in conduit; third, supported on porcelain cleats or insulators.

The advantages of the use of moulding are obvious. It is cheap, easily and quickly put up, unobtrusive and is flexible in the sense that it readily accommodates itself to varying conditions. Its disadvantages are: that it is rarely if ever fireproof, the capping is frequently removed after the work is done, allowing the wires to hang down, and it is not nailproof; in fact, when it is run along the wall, it presents a splendid means of support for coat hooks, picture frames, etc. There are cases where it is wise to use it, however, simply and solely because it is better than anything else we now have to replace it.

Conduits are rarely available for exposed work, because they are generally unsightly, expensive, difficult to put up and because of the number of bends and elbows usualy necessary in crossing beams and to avoid other exposed work. For the rising portions of the feeders and mains, and for the portions run in the cellar and other places where it is not objectionable on account of its appearance, it is to be preferred to either of the other two methods.

Running the wiring on porcelain insulators or cleats has one overwhelming advantage over either of the other methods, which is that the defects in the wiring, where there are any, are plainly visible, and for this reason the wiring is usually put up with great care, and the defects are few in number: like moulding, it is also cheap, easily and quickly put up and has a certain amount of flexibility.

In some instances it may be desirable to use all three methods, each being most suitable for some particular portion of the building. In fact, sometimes it is even wise to use flexible tubing, "fishing" it between the floors and the ceilings where there is sufficient space, running up between "studs" in the partitions and by other similar methods. This is very likely to be the case in a building already built, no provision having been made for electric light, the walls and ceilings being expensively decorated and parquet floors laid. In such instances cutting the walls and ceiling or taking up the floors would not be permissible. When the building has been built for several years, and has thoroughly dried out, and if great care be exercised in the installation of the work, a fairly safe and satisfactory piece of work may be accomplished in this manner.

* * *

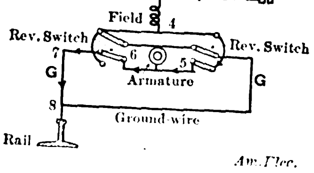
ELECTRIC RAILWAY PRACTICE.

BY EUGENE C. PARHAM.

INSTALLATION.

In our last complete article under this caption we considered the placing of the several devices which comprise a car equipment, and left off where the devices were temporarily connected to the hose. We will now cite some of the commoner difficulties incidental to starting a car on its initial trip, and give the methods of locating them.

The temporary connections between hose and devices being made, the next step is to see that both controller handle and reverse handle, or drum on both controllers, are at the "off" position; then, putting on the trolley and closing both hood switches, "give 'er a notch," to see if the motors conspire to run the car in the same direction; and if in the same direction, in accordance with the reverse handle indication on both ends of the car. It is undesirable to have the reverse switch on one end of the car direct the car north and the reverse switch on the other end direct the car south, for, as can be seen in Fig. 1—a symbolical drawing involving a single motor controlled from both ends by means of two reverse switches and two ordinary rheostats—the result will be a short circuit, as through path 1, 2, 3, 4, 5, 6, 7, 8. As soon as the rheostat is pretty well cut out, the car fuse blows if the motor field does not.



Am. Elec.

FIG. 1.—CAR CIRCUITS.

Before we proceed further, let me say that many railway men agree with me that the customary method of connecting the motors to the hose by means of ordinary two-way connectors sewed with tape is awkward and expensive. Occasions often arise for raising the car body from the truck, necessitating disconnection of the motor and loss of time and tape. This loss is a small matter on a single equipment, but when we consider the case of a dozen or more trucks to be shifted from summer to winter, and from winter to summer cars, year in and year out, besides the number of times it may be necessary to disconnect the motors for testing or repairing, the desirability of improvement presents itself more forcibly.

If upon giving the controller a notch the car fails to move, any one of several conditions may be responsible. If upon throwing off no flash is observed, it shows that the car is taking no current, and that, therefore, there is want of power on the line, or that there is either an open circuit or—what may amount to the same thing—a wrong connection. Sometimes failure to move is traced to a very trivial cause, such as the trolley being tied down, or resting on a circuit breaker, or a hood switch left open or no brushes in the motors. Absence of power may be due to temporary trouble at the power house or to neglect in closing a local switch.

A difficulty commonly contended with is a "dead" or dirty rail. In the first case, the rails upon which the car wheels rest are not bonded to abutting rails; in the second case, dirt on the rail, however well bonded, insulates the flat surface of the wheel tread so no current can pass. In either case a man standing on good ground and touching the truck, dash rail or grab handle, and in wet weather even the car side, is liable to have his ideas confused. In case of a "dead" rail a wire must be run from the "dead" rails to the live ones. The troubles due to dirty rails can be generally removed by laying a switch iron or crowbar on the rail and pinching the wheel. The operator must be very careful to get the iron well on the rail before touching the wheel or the current will ground through him, ordinary earth being absolutely useless as a conductor of large currents, but a good shock medium.

If the car lamps burn all right, it shows the trouble to lay between the positive side of the first hood switch and the rail. If the car lamps fail to burn (assuming their circuit to be intact), and the test lamps, described in a previous article, burn all right, when one end of their circuit is attached to the trolley wire and the other end to what is known to be good ground, the fault may be located as follows:

Leaving the test circuit's ground end secure, and the trolley wheel on the wire, close both hood switches, and with the trolley end of the test circuit touch successively the wire, wheels, hasp, stand, positive and negative side of both switches, and finally the controller trolley connecting post; if the lamps continue to respond up to and including the last-named point touched, it indicates the wiring to be intact between the trolley wire and controller. If at any test the lamps fail to glow upon making good contact with a given point under test, it shows the open circuit to lay between the point of failure and the preceding point touched, and this part of the circuit must be investigated.

The next step is to test the circuit from the rail to the controller ground connecting post. Leaving the trolley test line attached to the trolley wire, the other test line is touched, first to good ground, to insure that the test circuit is in good order, and is then touched successively to the rails on which the wheels rest, an unpainted part of the truck, a bolt head on the motor frame, the terminal connecting the motor frame to the ground wire, and at last to the controller ground connecting post. Just as before, any two points on one of which the lamps glow, and on the other of which they do not, include the open circuit.

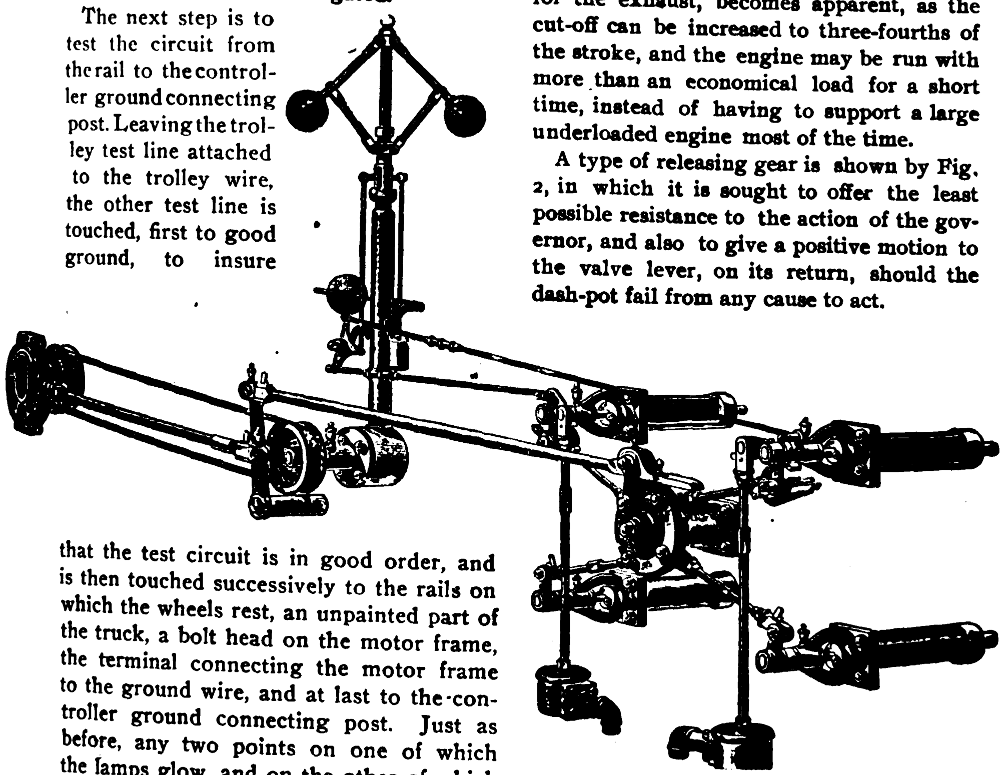


FIG. 1.—A TYPICAL CORLISS-VALVE GEAR.

We have thus far, with the exception of several wires inside the controller, gone over all wires which carry the current of both motors under all conditions, and in doing so we have shown that the trouble must be included between the trolley and ground controller connecting posts. To proceed with the test, some knowledge of the car wiring is required, and this will be considered in the succeeding article.

VALVE GEARS.

Undoubtedly, the Corliss-valve gear has done more to improve the efficiency of the steam engine than has any other gear. It must be acknowledged, however, that some less complicated gears are doing almost, if not quite as much, in this line as are the complicated forms of Corliss gears, a type of which is shown by Fig. 1. It is claimed by the makers that the simple little gear shown by Fig. 3, of the preceding article, does everything, and secures all the efficiency commanded by the elaborate Corliss gear of Fig. 1.

But there are a great many forms of "Corliss valve" now on the market, the varieties being almost as numerous as the makers thereof. Some forms have one wrist-plate, as seen in the engraving, other forms have two wrist-plates, and still others have the two eccentrics, but no wrist-plate at all. The methods devised for detaching the valve from the rod whenever the cylinder has taken sufficient steam for that stroke, are also very many, and a few of them will be described here.

When the engine is to be driven all the time with a stated load which varies very little, then the single eccentric, one-wrist-plate variety leaves little to be desired; but when the work is to vary through a wide range, as when driving street railways and rolling mills, then the value of one eccentric for steam admission, and another eccentric for the exhaust, becomes apparent, as the cut-off can be increased to three-fourths of the stroke, and the engine may be run with more than an economical load for a short time, instead of having to support a large underloaded engine most of the time.

A type of releasing gear is shown by Fig. 2, in which it is sought to offer the least possible resistance to the action of the governor, and also to give a positive motion to the valve lever, on its return, should the dash-pot fail from any cause to act.

A is the valve-lever, keyed upon the valve stem, *B*; *C* is the tripping-lever, carried upon the fulcrum pin, *D*, on the lever, *A*; *E* is tripping-lever pin on trip-lever, *C*; *G* is valve-connecting rod connecting tripping-lever pin, *E*, to wrist-plate pin; *H* is latch-lever hung on stud-pin, *L*, on valve-lever, *A*; *I* is a roller carried in joint of latch-lever upon stop-pin; *N* is a spring pressing stop-pin against valve-lever, *A*; *O* is a valve-stem bearing, shown broken, and forming part of steam chest cover; *P* is a reverse catch bar attached to tripping-lever *C*; *Q* is a dash-pot lever.

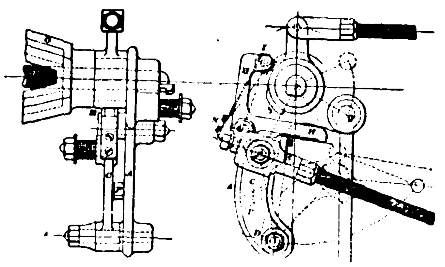

FIG. 2.—CORLISS-RELEASE GEAR.

In operating this releasing gear, when the parts are in the position as shown in Fig. 2, with the latch securing the tripping-lever, the movement of the wrist-plate by means of the connections causes the valve to be opened, and, according to the position the governor lever cam, *I*, is set in it, will determine, in relation to the speed of the governor, the point at which the latch-lever will be released.

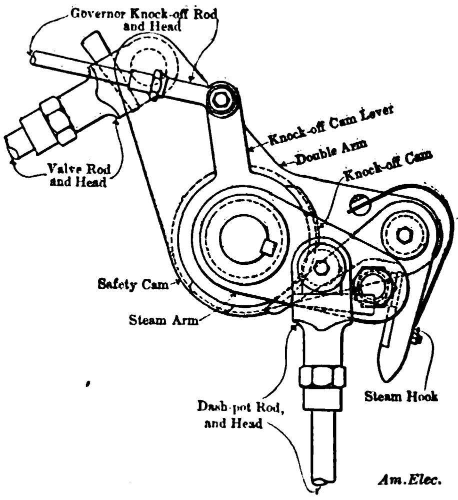

FIG. 3.—RELEASE WITH SAFETY CAM.

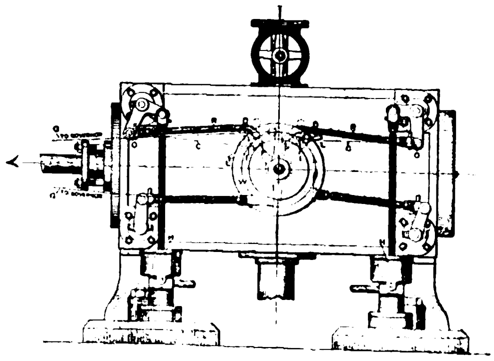

FIG 4.—WRIST-PLATE RELEASE.

It will be noticed that the inner corner of the latch on latch lever where it engages the toe of the tripping-lever, is in a direct line with the center of the pin, *L*, upon which the latch-lever is hung, so that the holding part of the latch is confined to a line central with the pin when the movement of the wrist-plate is transmitted to the tripping-lever, which is held by the latch-lever.

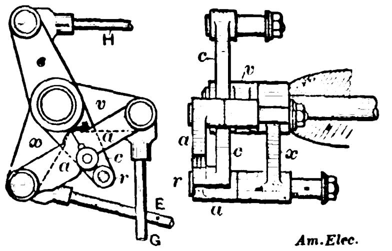

FIG. 5.—COLLAPSING RELEASE.

The slightest contact of the roller on the latch-lever with the governor lever cam disturbs this narrow line of pressure, and the further movement of the tripping-lever, causes the latch jaw to move upward and away from the toe of the tripping-lever, thus taking the strain off of the roller of the governor cam, and allowing the governor to act freely.

The further movement of the toe of the tripping-lever causes it to travel in a curve the reverse of the curve on which its fulcrum on the valve-lever travels. Thus all drag or friction which is common to tripping-levers which work around the center of the valve-stem, is avoided, and the evils incidental to that system of liberating gear are got rid of.

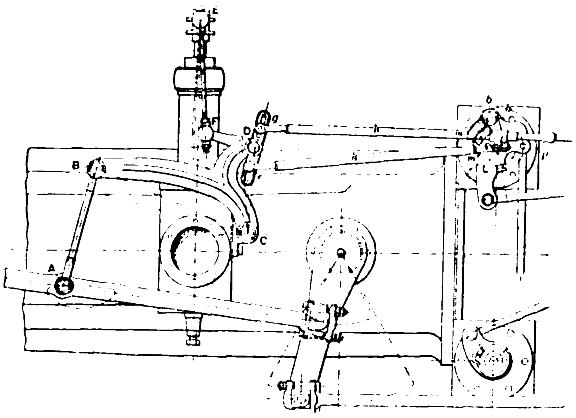

FIG. 6.—RELEASE FOR LONG CUT-OFF.

Another form of releasing gear is shown by Fig. 3, where a safety cam is attached to the bottom of the knock-off cam, in such a manner that should the governor belt break, or the governor be stopped by accident, the engine will be stopped at once. The simplicity of the gear is also clearly shown by the engraving.

Another gear is the one marked Fig. 4. In this, all steel blocks, springs, hooks and small parts have been eliminated, and the release gear is attached direct to the wrist-plate, nothing but a simple folding device being used. This makes the valve motion practically noiseless.

The operation is as follows: The wrist-plate, *W*, moving in the direction indicated by the arrow, would cause link, *L*, to tighten and keep its hold on valve rod, *R*, until the end of link, *L*, comes in contact with roller, *D*, at which point the center of pin, *P*, is raised above center line, *C*, allowing the dash-pot to instantly close steam valve, the link assuming similar position to that shown on the left hand. When the wrist-plate completes its motion in direction indicated, the left-hand link, *L*, and rod, *R*, will fold together like that on the right side.

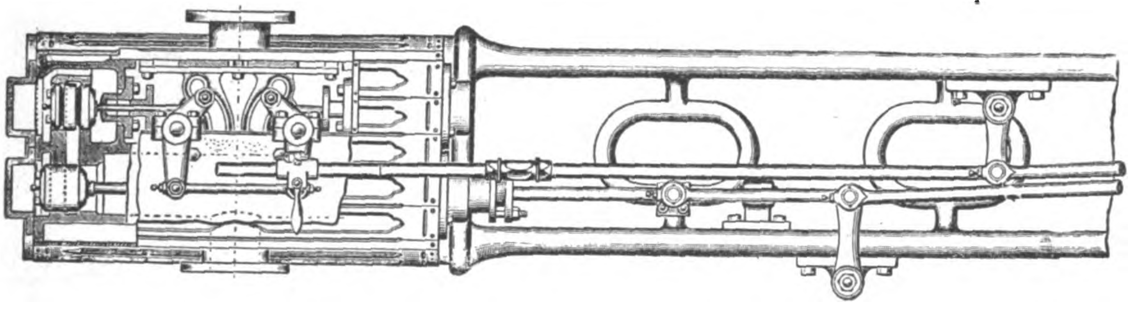

FIG. 7.—PISTON-DETACHING GEAR.

Another form of folding, or rather of collapsing gear, is that in Fig. 5, whereby the steam arm is held to the valve rod by means of a sort of knuckle joint, which doubles up at the end of the travel, or when affected by the governor rod, and allows the dash-pots to assume control of the admission valves.

Another form of Corliss gear (Fig. 6) is for securing the effect of the double eccentric, and thereby allowing the engine to work under overloads up to a cut-off of 75 per cent. or even more. The gear is a complicated one, and it is a question whether the double eccentric is not the most advisable form. Other forms of valve gear dispense with the wrist-plate and the unhooking devices. The same eccentric motion is used as with the Corliss, and in some cases, the same form of valves, a sliding block being used instead of the wrist-plates and releasing hooks.

In Fig. 7 a gear with four piston valves is shown, two eccentrics being used, and the steam valves controlled independent of the exhaust. This is a form of piston-valve gear where there is an unhooking device, allowing the valves to be controlled by hand at will.

One other gear must receive notice in this article. It is a double-eccentric device, with a differential attachment whereby the admission valve partakes of the same motion given to the exhaust valves, but is modified by the second eccentric, which in turn is controlled by a wheel governor. The three large diagrams show the action of the device very plainly. The small diagram delineates the geometrical movements of the several parts; as seen in the center of Fig. 8.

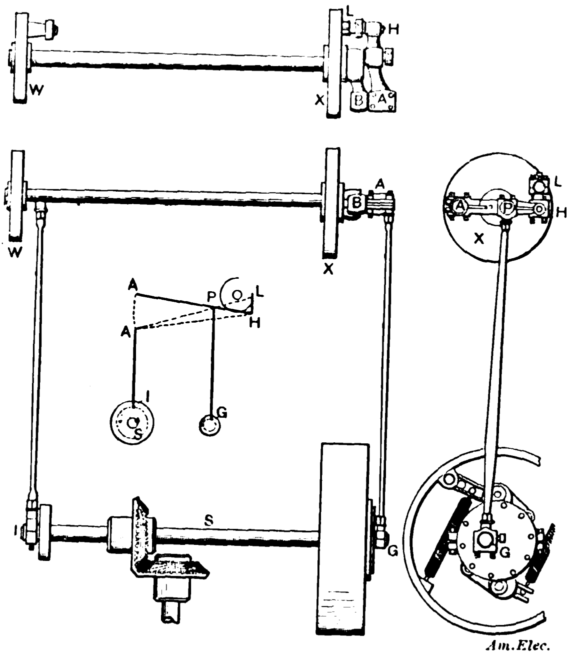

FIG. 8.—DIFFERENTIAL, DOUBLE-ECCENTRIC GEAR.

In some cases, particularly in compound engines, the rods, instead of being attached directly to separate valves, are carried to wrist-plates and all the valves of a compound or triple expansion engine are worked therefrom. In such a case, there would be two wrist-plates, one for the steam, the other for the exhaust valves.

LESSONS IN PRACTICAL ELECTRICITY

INDUCTANCE AND CAPACITY IN PARALLEL.

In the preceding article the subject of inductance and capacity in series was considered, and in the present one their arrangement in parallel will be taken up. To some readers the calculations may appear somewhat complex, but they have been made as simple as the subject admits. No knowledge beyond arithmetic and the use of formulas is actually necessary, as the trigonometrical calculations have been reduced to the solution of right-angled triangles and a formula.

The subject, in fact, is one very difficult to simplify from its very nature. When treated analytically or in a general manner, a considerable mathematical education is required, while graphical solutions are so involved as to be usually unintelligible to few besides those who construct the diagrams.

The reader who wishes to make calculations similar to those given here should have a table of sines and tangents, which are usually found in mechanical handbooks. To use such tables in the present instance requires no knowledge of trigonometry, as they only serve to identify angles, or vice versa.

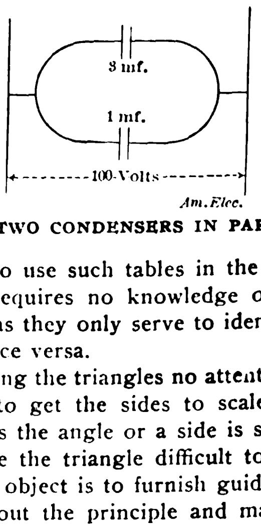

FIG. 1.—TWO CONDENSERS IN PARALLEL.

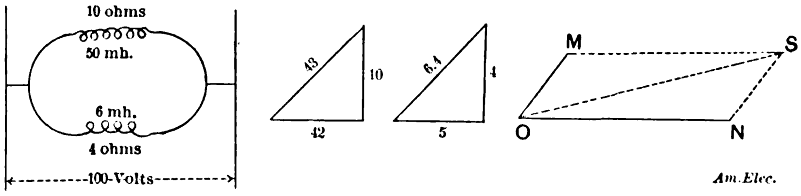
In drawing the triangles no attention will be given to get the sides to scale, as in many cases the angle or a side is so small as to make the triangle difficult to represent. The object is to furnish guidance in following out the principle and make the solution as mechanical as possible. The three triangles used will be distinguished

LIBRARY

as inductive, capacity and current triangles, respectively.

Referring to Fig. 1, suppose that across a 110-volt alternating current circuit having a frequency of 133, two condensers are placed in parallel, one having a capacity of 3 microfarads and the other of 1 microfarad.



FIGS. 2, 3, 4 AND 5.—TWO INDUCTANCES IN PARALLEL.

In a preceding article the deduction was given of the formula for calculating the E. M. F. set up at the terminals of a condenser in a circuit through which current is flowing, the formula being

$$E = \frac{1000000\, C}{2\, \pi\, n\, k\, E}; \qquad (1)$$

solving this for $E = 100$, $n = 133$ and $k = 3$, we find that the value of the current in the three-microfarad condenser circuit will be

$$C = \frac{2 \times 3.1416 \times 133 \times 3 \times 100}{1000000} = .2507.$$

As the capacity of the other condenser is one-third that just calculated, the value of the current in its circuit will be .083. As these two currents will be in phase with each other, the current flowing in conductor *A B** will be their sum, or .3337 amps.

Taking up now the case of two inductances in parallel, suppose, as in Fig. 2, one of the parallel branches has an inductance of the value of 50 millihenrys and a resistance of 10 ohms; and the other an inductance of the value of 6 millihenrys and a resistance of 4 ohms; substituting in the formula for inductive E. M. F. deduced in the preceding article

$$E = \frac{2\, \pi\, n\, L\, C}{1000} \qquad (2)$$

we have in the case of the upper branch for $C = 1$, $n = 133$ and $L = 50$,

$$E = \frac{2 \times 3.1416 \times 133 \times 50 \times 1}{1000} = 42$$

or 42 volts inductive E. M. F. when a current of 1 amp. passes.

Referring now to the inductive triangle, Fig. 3, the length of the base, which represents the inductive E. M. F., will be 42. As 1 amp. is flowing, there will be 10 ohms ohmic drop in the coil, which will be the perpendicular of the triangle. Solving the triangle, we find that its hypothenuse will be 43, which will represent the impressed E. M. F. Since, however, the E. M. F. between the mains is 100 volts, the current flowing will be in the ratio of 100 : 43 or 2.32 amps.

Proceeding as above, it will be found that the inductive E. M. F. corresponding to 1 amp. flowing through an inductance of 6 millihenrys is 5 volts, and the ohmic drop from 1 amp. through 4 ohms is 4 volts. Referring to the triangle of Fig. 4, this gives an impressed E. M. F. of 6.4 volts. Since, however, the E. M. F. between the mains is 100 volts the current flowing will be in the ratio of 100 : 6.4 or 15.6 amps.

As will be seen from the triangles, Fig. 3 and Fig. 4, the two currents will not be in phase since the angles between the perpendicular and hypothenuse are different. The tangent of the angle is in each case the base divided by the perpendicular, or 4.2 for the triangle of Fig. 3 and 1.25 for the triangle of Fig. 4. Referring to a table of tangents, it will be found that these correspond to angles of 76 deg. and 51 deg. respectively.

In other words, since the current is in phase with the ohmic E. M. F. or the perpendicular of the triangle, in one case the angle between the impressed E. M. F. and current of 76 deg. and in the other 51 degs., or the currents have a phase difference of 76-51, or 25 degs. What we now require to know is the resultant of these two currents which will give the current flowing in the conductor, *A B*.

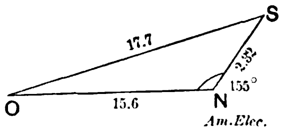


FIG. 6.—CURRENT TRIANGLE.

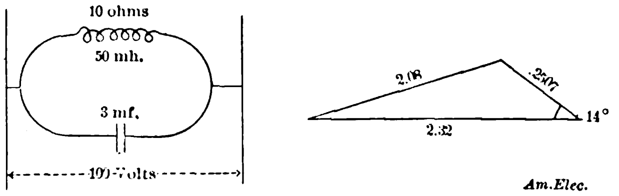


FIGS. 7 AND 8.—INDUCTANCE AND CAPACITY IN PARALLEL.

Fig. 5 represents a parallelogram of forces, of which the two sides represent in length the values of the two currents above found, while the angle, *M O N*, represents the phase difference of the currents; therefore, the diagonal, *O S*, will represent the value of the current flowing in the circuit. It will also be seen that instead of drawing the parallelogram we might have laid down the lines corresponding to the value of the currents, at an angle equal to the supplement of the phase angle, or the difference between 180 degs. and that angle—155 degs. in this case. This gives us a simple triangle, as in Fig. 6, of which the unknown side is the resultant whose value we wish to know. This triangle may either be laid down by means of a protractor and the side, *O S*, measured, or the triangle may be solved trigonometrically.* In either case it will be found that the length of the line, *O S*, is 17.7, which gives the value of the current that will flow through, *A B*.

It will be seen that this current is greater than either of the component currents and less than their sum. With two inductances in parallel the current will always be less than the sum of the component currents, except in the limiting case, and the angle, *O N S*, of the current triangle will always be obtuse.

Fig. 7 represents the case of an inductance and a capacity in parallel. The value of the inductance is 50 millihenrys and its resistance 10 ohms, the value of the capacity being 3 microfarads.

We found in the first case considered that the current flowing under an impressed E. M. F. of 100 volts through a condenser of 3 microfarads is .2507 amp., and in the second case that the current flowing under the same impressed E. M. F. through an inductance of 50 millihenrys and 10 ohms is 2.32 amps., the angle of inductive lag being 76 degs. But the current flowing through the condenser leads the E. M. F. by 90 degs., so that the two currents have a difference of phase of 90 + 76 = 166 degs.

Instead of drawing the parallelogram of forces, as in the second case, in order to find the resultant current, we may use a simple triangle under the condition that instead of the angle of phase difference, its supplement be used, which in this case is 180 — 156 = 14 degs. (Fig. 8). Solving this triangle as explained in the footnote, we find the resultant current to be 2.08 amps.

That is, the current in the conductor, *A B*, is actually less than the sum of the two currents in the parallel circuits. This follows from the fact that, owing to the difference in phase between the parallel branches, a current surges back and forth between them. A practical application of this peculiar phenomenon is that with a given E. M. F. a greater current may be passed through an inductive circuit by shunting it with a condenser; and there is one value of a condenser capacity that will entirely nullify the inductive E. M. F., as in the case of an inductance and capacity in series.

Fig. 9 represents the case of a branch having in circuit a condenser of 5 microfarads in series with a 50-volt lamp, the

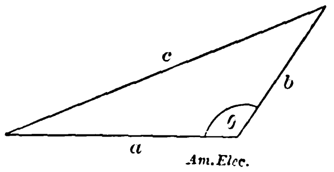
---

**A B*, omitted by the engraver, designates here and following the conductors connecting the parallel circuit to the line.

* The triangles used in these problems other than right-angled triangles may all be solved by the following formula:

$$c^2 = a^2 + b^2 - 2\, a\, b \cos \theta$$

in which the letters correspond to the sides of a triangle, as shown in the accompanying cut, *c* being the unknown side. When, however, the angle is more than a right angle, the negative sign become plus. For example, in the above case, $a = 2.32$; $b = 15.6$ and $\theta = 155$ deg. The cosine of 155 deg. is .906 (sign being neglected). Therefore $C^2 = 5.38 + 243 + 2 \times 2.32 \times 15.6 \times .906 = 314$, or $C = 17.7$.



Am.Elec.

branch in parallel with another containing an inductance in series with a 50-volt lamp; in addition there is a 50-volt lamp in the conductor, *A B*. The resistance of the inductance will not be considered, as in any practical case it would but very slightly affect the result. We will anticipate somewhat by stating that this arrangement represents a paradox somewhat similar to that in the previous article, and is therefore of particular interest.

FIGS. 9, 10 AND 11.—INDUCTANCE AND RESISTANCE IN PARALLEL WITH CAPACITY AND RESISTANCE.

We will assume that .4 of an ampere passes through the lamp in series with the condenser, and 1 amp. through the lamp in series with the inductance; that is, the latter lamp will be at full candle power while the filaments of the former will barely glow. It is desired to know what current will flow through the lamp in the circuit, *A B*, and also the value of the inductance in millihenrys in order to bring about the desired result.

CONVENTIONAL DIAGRAMS OF ELECTRICAL APPARATUS.

From formula (1) it will be found that when 4 amps. flow through a condenser of 5 microfarads, a capacity E. M. F. of 95.7 volts will be set up; and it is evident that .4 amp. will produce a drop of 20 volts in a 50-volt lamp, the resistance of a 50-watt, 50-volt lamp being 50 ohms.

Referring now to our capacity triangle, Fig. 10, the base will represent the capacity E. M. F. or 95.7 volts, and the perpendicular the ohmic drop or 20 volts; consequently by solving the triangle we will find that the impressed E. M. F. is 97 volts. This must, however, also be the impressed E. M. F. of the inductive circuit, so that in our inductive triangle, Fig. 9, the hypothenuse will be 97; and since a current of 1 amp. is flowing through 50 ohms resistance, the perpendicular will be 50. Solving the triangle, we find that the value of the inductive E. M. F. is 84 volts. By means of formula (2) it will be found that this corresponds to an inductance of 111 millihenrys.

In the case of the inductive triangle, the tangent of the angle between the impressed E. M. F. and current is $84 \div 50 = 1.68$, which corresponds to an angle of 59 deg; and in the capacity triangle the tangent is $95.7 \div 20 = 4.78$, which corresponds to an angle of 78 deg. That is to say, the inductive current lags 59 deg. behind the impressed E. M. F. and the capacity current leads the impressed E. M. F. by 78 deg., or the difference of phase between the two currents is $59 + 78 = 137$ deg.

In Fig. 11 we represent the two currents by two lines drawn to scale and separated by an angle of $(180 - 137) = 43$ degs. Solving this current triangle by means of the footnote formula, or by laying it down geometrically and measuring the length of the third side, we find that the current that will flow through, *B A*, is .76 amp.

In other words, while 1 amp. flows through the lamp in series with the inductance, and .4 amp. through the lamp in series with the condenser, only .76 amp. will flow through the lamp in A B connecting the series parallel arrangement **with the main circuit.**

As the condenser is approximately of the same size as that used in the preceding article, this paradox could be shown in connection with the one there described. Such an arrangement would be a valuable equip-

ment for an alternating current central station, not only for the amusement of visitors but for instruction.

As shown in Figs. 9 and 10, the impressed E. M. F. is 97 volts, but this would not be in phase with the current flowing through, *A B*. This difference of phase may be very simply calculated from the current triangle, but we will not go here through the operation. Its value is 38 deg., from which we find that the component of the E. M. F., which is in phase with that in, *A B*, is .72 amp. Since .76 amp. flows through the lamp in *A B*, the drop in that circuit will be $50 \times .76 = 38$ volts, and consequently the E. M. F. of the mains should be 110 volts. If the circuit available is one of 100 volts, the several currents calculated will be reduced in the proportion of 100 to 110.

CONVENTIONAL DIAGRAMS OF ELECTRICAL APPARATUS.

The illustrations on the preceding page show a system of conventional diagrams of electrical apparatus which has been under preparation for some time by a committee of the Chicago Electrical Association. At a recent meeting of that body the report of the committee, consisting of Mr. Thos. G. Grier, chairman, and Messrs. Kempster B. Miller, S. G. McMeen and C. Wilder, was adopted, and the result of its work is presented to the electrical public for approval and adoption.

As will be noted, the committee has endeavored, as far as possible, to present diagrams which are in themselves explanatory of the object represented. There is no doubt but that this method is preferable to the one in which the symbols only have a significance to the initiated. To some it may seem that the principle has been carried to an extreme in the case of some of the symbols, but even these will probably admit that it is better to err on the safe side than to endanger the adoption of the system by introducing into it what may be considered purely arbitrary representations.

Letters on Practical Subjects

BEHAVIOR OF DRY CELLS.

To the Editor of American Electrician :

If Mr. N. F. Jarvis will make sure that his cells are properly connected in series (that is + to — throughout, and none connected backwards), and measure the voltages with a reliable voltmeter, he will find that the voltage of the whole series is equal to the sum of all the voltages of the cells measured singly. This is true whether the measurements are made on open or closed circuit, providing all the measurements are made under precisely similar conditions. It would appear from Mr. Jarvis' letter that he measured the open circuit voltage of the separate cells when fresh, and then the total voltage of a series of 12 cells after they had been used. Even if this total voltage was measured on open circuit, which is not certain from the letter, the polarization of the cells might account for the discrepancy if the cells had been working for some time at or near their maximum capacity, which seems to have been the case.

Townsend Wolcott.
New York, N. Y.

To the Editor of American Electrician:

In your February issue Mr. M. F. Jarvis gave an account of a supposed discrepancy in the behavior of some dry cells, and asks for an explanation. From the figures given it would appear, however, that the action of the cells was quite normal.

It is evident that 12 cells in series will not send twice the current through a given external resistance that six cells would, as the internal resistance of six cells is added to the resistance of the circuit at the same time that the voltage is doubled. That eight cells in series only showed 5½ volts while each cell gave about one volt may be explained by assuming that the voltmeter used in making the measurements was a low reading instrument of low grade, having only a small internal resistance—about 32 ohms, according to the figures given, which is rather small even for a voltmeter of not more than 10 volts range.

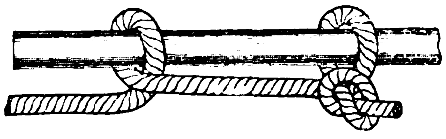
In order to get the right current—twice that given by six cells—Mr. Jarvis requires 24 cells connected in two parallel groups of 12 in series.

Chicago, Ill. P. M. Heldt.

A COME-ALONG KINK.

To the Editor of American Electrician:

Some time when your come-along clamps have failed to come along with the rest of your line-erecting materials, and it would take an hour to go back to the station for them, or when you have the clamps and have been stripping off insulation until you are tired of it, try the scheme shown in this illustration, taken from the German "Elektrotechnischer Anzeiger." It will hold on like a customer to a flat rate when you try to put him on a meter, and it seems to work equally well whether the wire is bare or insulated. After practising it a few times with a piece of wire and a rope, it will come naturally, and is one of the many kinks (in a rope) that it is well to know about.



SUBSTITUTE FOR A COME-ALONG.

Milwaukee, Wis. H. L. Schweigger.

More Electrical Sport.

To the Editor of American Electrician :

Electrical sports seem to be very popular among your readers, and justly so, for "all work and no play makes Jack a dull boy." Another little fragment of "sport" comes to mind with dynamite as an accessory. Close to our electric light station is a maple tree, on which during the past summer an enormous nest of wasps of the genuine "yellow jacket" variety had developed. It was a monster nest, over a foot in diameter. One of the linemen found it. He said the nest contained at least 1,000,000 inhabitants—all fighters. At any rate, we had to put the hose on the lineman before he could get down the tree again past the nest.

On the Fourth of July morning this same lineman came in with an electric cartridge exploder and about two inches of a dynamite cartridge. He pushed a lead pencil into the cartridge, inserted the cap, and taped the whole business so the cap couldn't fall out. A couple of light wires were attached to the leads of the cap, and then the bit of cartridge was placed on a pole and poked up beside the hornets' nest.

The manner in which the hornets punched sting holes in the cartridge was a caution, until a couple of the boys touched the wires to the bus bars. There was a bang, and a puff of smoke, but not a single wasp remained. Not a fragment of the big nest remained, and never a bit of the paper which composed it was to be found. The whole business seemed to have been utterly pulverized and dissipated in the atmosphere. Even the bark was blown from the limb of the tree.

Andrew J. Rodgers.
East Pepperell, Mass.

Another Electric-Bell Arrangement.

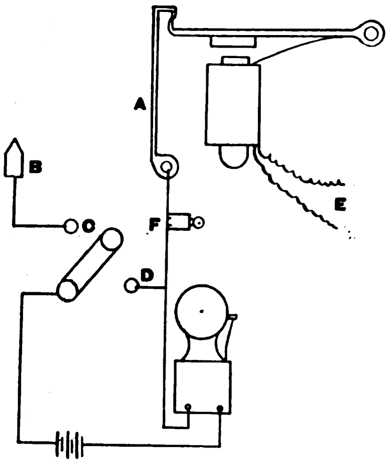
To the Editor of American Electrician :

The account of Mr. Roy J. Tompkins in the January issue reminds me of another annunciator arrangement on somewhat similar lines. In a certain shop there was a private telephone, and at night it was often desirable to call up the watchman, who, having a watchman's clock to attend to, could not always be where he could hear the telephone bell, and delays were frequently met with in getting connection with him.

To cure this trouble the annunciator, *A*, was put in, the wires, *E*, being the main line wires to the instrument. This told the watchman that a call had been made for him, but he was obliged periodically to inspect the office to see if a call had been made. In the centre of the shop was a ten-inch gong, rigged with a vibrating stroke arrangement by means of a small vibrating bell at, *F*. The hammer of this bell was weighted so as to work slow enough to allow the large gong to respond, and when the annunciator drop fell as a call was received, contact with the local system was made at, *B*, by the annunciator drop falling upon *B*, in metallic contact therewith.

At night, upon leaving his office, the foreman would place the switch upon, *C*, so that the local circuit could be closed by the falling of, *A*, upon, *B*, thereby letting the ten-inch gong set up a racket which could be heard all over the works, and which would continue until the watchman appeared and reset the annunciator.

In the daytime the large gong was used for another purpose. Each of the shop foremen was given a number, 1, 2, 3, etc., and when the number was struck on the large gong, it was understood to be a signal for that particular foreman to hustle, post-haste, to the office. By swinging the switch lever to contact, *D*, thereby completing the local circuit through the battery and gong, but not through the jingle bell, the switch was used to give the required number of strokes to make the signal.



ELECTRIC BELL ARRANGEMENT.

◆

Magnetizing Galvanometer Needles.

To the Editor of American Electrician:

Under the above heading in the February number of this journal is a criticism of the method for magnetizing galvanometer needles, given in an article by me in the January number. To be sure, such a method would be unnecessarily refined for making galvanometer needles when sewing needles, watch spring and steel tape ⅛ in. wide are used, and comparatively few of them at that; but when a large number of needles must be made up into an astatic pair, where sensitiveness is required, experience has proved the method which I described to be exceedingly successful and satisfactory.

None of our galvanometers contain less than ten wire needles, and one had as many as sixty-eight fine ones; the suspension holding the latter number being also remarkably light in weight, considering the large number of needles on it. Now, to have first magnetized all these needles, even in pairs, and then to have assembled them properly, would have been exceedingly tedious, for besides being so small, they would be continually sticking to each other and getting out of place. Even if this was successfully accomplished, the set would not necessarily be anywhere near astatic, because even if they were originally magnetized equally and half of each needle used on each set, assuming that none were mixed, which is unlikely where there are ten or more, the working and handling of them would be very apt to alter their magnetic strength unequally, and consequently give a system far from astatic, and therefore not as sensitive as it ought to be.

By first assembling the needles and magnetizing them in an apparatus, as described by me, just before the final setting up of the galvanometer, the set will be as nearly astatic as it is possible to make it, for the same magnetizing force acts alike on each set. This magnetizing apparatus only requires from two to four bichromate cells to give a sufficiently intense field. Furthermore, it can be easily made by the use of a few ordinary tools, such as a hammer, saw, brace, bit, hacksaw and file. The one illustrated in my original article was made adjustable, so that it could be used to magnetize systems of various dimensions, but where only one set or size is to be magnetized, it could be simplified. It seems to me that this would be evident to any one.

A 393 ohm galvanometer, which has been in constant use and whose needles have never been re-magnetized since they were made, about three years ago, was recently tested. Its figure of merit was 91x 10^{-10} amperes; that is .0000000091 amperes gave a deflection of one millimeter when the mirror and scale were one meter apart. I have good reason for believing that by re-magnetizing this set the figure of merit could be reduced to 40x10^{-10} amperes. This set of needles was tempered by an inexperienced person, which may account for a slight loss in sensitiveness which I am reasonably sure has taken place. Considering that such good results were obtained with the first and only set of needles made by this person is to me certainly a recommendation of the method used.

While it may be possible to get ordinarily good astatic sets when a few needles only are used, by the method described in the February number, I should be very much surprised if they can be made as nearly astatic, and therefore as sensitive, as by the method described in my article; and where the number of needles are large, the use of the latter method is still more advantageous.

Some Testing-Set Adjusting Kinks.

To the Editor of American Electrician:

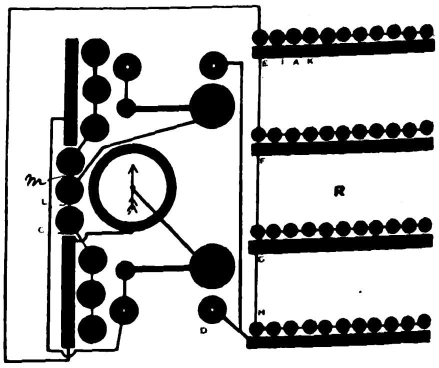
In constructing the testing set, or, more properly speaking, the Wheatstone bridge, which was described in recent issues of this journal, there came up points too numerous to mention in the constructive description, without lengthening the subject matter a point beyond the limit.

The manner of placing pins or nails has already been mentioned, but nothing was said about placing on the pins a sufficient quantity of wire to form one of the coils—two turns, one up and down, for the 100-ohm coils, and then putting on ten turns down, and ten up, for the 1000-ohm coils. But that was the method I employed, and after putting the wire on the pins double, the ends were connected to a battery with a 1000-ohm resistance galvanometer in series, as a test for continuity of the wire.

Then the central fold of the wire was cut, and the galvanometer watched for any evidence of short-circuiting. The instruments were kept connected until the coil was entirely wound, thereby detecting, at the instant it occurred, any contact of the wires through the insulation.

As described in the article, some of the coils were wound double many fold, by catching all the ends of the doubled wires and winding the ten on together. This was found to be considerable trouble; therefore the wooden reels, or spools carrying the graduated coils, were fitted with a bit of sheet brass at each end, and a bit of wire soldered to each bit of the brass. One piece of wire served as a crank for revolving the spool; the other wire was left straight as a bearing for the other end of the spool. Three bits of wood, nailed up together, with a couple of holes slotted in for the wires, served as a mount for the spool and its crank.

My assistant lifted one loop after another from the pins, while I wound the wire on the spool and watched the galvanometer. After the coils had been wound, and tested down to within a fraction of an ohm, they were soaked in melted paraffin, before being soldered on and finally adjusted. This prevents, once for all, any possible change in the conductivity of the insulation of the wire, through two or more of the coils being pressed together—something which is very apt to happen if the precaution noted is not taken in time.



ADJUSTING RESISTANCE COILS.

After making all the wire connections of the box according to Fig. 63 (December number) the unit coils were soldered on and tested up to the one-ohm coil, which is sent out with the plans. Before this is done, the plugs O, P, Fig. 67, should be placed in contact, and the balance bridge carefully adjusted so that the resistance of the flexible connections are included in the balance of the bridge.

With one of the plugs at D, L, and the other, which may be caught in the binding post shown in the engraving herewith, at D, we can, by putting working plugs in C, E, F, G and H, secure a circuit through the instrument with practically no resistance except that of the connections and contacts. Then, by moving plug E to hole I, and placing the one-ohm coil in the mercury cups on bridge, the first one-ohm coil can be adjusted so as to include all the resistance of the connections and the necessary plug contacts in the bridge.

By replacing the plug at E, and putting the slit plug so as to bear against 3, at M, the one-ohm divisor coil at L may be adjusted. In the same manner, by making a 10-ohm coil and balancing it in the bridge mercury cups against the sum of the 10-unit coils, the 10-ohm coil of the divisor may be adjusted, then the hundreds and thousands may be worked up in the same manner.

But after the first coil of the units has been adjusted, different connections are necessary. The box and plug resistance has all been deducted from the first coil of each set; therefore the rest must be full measure—1, 10, 100 and 1,000 ohms. To adjust the other coils, remove the split plugs from M or L, and from D, and place one at I, the other at A, and balance as before, by adjusting the length of wire in the coil. So proceed with all the other unit coils, then with the tens, hundreds and thousands, adjusting the first of each with all the contact resistance in circuit, the other nine coils to full resistance.

The multiplying coils may be adjusted as we go along, by simply changing the contact plug from D to 2, and testing with the other plug at L, instead of at M, when the ratio coils are being adjusted or measured. Remember this point: Plug goes in L, when adjusting graduated coils (those at R) and the multiplying coils, and it goes at M when adjusting the divisor coils.

If another bridge is at hand it may be used for adjusting all the coils, the balance bridge being dispensed with, and each of the coils measured up to the other bridge. But first, the resistance of the flexible connections must be measured when both the split plugs are in adjacent contact with a bar, say at E, I. In the rigging I used, the resistance was .017 ohm. A split plug was then made to go in the completed box, and the two parts connected with enough resistance wire to give exactly .017 ohm resistance. In other words, with the split plugs at I, A, a balance on the master box was obtained by placing the new split plug in one of the O holes of the R coils, and then adjusting the wire until a balance was obtained.

With this arrangement, to adjust the coils it is only necessary to plug them in one after the other, and also plug in an equal resistance in the master box, adjust the coil, then plug in another coil, etc. In this fashion all the coils may be adjusted without moving the split plugs, except to work the multiplying coil.

It is a delicate work to adjust the coils exactly, or as near as the sensibility of the galvanometer will permit, and it is a still more delicate operation to solder the twisted ends of the adjusted coils, and not have the solder change the resistance during the operation. I gave up trying it, and cut up some bits of sheet lead one-eighth inch square and thick. After close adjustment, one of these bits of lead, with a small awl hole through it, would be slipped on the twisted wires and then squeezed solid with heavy pliers. After this the lead was covered with very hot sealing wax. I don't know how long this adjustment will stand, but it has not yet shown any signs of failure, with the box in daily use, under 12 to 24 volts of battery.

Brooklyn, N. Y. JAMES F. HOBART.

ELECTRICAL CATECHISM

191. Explain how a rotary transformer changes current from alternating to continuous.

Let Fig. 1 represent a simple ring armature revolving between a pair of magnetic poles; suppose the ring is wound with wire as shown, two opposite points being connected with collecting rings, *C* and *C*, upon which brushes make contact to take off the current; for the present neglect the commutator and the two brushes shown in heavy lines. When the armature is in the position shown, all the wires on each half are sending current in the same direction, say, up, making the outer ring positive and the inner ring negative. Now suppose the armature has revolved a quarter turn so that the connecting wires are horizontal instead of vertical, as in the figure; then, as before, all the wires on each side are trying to send current up toward the top, but there is no connection at the top to take it off; the E. M. Fs. on the two sides of each half are opposed and exactly equal, so that there is no net E. M. F. between the collecting rings, and there is no current at that instant. Between these two positions, the current and E. M. F. vary more or less uniformly, each following closely the sine curve described in earlier numbers. Next suppose that the armature is provided with a commutator, each section of the winding being connected with a commutator bar, as suggested by the circle of heavy lines; the brushes, *B* and *B*, will make contact with different bars and therefore with different sections of the armature winding, unlike *C* and *C*, which always connect with the same armature section. It is seen that the armature wires between *B* and *B* all tend to send current in the same direction at all positions of the armature, so that a continuous current may be taken from *B* and *B*, while at the same time an alternating current may be taken from the same armature by *C* and *C*. Since either a continuous or an alternating current may be obtained from the same armature, it makes no difference what causes the armature to rotate, whether mechanical power applied at the pulley or electrical power applied at either pair of brushes. As will be explained later, the same armature is equally adapted for use as a dynamo or as a motor. Therefore, if continuous current be applied to the brushes, *B* and *B*, alternating-current may be taken from the brushes, *C* and *C*.

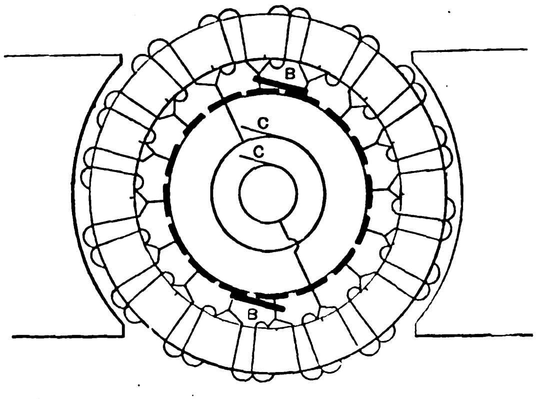


FIG. 1.—DIAGRAM OF ROTARY TRANSFORMER.

192. In a rotary transformer, is the voltage between the alternating-current brushes the same as between the continuous-current brushes?

No. The alternating voltage is only about seven-tenths of the continuous voltage. By reference to Fig. 1 it is seen that the alternating voltage is at a maximum when the armature coils connected with the collecting rings are also connected with the continuous-current brushes. The maximum value of the alternating voltage is therefore equal to the steady value of the continuous voltage. But the effective or mean value of the alternating voltage, supposing it to follow the sine curve, is only 71 per cent. of the maximum. For example, if the continuous voltage is 500, the alternating voltage is 500 × 0.71 = 355. In practice the alternating voltage is somewhat less than the simple theory calls for, being influenced by the setting of the brushes, the distribution of the magnetic field and some complex elements.

193. What kind of alternating currents are given by a rotary transformer such as described in 191?

Such a rotary with only two collecting rings would give a single-phase or monophase current.

194. How could a two-phase current be obtained?

Two phase currents could be obtained by having a second pair of collecting rings connected to the armature winding at points midway between the first ones. The E. M. F. between the second pair would be at a maximum when that between the first pair was at zero. The two currents would thus be at right angles, or in other words, in quadrature, or 90 degs. apart. The effective values of the two currents would be equal.

195. How could three-phase currents be obtained from a rotary?

By connecting three collecting rings to three equidistant points, as suggested in Fig. 2.

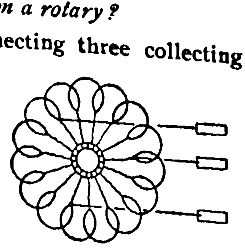

FIG. 2.—DIAGRAM OF THREE-PHASE ROTARY TRANSFORMER.

196. What is the relation between continuous and alternating voltages in a three-phase rotary transformer?

According to the elementary theory, the effective voltage between any two of the three lines is 62 per cent. of the continuous voltage. Actually it is somewhat less, for reasons similar to those mentioned in 192.

QUERIES AND ANSWERS

What is the discharging rate of storage batteries per square foot of positive surface? C. H.

From 8 to 9 amperes. More ampere-hours will be obtained if this rate is decreased, and less if it is increased.

How are very high resistances made? J. A.

One kind consists of a lead-pencil mark on a piece of ground glass between tin-foil terminals. Another consists of one or more U-tubes of glass of small internal diameter, filled with water.

What will be the pole strain of a 60-foot span of 5-16-in., 7-strand steel wire supporting two No. 0 trolley wires, 10 ft. apart, the sag being 14 ins. E. J. B.

The strain will be 1,000 pounds, the distance between spans being assumed 125 feet.

1. Can I use a 1-16 h.p. 500-volt motor as a dynamo? 2. What would be the winding of such a motor to run as a 55-volt machine? F. F.

1. Probably yes, though this cannot always be predicted in the case of small motors; belt to power and see the result. 2. See articles by Mr. Cecil P. Poole in this and February issue.

Would a neutral wire, grounded at both ends and run between two grounded telephone circuits, prevent induction between the circuits? D. W. M.

No. For instance, if the current in one circuit were falling at the same rate as the current was rising in the other, the neutral wire would be "dead" and the two circuits would react on each other as if the neutral were not present.

Does any current flow in the induction windings of a three-phase synchronous motor after the armature has gotten into step? J. N. R.

Yes. The torque of the motor depends upon three factors—strength of field, amount of current in the induction windings, and the angle of phase between the induced current and the field current. If no current flowed there could be no power.

I have a dynamotor, the primary cummutator of which has every other bar blackened. What is the cause? G. W. B.

This occurs when, of two sections in an armature slot, one has a greater number of turns than the other. One section of the winding has in this case a greater self-inductance than the other, and every other bar may become blackened at the retreating edge from the consequent sparking.

Why are shunt-wound instead of compound-wound generators used in large direct-current central stations? E. G.

In order to give greater control over regulation. The ideal advantages of compounding only apply in the case of a generator running singly and always on the same circuit. When a machine may be switched from one circuit to another, and run in parallel with two or more machines, shunt regulation is ordinarily necessary.

How can I find the size of a wire for a three-phase system? B. H.

Leaving aside inductance, calculate the size of wire for the ordinary direct-current two-wire system for the same voltage and kilowatts; then each of the three wires of the three-phased system will be one-half the size thus found. If inductance and power factor are considered, use Mershon's table and chart, published by the American Electrician Company.

1. When a condenser and an inductance are connecting in series across an alternating circuit of 100 volts, and the pressure at the condenser terminals, as measured by a volt-meter, is 250 volts, is the strain on the insulation of the condenser as great as if the condenser above were connected across a 250-volt alternating current circuit? 2. What insulation should be placed between the alternate sheets of tinfoil when the voltage is not to exceed 250 and 500, respectively. L. C. W.

1. Precisely the same. 2. No practical data on condenser insulation have been published.

Keeley says that his new force, which he calls "opergy," is obtained by "blending positive and negative electricity with electricity of the third stage or element," thereby enabling the force of gravitation to be partly reversed. What is the third state of electricity? W. M. C.

Adopting the Socratic method and using the nomenclature of Keeley we may reply as follows: The blending of anhydrous aqueous vapor with non-thermic isotropic caloric in the presence of static etheric vibrations produces the elixir of life. What is non-thermic isotropic caloric?

How can I connect an annunciator to a 110-volt circuit? J. W.

Disconnect the leads from the battery, connect one direct to one side of the 110-volt circuit, and the other to a 110-volt lamp, the other side of the lamp being connected to the second circuit wire. To provide for lamp breakage, use four lamps connected in parallel series; that is, each pair in series, and the two pairs in parallel. If one lamp breaks, half the current will pass through the other pair.

When is it necessary to know which is the positive or negative terminals of a dynamo or of a line, and how is this determined for an incandescent lighting machine? H. E. K.

Usually only when a storage battery is to be changed from the circuit. When ammeters or voltmeters are marked + and —, they can ordinarily be connected up by trial. To determine polarity, place two pieces of lead in a glass containing a solution of sulphuric acid (10 of water to 1 of acid), and connect to the circuit with a lamp in series; the plate connected to the + side will turn brown.

I have rewound the field of a railway motor, but in one section where there have been two before, using the same wire and same number of turns. On trial the motor sparked badly, jumped and threw out the circuit brakes. Could this be due to winding in one section instead of two? S. B.

No. Part of the field is probably cut out by a double ground or short circuiting of part of the windings, as this would cause an abnormal current to flow and increase the speed. Find the drop in each coil by sending through a normal current and measuring the voltage between the terminals, which should be indentical.

Does a booster generate current in raising a voltage? L. H. P.

Where there are several circuits from the same bus-bars, and the drop on one of the circuits—usually feeding a distant point—would otherwise be too great, a booster is put in that circuit, which adds an E. M. F. equivalent to the excess of drop. The current flowing in the booster circuit will be the total E. M. F. in it divided by the total resistance of the circuit; part of the current will thus be due to the booster E. M. F., if one chooses to look at it in that way.

I have a 30 k.w. alternator with exciter on the same shaft. How can I charge a couple of storage cells from the latter? P. G. C.

Put the cells in series with the alternator field windings; the small back voltage thus introduced may be compensated for by a segment or two of the exciter rheostat. To determine the polarity of the circuit, connect the exciter binding posts with two pieces of lead in a glass of water acidulated with sulphuric acid, having a 50-volt lamp in the circuit. One of the pieces of lead will turn brown, and the brown plate side of the battery should connect to that side of the exciter.

What is the length of the longest and shortest wave of electricity, and the length of a wave of light? W. M. C.

The length of a given electric wave is found by dividing the velocity of light per second by the electrical frequency per second. Consequently, with a frequency of 25 the corresponding electric wave has a length exceeding 7,000 miles. Lodge, it is said, has produced and measured electric waves only eight inches in length. The length of light waves varies from 3 to 1.6 hundred-thousandths of an inch, the latter corresponding to the violet portion of the spectrum, and the former to the red portion.

What should be the windings of a magnet for a coil clutch for a current of 8 volts and 1 ampere? G. W. L.

A "current of 8 volts and 1 ampere" is a very ambiguous expression. If you put 1,000 ohms in circuit would you still have 8 volts and 1 ampere? If the source of E. M. F. is an 8-volt battery which gives one ampere when on short circuit, then the winding should be a coil embedded in a circular groove in the face of one of the cones; the gauge of the wire will depend upon the size of this groove and should be so selected that the coil which fills the groove will have a resistance of 8 ohms, using, of course, copper wire.

In making a 5-inch induction coil, using 5½ pounds of No. 36 wire, will cotton-covered wire answer, the layers being separated by writing paper? B. H.

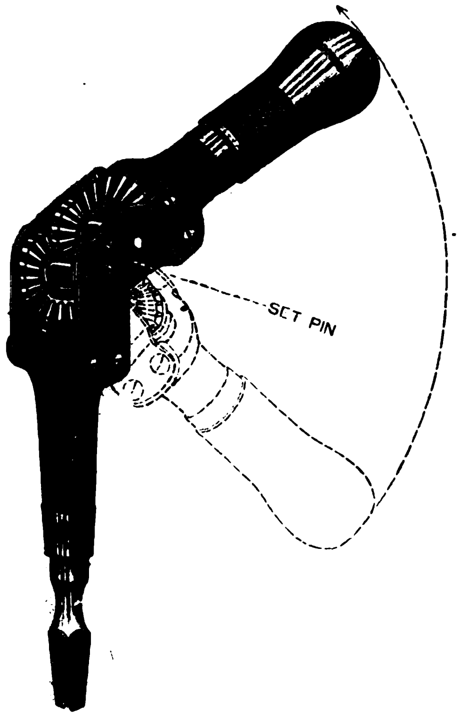
Use cotton-covered wire loosely wound, and separate the layers with one or two thicknesses of filter paper; then bake and saturate with hot paraffine, filling in also with hot paraffine when the coils are in place. Leave at least a half-inch space between primary and secondary. Wind primary with a single layer of No. 12 or 14 wire, the spirals of which may be separated considerably if the supply of current is large. The amount of current will be fixed by the heating of the primary, and to adjust the current if taken from a lighting circuit, use non-inductive resistance in the exterior circuit. You may be disappointed in your assumption that you will get a 5-inch spark from 5½ pounds of secondary wire.

Apparatus and Appliances

NEW ANGULAR BIT STOCK.

The accompanying cut shows a tool especially adapted for the use of electricians, who frequently have many holes to bore in wiring, where there is not room enough to work the ordinary brace and other boring tools. The tool is also useful in electric railway work, power plants, telephone work, etc.

The gearings are of steel and the tool is nickel-plated and japanned. It is 22 ins. long over all and weighs 2 lbs. The gear attached to the chuck is 1½ ins. in diameter, and the other is 1 in. By turning the bit stock with a brace three times around, the chuck revolves only two times, which gives one-third more power on the bit than if the gears were all the same size. By pulling out a set-pin, this can be turned and locked at the various angles, as shown by the dotted lines. At the limit, which is beyond a right angle, the tools works as easily as at other adjustments. By reason of the large gear attached to chuck, it is claimed that an inch can be bored with less power than a ¾ in. hole can be bored with any other angular bit stock in the market. The manufacturers are C. Meister & Co., 726 Union Street, Allentown, Pa.

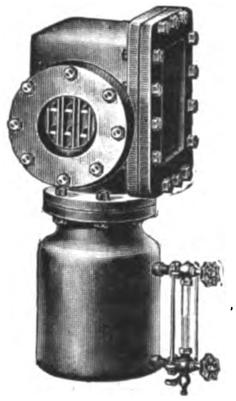


ANGULAR BIT STOCK.

STEAM AND OIL SEPARATOR WITH SIDE FLANGE.

The importance of frequent cleaning of a separator, and especially an oil separator, is as marked as the need of thorough working, as the one is dependent upon the other, and in the matter of making a selection one should consider carefully this convenience. There are very many places in which there is not sufficient headroom for the removal of the baffle plates of a separator, even though it be constructed with such plates. This apparent need has caused the makers of the Bundy separator to produce one with side flange through which the baffle plates may be slipped with perfect ease.

The separator shown herewith is interchangeable; that is, it may be put in so that the side flange may be on either side, but care must be used to see that the baffle plates are put in so that their flat front may face the incoming steam, as this side alone has the capillary openings through which the oil and water may enter and go to the receiver below on gravity action.



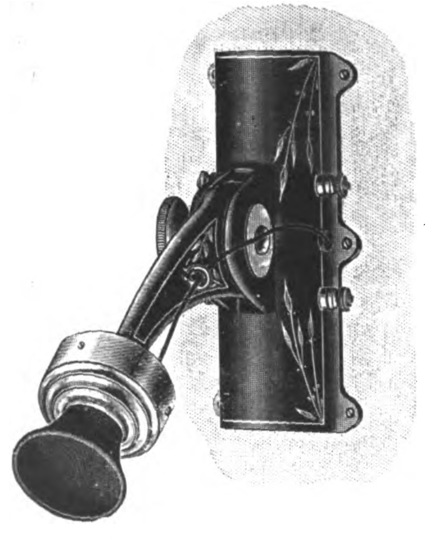
SEPARATOR WITH SIDE FLANGE.

The rear side of the Bundy separator baffle plates has the vertical posts rounded for the easy passing of the steam. They are so constructed that the posts set staggered to each other; in other words, a post in one baffle plate sets directly back of a space in the plates in front of it, thereby causing the steam to pass through in a zigzag course.

The Bundy separator described is made by the A. A. Griffing Iron Company, 66 Centre Street, New York.

TELEPHONE TRANSMITTER ARM.

Arm transmitters are never satisfactory when the contact between lever and base is used for the return of current from transmitter to battery, as any looseness of the parts or foreign substance therein will seriously impair the efficiency of the instrument. In the arm transmitter shown herewith, a new path is provided, which acts independently of the contact between lever and base, and thus prevents the trouble which has done so much toward limiting the popularity of arm transmitters. While the contact between lever and base is no longer for electrical connection, at the same time the mechanical features of this contact have been greatly increased, and the adjustment is very simple. The arm described is made by the Chicago Telephone Supply Company, 118 Quincy Street, Chicago.

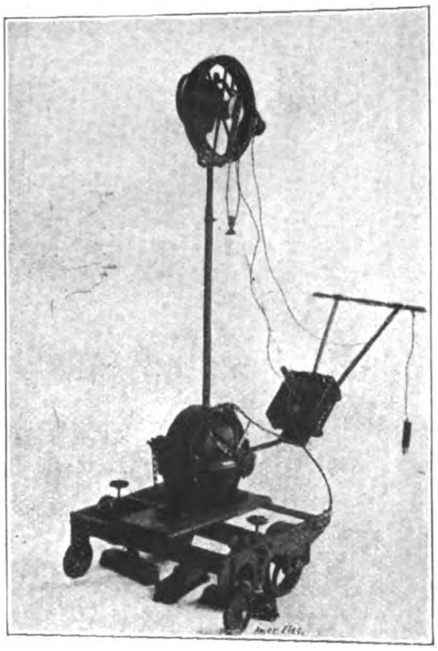


TRANSMITTER ARM.

ELECTRIC FLOOR SCRUBBING MACHINE.

The accompanying illustration represents a machine for floor scrubbing. The main frame carries several scrubbing brushes, which are pressed against the floor by means of a spring, and are geared with an electric motor so as to be revolved at the rate of about 400 revolutions per minute. The wheels are rubber tired, and the machine is easily shoved along the floor by its handle.

The machine weighs about 300 lbs., its frame being about 30 ins. square. The brushes are so set that they will run practically to the base board of a wall. The motor receives its current by means of an attachment to any convenient incandescent lamp circuit. In action, water is thrown on the floor, and the scrubbing machine guided over by the operator. In place of the scrubbing brushes, however, sand-paper blocks, or blocks of stone, may be substituted, and thus the machine may be used to dress down wood or mosaic floors.



FLOOR SCRUBBING MACHINE.

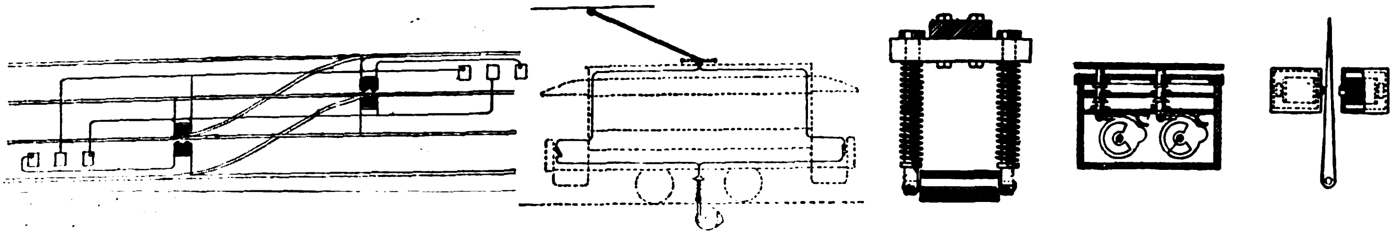
The machine illustrated has been in actual service for two years in the Hickox Building, Cleveland, doing work on eight floors; formerly it required 10½ hours' labor to clean these floors, which has been reduced by the machine to 2½ hours, making a saving of $75 each month in this one building.

The inventor is Mr. H. F. Ackerman, chief engineer of the Hickox Building, Cleveland, O.

SWITCH OPERATING MECHANISM.

The device illustrated is an arrangement for operating switches for electric railways, the object being to provide a mechanism simple and comparatively inexpensive, and which will be completely under the control of the motorman. From the car shown in Fig. 2, is a projection, shown in detail in Fig. 3. Under the track is a box shown in Fig. 4, on the top of which is mounted a plate against which the roller of Fig. 3 strikes when the car passes over it. The plate is thereby depressed, which makes an electrical contact within the box whereby the magnets shown in Figs. 1 and 5, and situated at the switch points, are actuated. When contact is made from the car with the plates, the magnets are energized and the switch tongue shown in Fig. 5 is drawn toward one of the magnets. As the car approaches the switch, the tongue closes the latter, and when the car leaves the switch the opposite magnet attracts the tongue the other way, thereby opening the switch. This mechanism can be applied to a siding, car house entrance, cross-overs, etc., and is of particular utility in side-tracking a disabled car. As will be seen in Fig. 2, the current is taken from the trolley, the switch current being controlled by the motorman.

The inventor of the above described apparatus is C. W. Yerbury, 6 Belleville Avenue, Newark, N. J., who will be pleased to send a more detailed description to any one who may apply.



FIGS. 1, 2, 3, 4 AND 5.—ELECTRIC RAILWAY SWITCH OPERATING MECHANISM.

ENGINE STOP AND SPEED LIMIT.

The accompanying illustrations show two devices which will be recognized as of great value in the prevention of steam engine accidents. Fig. 1 shows an attachment to an engine stop valve which, in case of accident, will close the valve by simply pressing a button, of which any number may be used, distributed throughout a shop or factory. The apparatus is connected with the throttle valve by a chain from a sprocket wheel, shown on the right. The power for operating the stop is supplied by means of a cable winding about the drum on the left and having attached to it a weight. When an electric circuit is completed, the magnet shown releases the mechanism and the falling weight closes the throttle valve.

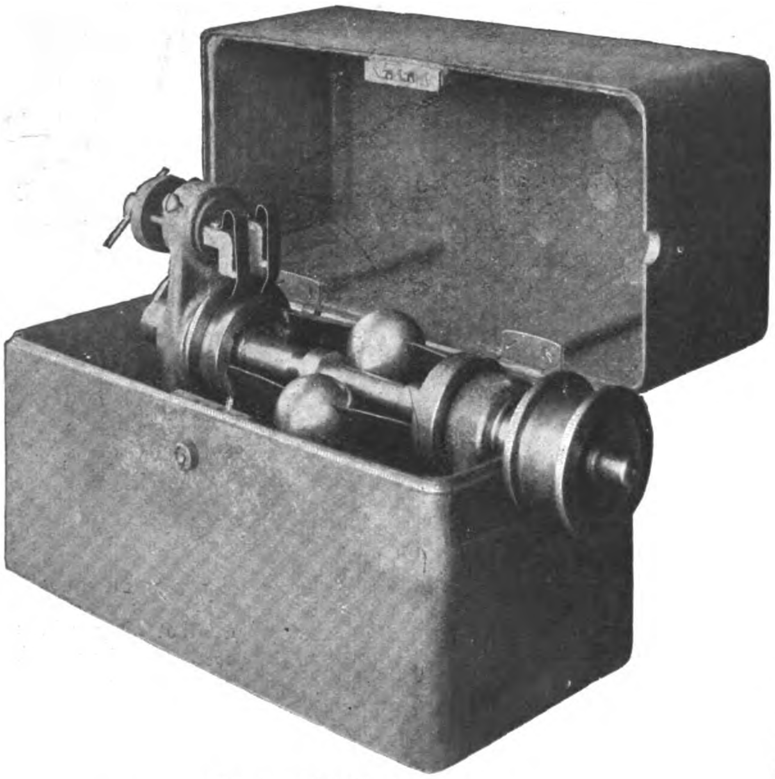


FIG. 1.—ENGINE STOP.

In Fig. 2 is shown a speed limit, the pulley to the right of which is belted to the engine shaft. When the speed exceeds a predetermined amount, the governor balls in flying out complete an electrical circuit through the engine stop, whose mechanism is thus released and the throttle valve is closed. Connected with the engine stop is a bell circuit, and a gong is sounded when the throttle is closed. The above devices, known as the Monarch stop and Monarch speed limit, are made by the Monarch Manufacturing Company, Waterbury, Conn.

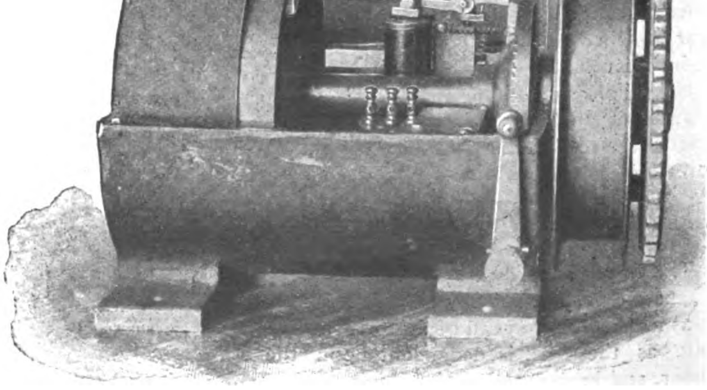

FIG. 2.—SPEED LIMIT.

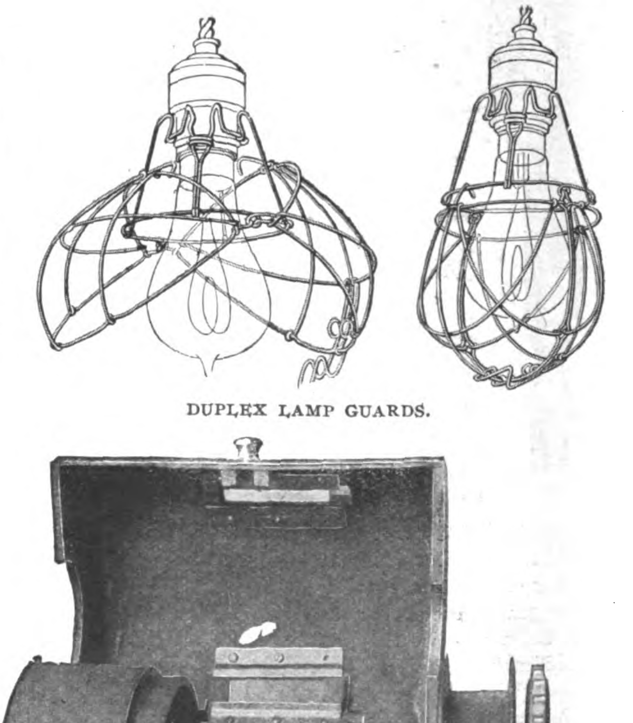
DUPLEX LAMP GUARD.

The illustrations shown herewith represent the Duplex lamp guard, designed to fit any lamp of 16 or 32 candle power. The lamp can be removed and replaced without taking the guard from the socket, a very material advantage over the average lamp guard; it can also be attached without using a shade holder or other extra



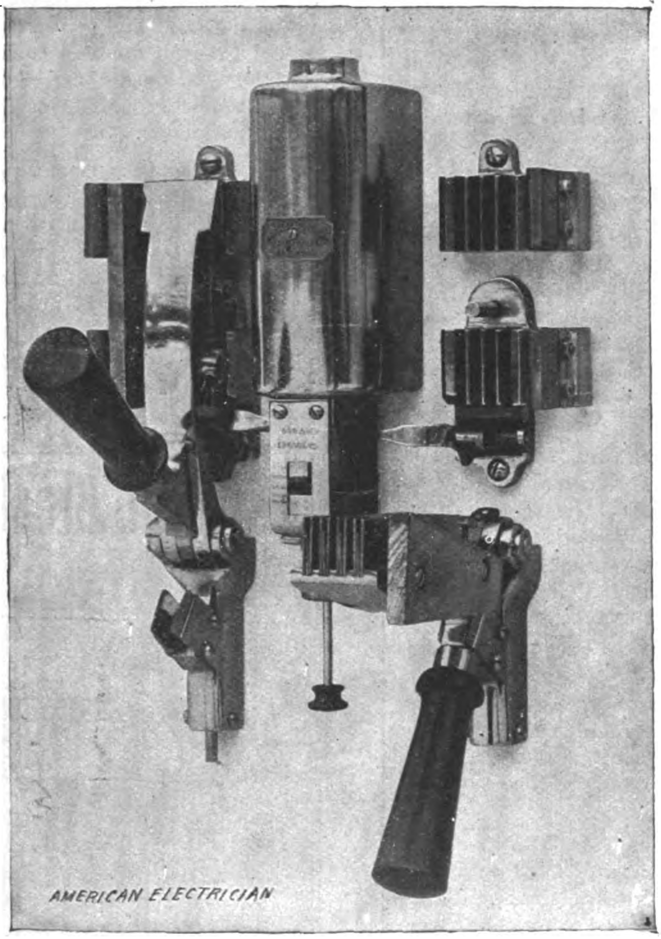
DUPLEX LAMP GUARDS.

contrivance for holding it in place. This particular guard has also a strong steel spring catch to prevent it from joining open. These guards, which are made in several styles and to fit any lamp, are manufactured by the Duplex Manufacturing & Electric Company, 84 Adams Street, Chicago, Ill.

◆

SWITCHBOARD CIRCUIT BREAKERS.

The circuit breaker shown in the accompanying illustration is so constructed that each side of the circuit with the double-pole type is separately closed. Should an overload occur and the operator be holding one side of the switch, the other will automatically fly out and open the circuit, or if both are free, they will open simultaneously upon the occurrence of an overload. All of the arcing occurs on carbon, and the carbon blocks are readily replaced by loosening a couple of screws. The contact blades are detachable by removing one screw, and the blades can be mailed in an ordinary envelope. The construction of these blades is a special one which always insures a perfect contact. The only adjustment necessary consists in raising or lowering the vertical movable core of the solenoid. A scale back of a projection from the core enables the necessary adjustment to be made, this adjustment ranging from 25 per cent under, to 50 per cent over the current which the circuit breakers will continuously carry. This type of circuit breaker, which is particularly applicable for switchboard work on account of all the connections being made on the back, is made by the H. Ward Leonard Electric Company, Bronxville, N. Y.



SWITCHBOARD CIRCUIT BREAKER.

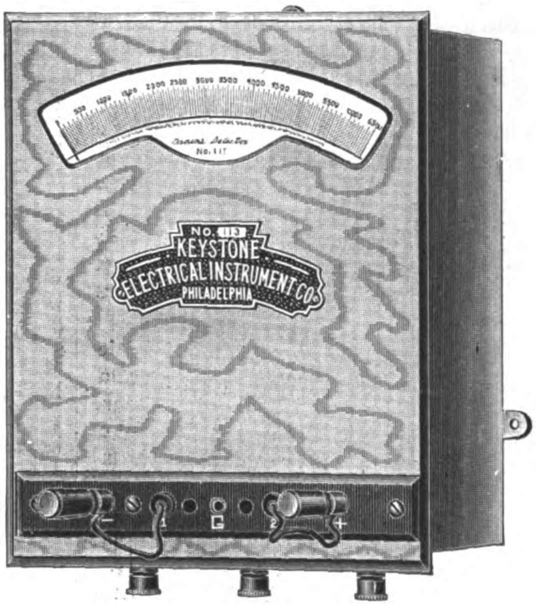
ARC LIGHT VOLTMETER AND GROUND DETECTOR.

The instrument shown in the accompanying illustration is applicable to three uses—as a voltmeter, a ground detector and a galvanometer. As a voltmeter it is used on arc light circuits, and can be so connected as to indicate the voltage of the generator, the voltage of any one of a number of circuits, and also applied as a ground detector to indicate a ground and determine its character and location. It will also replace a cable testing set, which apparatus is apt to be extremely unsatisfactory, owing to the many microphone contacts in the circuit. In connection with a set of switches and a battery of primary cells, or an ordinary incandescent circuit, it can be used to test the continuity of the line and the resistance from the line to the earth during the day, for this purpose being much easier to handle, more accurate in results and quicker in action than the usual sensitive galvanometer and Wheatstone bridge method.

The instrument consists of a compound galvanometer system mounted in a case which effectually shields the parts from the influence of external magnetic action. The scale is practically uniform from zero to maximum reading, the indications are dead beat, and the temperature coefficient of the wire employed is so small that external changes of temperature make no difference in the indications.

At any moment, by means of this instrument the condition of the line may be determined. If there is a dead ground, by means of three readings it may be exactly located, the formula used for this purpose giving the number of the lamp beyond where the ground occurs. If the ground is only partial, its resistance may be similarly determined and also its location. In testing for insulation, only a single reading is necessary, substitution of the value of which in a simple formula enabling the insulation resistance to be exactly determined.

With such an instrument the night attendant may keep a log and in the morning the data thus obtained may be worked out and thus the condition of the line be determined, thereby saving the expense of patrolling the line daily. The instrument described is made by the Keystone Electrical Instrument Company, Ninth Street and Montgomery Avenue, Philadelphia, which has issued an interesting pamphlet in which the principles involved are explained and instructions given for the use of the instrument.



ARC LIGHT VOLTMETER AND GROUND DETECTOR.

TRADE PUBLICATIONS.

DUNCAN METERS.—In a fifty-page catalogue the Fort Wagner Electric Corporations gives a description of the Duncan integrating meter for alternating currents, directions for its installation, care and reading, with other useful information, such as tables of equivalent meter rates, wiring formulas and tables, etc.

STORAGE BATTERIES.—The eleventh edition of catalogue A of the Electric Storage Battery Company, Drexel Building, Philadelphia, contains a number of reproductions of photographic views of storage battery installation in central stations and power houses, which will be of interest to central station and electric railway men. A set of instructions for setting up and operating storage batteries is a valuable feature of the catalogue.

Indicator Piping.—James L. Robertson & Sons, 208 Fulton Street, New York, have issued a circular illustrating indicator piping, of which several styles are shown—with three-way cocks, long-turn elbow cocks, and straight cocks.

Education by Mail.—In a 96-page pamphlet the United Correspondence Schools, 154 Fifth Avenue, New York, give full information concerning their various courses, methods of instruction, etc. In electrical engineering there are three courses, a complete electrical engineering course, an electrical station engineering course and a complete station engineering course. Sample pages of instruction papers are given, which show that the instruction is both practical and thorough.

C & C Bulletins.—It has become the custom of the larger electrical manufacturing companies to issue periodical bulletins descriptive of new apparatus, and of these the bulletins of the C & C Company, 143 Liberty Street, New York, are easily the neatest in form and handsomest in execution. The last three issues (Nos. 120, 121 and 122), are devoted to bipolar, multipolar and ironclad dynamos and motors, respectively. The descriptions are clear and concise, and the illustrations are clear and good.

Outlet Boxes.—Porcelain-lined outlet boxes formed the subject of a catalogue issued by the H. Ward Leonard Electric Company, Bronxville, N. Y., of which type some scores of different forms are illustrated. A table shows that during the year 1897, 81,000 of this type of box were installed in New York City alone. Among the buildings thus equipped we note those of the New York Life Insurance Company, Western Electric Company, Delmonico's, Sherry's and the Astoria Hotel, the latter using no less than 14,000 boxes.

Fire and Burglar Alarm.—The Montauk Multiphase Cable Co., 100 Broadway, New York, has issued several handsome pamphlets descriptive of its multiphase cable and automatic system of fire and burglar alarm, the principal one being profusely illustrated with well executed black and white drawings, showing various applications of the system. The multiphase cable can be used for ordinary bell work, at the same time performing the function of a continuous thermostat which actuates when a temperature of 374 degs. is attained at any point of the cable.

Machine and Hand Tools.—The 1898 edition of the catalogue of the Brown & Sharpe Manufacturing Company, Providence, R. I., has been thoroughly revised, and contains 437 pages, 20 more than in the preceding one. The tables, which form such a valuable feature of this annual catalogue, have also been increased. The principal additions to the catalogue in the way of tools are automatic cutting-off, screw and turret forming machines, bell polishing and universal grinding machines, and new types of face milling cutters, micrometer guages and calipers, spiral gears, screw slottting cutters, and a twist-drill and steel wire guage.

BUSINESS NEWS.

Hugo Reisinger has removed his offices to the fourth floor of the Bowling Green Building, 11 Broadway, New York.

Mr. H. C. Thompson of the Electric Gas Lighting Co., Boston, Mass., was elected manager of the company at its annual meeting.

The Montreal Electric Company.—In a removal notice of this company, which appeared in the February issue, the new address should have been 1898, instead of 1819, Notre Dame Street.

The Buffalo Indicator Company has removed its offices and works to Jamestown, N. Y., and with increased facilities hopes to promptly meet the increasing demand for its indicator and other steam specialties.

Bryan & Humphrey, mechanical and electrical engineers, Turner Building, St. Louis, have issued a neat pamphlet, giving a list of their specialties in engineering work, and a long list of references, which includes some of the best-known names in the West.

The Crouse-Hinds Electric Company, and Pass & Seymour, of Syracuse, N. Y., have leased the store No. 23 Dey street, Havemeyer Building, and moved their place of business to that place. Mr. F. W. Hawkins will be in charge of the New York establishment.

Telephones.—The Allen-Hussey Company, 211 Randolph Street, Chicago, reports gratifying sales in February for its specialties—interior and short-line telephones. These instruments are deservedly popular for their ease in connection, their compactness and reliability.

Sale of Arc Lamps.—The number of arc lamps manufactured and shipped from the factories of the General Electric Company within the past fiscal year has exceeded 24,000. Many thousands of the General Electric enclosed arc are now in service and the introduction of the alternating enclosed lamp has still further increased sales.

Indicators.—It is seldom that a more handsome lot of indicators can be seen than three double sets shipped one day recently by Jas. L. Robertson & Sons, 204 Fulton Street, New York. Some idea of the territory covered by this company is indicated by the destination of the above sets, which went to St. Louis, Kalamazoo and Milwaukee.

Iron-Armored Conduit Outlet Insulator.—The Central Electric Company has taken the Western agency for the Erickson outlet insulator. This outlet insulator is brought out to meet the demands of engineers for a thorough and perfect protection at the ends of iron armored conduit outlets. It very effectually and thoroughly prevents possible grounding of the wires on the iron conduits.

J. A. Lang & Co., manufacturers of steam and electrical specialties, 44 Michigan street, Chicago, have just issued their 1898 catalogue of switches, switch and panel boards, special castings, etc. They call special attention to the metal used in the bases of their switches for all lugs, connections, etc. A very interesting test is shown giving the conductivity of cast copper manufactured by this company.

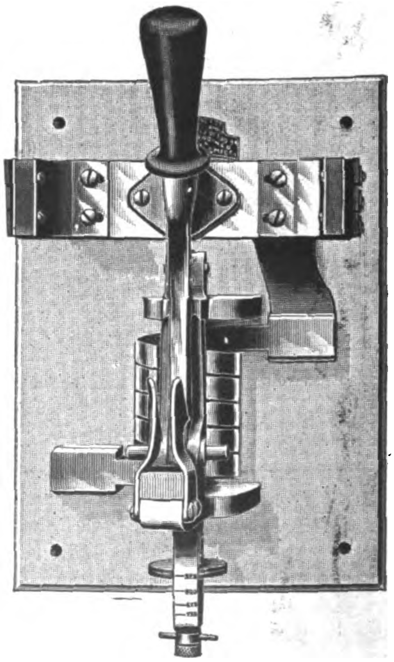
I-T-E Circuit Breakers



The above represents instrument of from 100 to 1250 Amperes. Standard Switch-board Type, Single Pole, Direct Current.

Affording Protection against Grounds and Short Circuits.

A prominent English Engineer is quoted as saying he would not hesitate to short circuit any dynamo, provided it be safeguarded by an I-T-E Circuit Breaker. A large number of these safety devices are in use upon the switch-boards of the leading tramways and lighting stations in Great Britain.

The CUTTER ELECTRICAL & MFG. CO.
1112 Sansom St., Philadelphia, Pa.
120 Liberty Street, New York.

Eyanson & Armpriester have removed to the large building on Commerce street, cor. Seventh street, Philadelphia, their constantly increasing business having made it necessary to seek larger quarters. With more room and increased facilities to handle work promptly they will continue to maintain the standard of the work that has always made the name of "E. & A. Knife Switch" everywhere known.

Carbons for Enclosed Arc Lamps.—Cored carbons and solid carbons for enclosed arc lamps can be made at home beyond all dispute just as good as the foreign article, and there is little doubt but that the Washington Carbon Company is building up a very handsome trade. This enterprising company is to be congratulated upon its work in this line, and every one will wish that it may meet with great success.

The Hercules Float Works, Springfield, Mass., have recently opened an office at 154 Reade Street, New York, which will be in charge of Mr. H. C. Enders, who will be pleased to show samples of the Englehardt Safety Electric Water Columns, which are meeting with so much favor. This company also manufactures seamless copper floats and air chambers, and has also just put on the market a very effective pneumatic tank indicator.

Frank R. Eager, who has recently opened headquarters at Syracuse, N. Y., reports a heavy business from Onondaga dynamos, Janders arc, and Buckeye incandescent lamps. Mr. T. H. Bailey Whipple, the general agent of the Buckeye Electric Company and of the Janders Electric Company, of Cleveland, Ohio, has been doing New York State, and stopped off a week at Syracuse to lend Mr. Eager a helping hand.

Mr. F. M. Hawkins, New York agent of the Crouse-Hinds Electric Company and the Pass & Seymour Company, of Syracuse, N. Y., has removed his office and show rooms to 23 Dey street, on the ground floor of the Havemeyer Building. This should be a very desirable location, as it gives not only a very attractive office, but a large show-window on Dey street for a display of samples in the line of switch and porcelain specialties manufactured by the above companies.

Electrical Equipment of a Sky Scraper.—The complete wiring system, as established and standardized by the Interior Conduit & Insulation Company, will be installed exclusively in the new Park Row Building, the largest office building in the world. Some 250,000 feet of interior conduit will be used in the installation, which will be made by the New York Electric Equipment Company. The Sprague high-speed, vertical electric elevators will also be used in this building.

The Diesel Motor.—During the past year the Diesel motor has created a sensation in both mechanical and scientific circles in Europe, owing to the high efficiency claimed for it and the new thermo-dynamic principles applied in the machine. Recently a company which has purchased the American patents of the motor has been incorporated under the laws of the State of New York as the Diesel Motor Company of America, and has established headquarters at 11 Broadway.

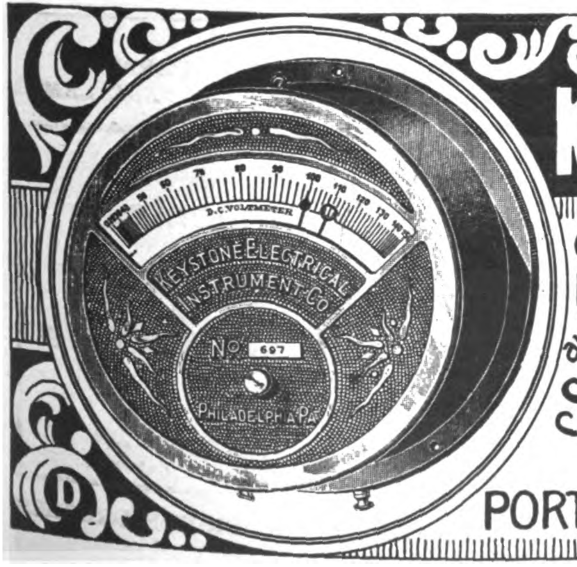
W. R. Garton, 414 Ashland Block, Chicago, has just been elected general manager of the Garton-Daniels Electric Company. Besides representing this company, Mr. Garton will also represent the Pittsburg Steel Hollow-Ware Company, Massachusetts Chemical Company, and other Eastern manufacturers. It is Mr. Garton's intention to devote himself to electrical railway supplies in general, but states that he will not give any attention to minor supplies or repair parts. Mr. Garton is a stockholder in the Raster Carbon Rheostat Company, as well as consulting engineer o. the same concern.

Automatic Circuit Breakers.—The Ward Leonard Electric Company, Bronxville, N. Y., has received a flattering testimonial from the Vance Electric Company, 136 Liberty Street, New York, on the merits of their circuit breaker. The latter states that for months past a 300-ampere automatic circuit breaker has been in use under peculiarly exacting conditions, and its performance leaves nothing to be desired, and adds: "I am well acquaintance with the various types of automatic circuit breakers, and have no hesitation in saying that your circuit breaker is the best now on the market. Your circuit breaker referred to above has been called upon to operate scores of times, and its performance has been perfect."

The Mica Insulator Company, of 218 Water street, New York, and 117-119 Lake Street, Chicago ,and 12 Camomile Street, London, reports a ..eavy increase in the volume of business. Many of the large manufacturers are using its "Micanite" segments in the construction of their generators and motors exclusively. The company has made many valuable improvements in its well known insulation, "Micanite," and are turning out a very fine commutator segment. They would be pleased

The Belknap Motor Co.
OF PORTLAND, MAINE,

are very busy in the manufacture of Chapman Voltage Regulators; about ¼ of their entire force is devoted to this work alone. Orders have recently been received from Bath (N. Y.) Illuminating Co., New Haven Electric Light Co.; Potomac Electric Light Co.. (third one ordered within few months). Northern Electric Light Co., Philadelphia; Middletown (Conn.) Electric Light Co., three regualtors. Pawtucket R. I. Electric Co.; Mutual Electric Light Co., St. Antonio, Tex.; Mt. Morris Electric Co., New York City, (two) recent shipments of Chapman Regulators have been made, (2) Johnstown, Pa.; Electric Co., Stockton, Cal., Gas & Electric Co., B. C.; Smelting & Refining Co., Trail, B. C.; People's Electric Co., Orange, N. J.; Thomas Oakes & Co., Bloomfield, N. J.; Clute Bros., Cohoes, N. Y.; H. T. Cushman Mfg. Co., North Bennington, Vt.; Lebanon (N. H.) Electric Co.; Haverhill (Mass.) Electric Co., &c., &c. The sale of Motors and Dynamos manufactured by this company is lively at the present time, their New York and Boston representatives, Brewster Eng. Co, 27 Thames Bldg., and the L. I. Fletcher Co., Boston, are hustlers and no mistake. About 200 H. P. in motors having been received from Brewster Eng. Co. since Jan. 1st, and a similar amount from L. I. Fletcher Co., more than 40 machines being sold since Sept. 25th by the latter company.



KEYSTONE ELECTRICAL INSTRUMENT CO.

to send a set of segments for any of the smaller machines, as sample, to electrical manufacturers or repair concerns who may make application. "M-I-C" friction tape and "Empire" Cloth are also meeting with a large sale. They are used for the winding of fields and armature coils, and furnish the highest possible grade of insulation.

The W. S. Hill Electric Company, New Bedford, Mass., is now doing more than double the business than at this period last year. Some of its recent work is a switchboard for the Manhattan State Hospital, Ward's Island, N. Y. This is a white marble board 24 feet long by 8 feet high. The same company has recently built a white marble board about half this size for the Long Island State Hospital, at King's Park, L. I. One of the finest boards ever built by this company was recently completed for Houghton & Dutton, Boston. Although not so large as those above mentioned, it is certainly a model of effective switchboard construction, and for a board carrying so many different circuits the back of the board is remarkably free from the mass of wire usually found on a board of this kind, owing to the very neat and simple but systematic bus bar arrangement.

The Dearborn Drug & Chemical Co., oil and water chemists, Rialto Building, Chicago, has recently been incorporated for $250,000. This concern has just opened an office at 408 Security Building, St. Louis, Mo., which is in charge of Mr. Chas. Standfield, manager. Mr. Standfield is a regular graduate in pharmacy, also a thorough and efficient chemist, and is considered by the Dearborn Drug & Chemical Co. one of its most able men. Mr. Standfield is becoming rapidly acquainted with St. Louis institutions, and reports that the outlook in his territory is a very promising one. The Dearborn Drug & Chemical Co. already has a large trade in St. Louis and contiguous territory, many of the most important steam plants being users of the Dearborn compounds. Mr. W. H. Edgar states that the Dearborn Company did over 30 per cent. more business in 1897 than in the previous year, and he is looking for a decided increase over this for 1898.

Transformers.—The New York and Ohio Company, of Warren, Ohio, well known as makers of the Packard lamps and transformers, has for some time past been developing a new series of transformers which is now ready for the market. These will be known as the Packard Model '98. It is claimed that these transformers are fully equal and in some respects superior to any in commercial use. Particular claims are made regarding regulation, a point in transformer design which in the endeavor to obtain an exceedingly low core loss has been too often considered of secondary importance. The New York and Ohio Company has secured the services of Mr. H. W. Wiswell, who for several years has been connected with the transformer department of one of the largest manufacturers of this apparatus in the world. Mr. Wiswell's comparatively long experience in this particular branch especially fits him for his new duties. The New York office has been established at No. 1 Broadway, under the personal supervision of Mr. J. W. Peale, president of the company, who assisted by an efficient force will handle the Eastern business.

Walker Apparatus.—The Standard Light & Power Company, of Dallas, Tex., has placed an order with the Walker Company for two alternators, one of 225 and the other of 325-k.w. capacity. They are to be direct connected to "Erie" engines, and are designed to run at 125 revolutions per minute. The machines will generate 2-phase currents at a frequency of 60. In addition to these the Walker Company will furnish them with two direct connected railway generators of 225 and 325-k.w. capacity, respectively. The alternating generators of 250-k.w. capacity each are being built for the North River Electric Light & Power Co., of New York City. They are to be of the belted type. Townsend, Reed & Co., of St. Louis, have purchased for the St. Louis, Belleville & Suburban Electric Railway two 200-k.w. direct connected Walker railway generators, besides eight double 10-S railway equipment with "S" controllers. On the other side of the Atlantic, the Glasgow municipal tramway will place a number of Walker motors on its cars at an early date, while the Electric Railway of Alexandria, Egypt, will increase its present Walker plant by the addition of one 150-k.w. belted generator with switchboard, and four double 3-N equipments.

TO EARN MORE LEARN MORE.

Our correspondence courses in Electrical, Mechanical and Steam Engineering will help you to do both. Our school is conducted by professional engineers of high standing and indorsed by educators and technical men. It has courses for those just able to read and write and for graduates of technical schools. Our catalogue, sent free on application, tells all about it. INSTITUTE FOR HOME STUDY OF ENGINEERING, 224 Seneca Street, Cleveland, O.

A TECHNICAL EDUCATION
10 CENTS A WEEK

THE new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary textbooks.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 48 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

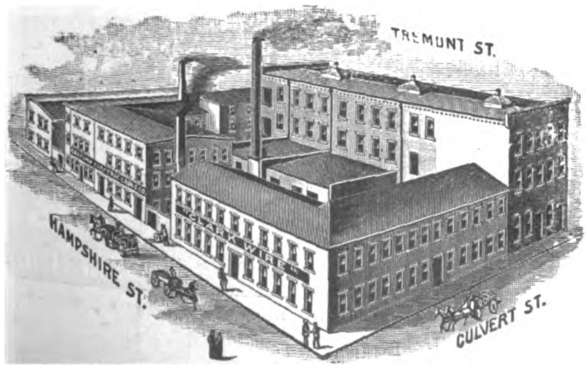
"CLARK WIRE"
TRADE MARK.



TREMUNT ST.
HAMPSHIRE ST.
CULVERT ST.

THE "CLARK" WIRE

In a Letter from the Inspector of the Boston Fire Underwriters' Union, he states:

"A Thoroughly Reliable and Desirable Wire in Every Respect."

For Switchboard, Railway and Motor use, we make all sizes of Stranded and Flexible Wire and Cables with Clark's Insulation.

The Clark Wire has been before the public and in use for the past nine years, and has met with universal favor. Thousands of miles of this wire have been sold, and are in use throughout the United States and foreign countries, and the demand for it is constantly increasing, because it always gives perfect satisfaction.

The Rubber used in insulating our Wires and Cables is especially chemically prepared and will not deteriorate, oxidize or crack and will remain flexible in extreme cold weather, and is not affected by heat.

We guarantee our Insulation wherever used, Ærial, Underground or Submarine, and our net prices are as low, if not lower, than any other first-class Insulated Wire.

We shall be pleased to mail catalogues with terms and discounts for quantities.

WANTED TO PURCHASE.

WANTED—A first-class, second hand, X-ray apparatus. Address, W. A. Price, D. D. S., 2238 Euclid Ave., Cleveland, Ohio.

WANTED—Mixed lot of about one thousand, 50 and 100 volt direct and alternating current fan motors. Address, THEO. K. JACKSON, Ann Arbor, Mich.

SITUATIONS WANTED.

WANTED—By a competent young man, a situation as telephone inspector or station lineman. Has had five years' experience. Would go anywhere. Can furnish best of references. Address, "R. J. M," care of AMERICAN ELECTRICIAN, New York.

WANTED—A young man with six years' practical experience, would like position as superintendent of a central station. Can furnish best of references. Good reason for wishing to make a change. Address, "Superintendent," care of AMERICAN ELECTRICIAN, New York.

WANTED—Situation by a competent man, now in charge of electric railway; thoroughly understands line work, trucks and motors, G. E. and Westinghouse winding and lamp wiring. Southern or western states preferred. Can furnish best of references. Address, "B. D.," care of AMERICAN ELECTRICIAN, New York.

WANTED—Position by an A1 practical man capable to install machinery. Now employed as station man at a splendid electric light and water plant. Salary moderate. Good reference for nine years' experience. Or would lease a plant in some live town. ENGINEER AND ELECTRICIAN, care of AMERICAN ELECTRICIAN, New York.

WANTED—Young man desires position in office or plant of a Light and Water Co. Has worked in a lamp factory and understands testing lamps. Desires to prepare for superintendent. Pay no object. Not afraid of hard work. Understands bookkeeping. Best references. Address, "G. T. A.," care of AMERICAN ELECTRICIAN, New York.

WANTED—A young married man, 26 years of age, would like position where there is good chance for advancement. Has had seven years practical experience as all-around man in large power plant. Can do line work, wiring, and arc lamp repair work. Understands handling Alternating Current working, and winding transformers and meters. Is also acquainted with work connected with the steam end of plant. Knows something of the office work connected with a plant, and has had extended experience in collecting "bad bills." Has position at present but prospects are not satisfactory. Can furnish best of references from previous employers. Address, "X. Y. Z.," care of AMERICAN ELECTRICIAN, New York.

ENGINEERS' AND MACHINISTS' POCKET BOOK.

SAMSON TURBINE

WATER WHEELS

ADAPTED TO ALL HEADS FROM

3 FEET TO 2000 FEET.

ESPECIALLY ADAPTED TO ALL KINDS OF

Electric Power and Lighting Plants.

Recent tests at Holyoke enable us to guarantee:

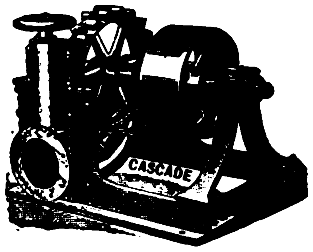
The largest power ever obtained from a wheel of the same diameter. The highest speed ever obtained for the same power. The highest mean efficiency when running from half to full gate. We guarantee also: *A runner of the greatest possible strength. A gate unequalled in quickness and ease of opening and closing.*

Our experience of **36 years** building water wheels enables us to suit every requirement of water power plants. We guarantee satisfaction. Send for pamphlet of either wheel and state your **head** and full particulars.

AUTOMATIC STEAM ENGINES

WITH SUITABLE BOILERS.

Built in latest style, of latest design and HIGHEST EXCELLENCE. Sizes from 3 horse-power upwards. Send for Engine Pamphlet D.



JAMES LEFFEL & CO.,
SPRINGFIELD, OHIO, U. S. A.

Case High Speed Steam Engines.

Sizes 2½ to 25 H.P., especially suited for direct connection. Cut shows combination 8 H. P. Engine and 4 K.W. Eddy Dynamo. One of a number of outfits furnished for Yukon river steamers. Its light weight in proportion to output being of advantage in Marine service and in shipping across the continent.

The New Britain Machine Co., **New Britain, Conn. U. S. A.**

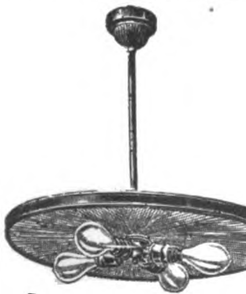
Frink's Sectional ☙ ☙ Glass Cluster Reflectors

and Reflecting Shades in metal frames lined with silver-plated corrugated, mirror or opal glass, are much stronger and are far superior in light-giving qualities to the ordinary opal reflector, and the cost is but little more.

They are very largely used for lighting stores, store windows, banks, offices, schools, hospitals, depots, office and public buildings generally.

Book of Light, Price Lists and Estimates Free.

Telephone 860, Franklin



Patented Dec. 14th, 1897.

Wabash Completes Extension of Its Line to Buffalo.

Will Operate Its Own Freight as Well as Its Passenger Trains Over the Grand Trunk and the Erie—Eastern Terminal Facilities—The Short Line.

The Wabash management has completed all arrangements for the operation of its own freight trains as well as its passenger trains to and from Buffalo. For some time past the Wabash has been operating its own passenger trains in and out of Buffalo, and it soon expects to extend its freight service from Detroit to Buffalo. This is to be accomplished by leases of the Grand Trunk and the Erie tracks, which have been ratified by the respective boards of directors. It is a practical extension of the Wabash system eastward to Buffalo, together with the use of terminal facilities at Buffalo.

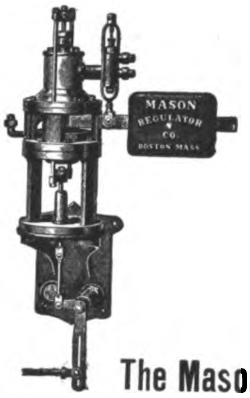
The Mason Rheostat Regulator



This apparatus was designed to automatically govern an electrically driven pump operating hydraulic elevators. Operating as it does a switch, which controls the passage of the current to the electric motor, it starts and stops the pump as often as the pressure in the tank rises above or falls below the desired point. The machine is very powerful, as it is operated by the direct water pressure in the system. It is also very positive and sensitive.

THE DOLGEVILLE (N. Y.) WATER-POWER ELECTRIC LIGHT AND POWER PLANT.

BY E. A. GRISSINGER.

ANOTHER substantial impetus was given to the generation of electrical energy through the medium of water power, when on Jan. 15 of the current year the Dolgeville Electric Light & Power Company put in operation its excellent and modern plant at High Falls, N. Y., on what is now known as the Auskerada River. That the opening day had been looked forward to for a long time was evidenced by the large number of people present on the occasion. Through the columns of other papers, the social and literary character of the gathering, subsequent banquet, etc., furnished interesting reading; and the purpose of this paper is to deal more particularly with the organization of, and certain technical details relating to, the installation.

The Dolgeville Electric Light & Power Company was organized and incorporated in December, 1891. The capital stock was fixed at $25,000. Early in 1892 some direct-current apparatus was installed, furnishing light and power in small units. This plant has always been operated by water power under 22 ft. of head. The calls upon the company for electrical energy expanded to such an extent that, previous to the opening of the new power, the company was operating the following machines: Two 50-k.w., 500-volt, direct current; one 90-k.w., 500-volt, direct current; two 45-k.w., 110-volt, direct current; one 20-k.w., 110-volt, direct current of General Electric make; and one 7-kw., direct current, type "Z," Edison generator, bearing the date of 1879 and numbered "No. 2."

The machines of 110-volt potential furnished current for the commercial lighting circuits. Those of 500 volts were used for power purposes, and also furnished current for street lighting. The latter was accomplished by clusters of five lamps in

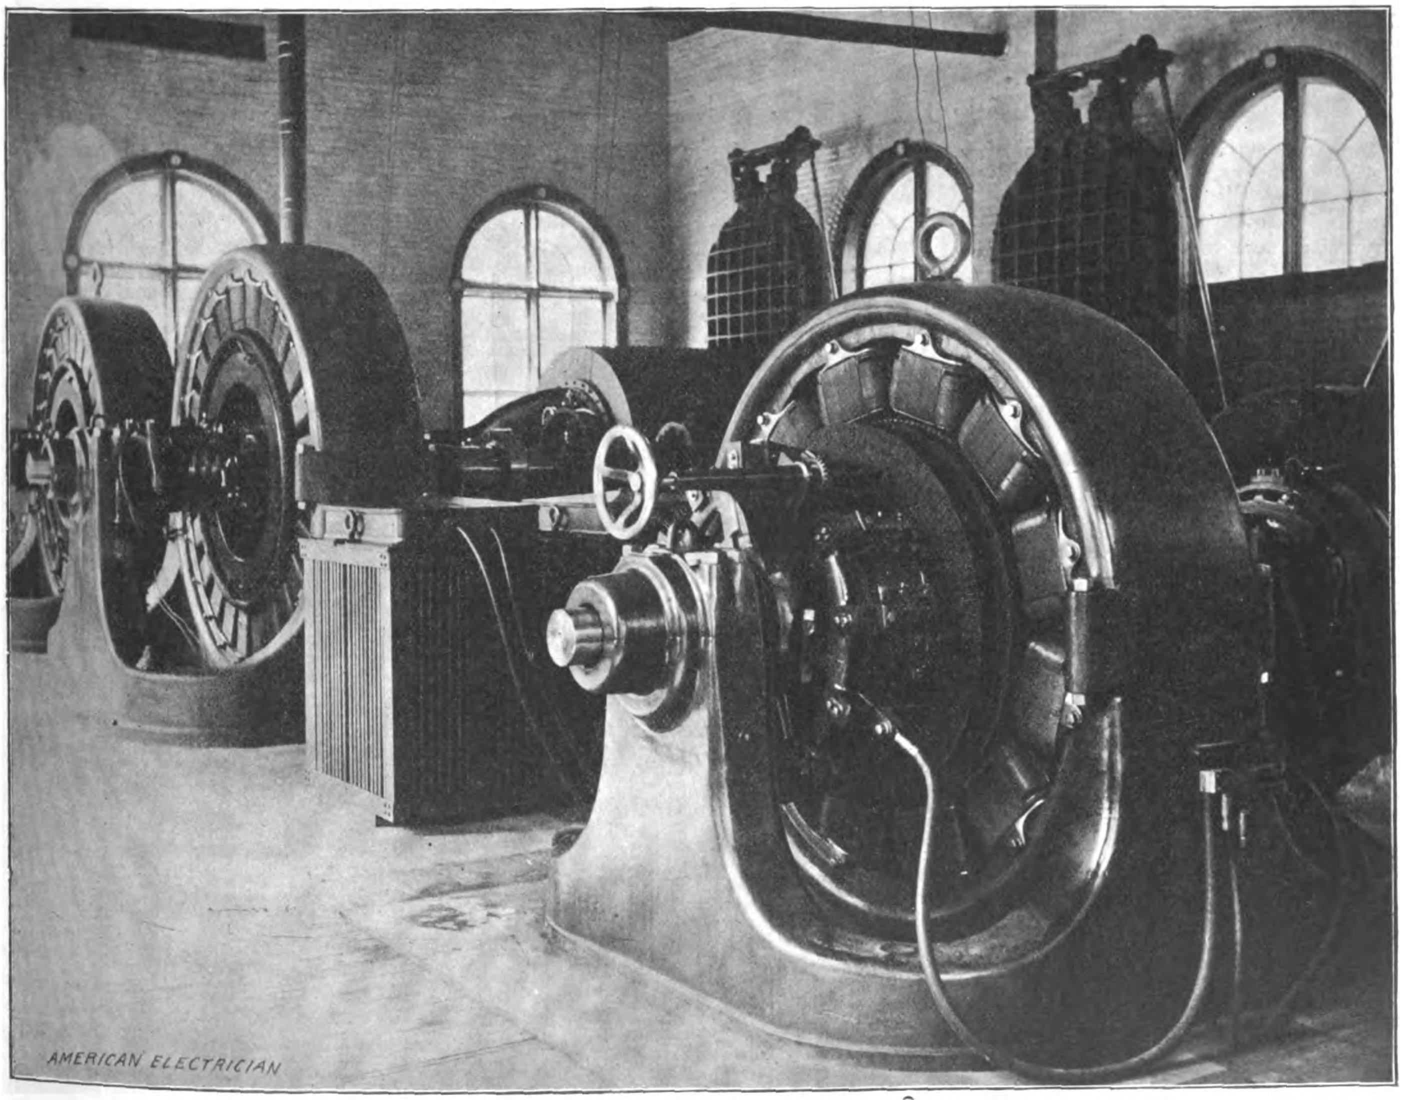

FIG. 1.—GENERAL VIEW OF THE PLANT.

series across the 500-volt mains. About forty such clusters were in use.

One pair of 35-in. horizontal Victor turbines, running at 168 r.p.m., and developing 480 h.p. under 22 ft. of head, furnished the power necessary to operate the plant.

The business of the company had outgrown its narrow confines. The directors were thoroughly appreciative of rapid strides made in the field of power transmission, and recognizing their own peculiar and great advantages for water power development, decided early last year to increase the capital stock of the company and proceed with development on a modern scale. Accordingly a contract was made in the early spring with the Stilwell-Bierce & Smith-Vaile Company for the hydraulic development, which company supplied all plans and built the plant complete up to the generators. Mr. A. C. Rice, general superintendent and engineer of the company, being in direct charge of the work. In July a contract was made with the Westinghouse Electric & Manufacturing Company for the electrical equipment.

FIG. 3.—CROSS-SECTION OF POWER HOUSE.

The Dam and Flume.—As soon as the weather permitted it, work was begun on the construction of the dam. This is a good example of masonry construction. The height at the spillway is 20 ft., and each abutment 6 ft. higher, the total length being about 195 ft. The width at the top is 7 ft., and at the bottom 26 ft. The upstream side of the dam is perpendicular, the down-stream side affording a good apron, the lower curve drawn to a radius of 10 ft. Limestone was used in the construction, the face stones coming from Ingham's Mills, 2 miles below the power site. The Glens Falls Portland Cement Company furnished the cement, which was their Victor brand. In mixing for use, one part was used with four parts of sand. Fig. 5 is a view of the dam, and Figs. 10, 11 and 12 show sections through the head gate, waste gate and main portion, respectively.

The westerly abutment contains a flush gate 4 ft. x 6 ft., to which is attached one set of No. 6 waste gate irons for operating the same. Beside this waste gate is the head gate, 12 ft. square in two sections, being fitted with a pass gate to relieve the pressure when filling the flume. These gates are operated with two sets of No. 2 head gate irons, as made by the Stilwell-Bierce Company. The steel flume extends from the head gate to the power house, 520 ft. away. This flume is 10 ft. in diameter, and is made of ¼-in. steel plate, all longitudinal seams being double riveted. Just outside the dam is a vent pipe, which will assist toward relieving the flume from any sudden strains. Masonry piers at intervals of 20 ft. furnish the necessary supports for the flume. The latter has two curves in its descent to the power house level, and was made of sufficient diameter to provide for the ultimate development of this plant. The flume terminates in the customary steel forebay used in connection with horizontal wheels. Fig. 6 gives a general view of the dam, steel flume and power house.

The Power House.—The power house is of brick construction, with its foundations and those of the machinery carried to bed rock. The building is 46 ft. x 64 ft. x 16 ft. to the roof trusses, which latter are of steel construction, four in number. The draught tubes from the wheels are arched over with substantial masonry arches, and the filling about these and the foundations of the machinery consists of broken stone and hydraulic cement. The whole is topped with a 6-in. layer of concrete, constituting the finished floor of the building. Telephone communication extends from the station to the village, and will have connections ultimately to all points where the power will be used. Fig. 2 is a plan of the building, showing the arrangement of the machinery. The switchboard has been placed at the right end of the building toward the dam. The power house is so situated and the excavations have been proceeded with in such a way as to permit of extensions longitudinally to the capacity of the plant, which will ultimately be 3600 h.p. From Fig. 3, showing a cross section of the station, it will be noted that the steel forebay is placed just outside and parallel to the building, extending the full length of same. Fig. 4 shows a partial longitudinal section and side elevation of the power house.

Hydraulic Equipment.—There are two 36-in. horizontal Victor turbines, each direct connected to one 450-k.w. two-phase Westinghouse generator. Each of these wheels will develop 600 h.p. at 300 r.p.m., under the working head of the water, which is 72 ft. They are mounted in cylindrical steel casings, discharging at the end downward through draught tubes, which latter, passing through the power house foundation, extend a few inches below the surface of tail water. Each wheel is supplied with a Giesler electro-mechanical governor, which gives satisfactory regulation. One of the wheels, with governor in the foreground, is shown in Fig. 7.

One exciter wheel, 15 ins. in diameter, has been installed, running at 375 r.p.m. and driving a 15-k.w., 110-volt multipolar exciter. As the load upon the exciter is approximately constant, no governing mechanism has been deemed essential. The gates at the larger wheels are operated through the medium of a double set of bevel gears and of the exciter wheel by means of an ordinary hand wheel. All of the turbines are of the cylinder gate pattern, the two larger ones being "Victor Specials."

From the supply main to the exciter wheel a relief pipe is tapped, which, by means of a suitable valve arrangement, permits of water being drawn from the flume when such procedure is deemed essential. The turbines run right-handed. The speed of the driving mechanism at the governors is 483 r.p.m. All of the construction pertaining to the hydraulic equipment is substantial and well made.

The Electric Equipment.—Fig. 1 gives a general view of all generators except the exciter. In the foreground will be noticed the rotary transformer of 250 k.w. capacity, to the left of which are two 450-k.w., two-phase alternating current Westinghouse generators, direct connected to the tur-

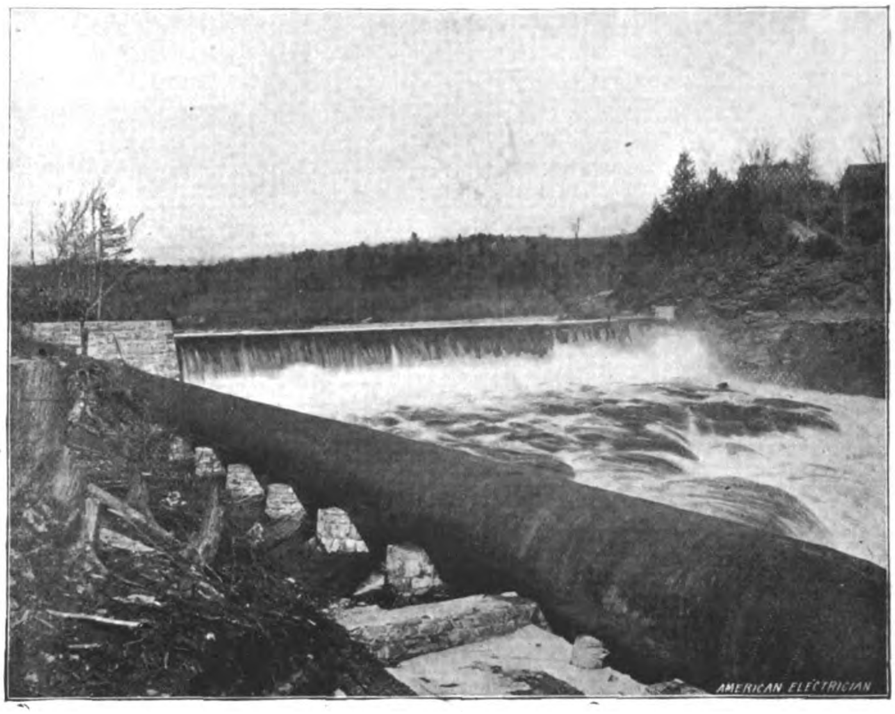

FIG. 5.—VIEW OF DAM AND FLUME.

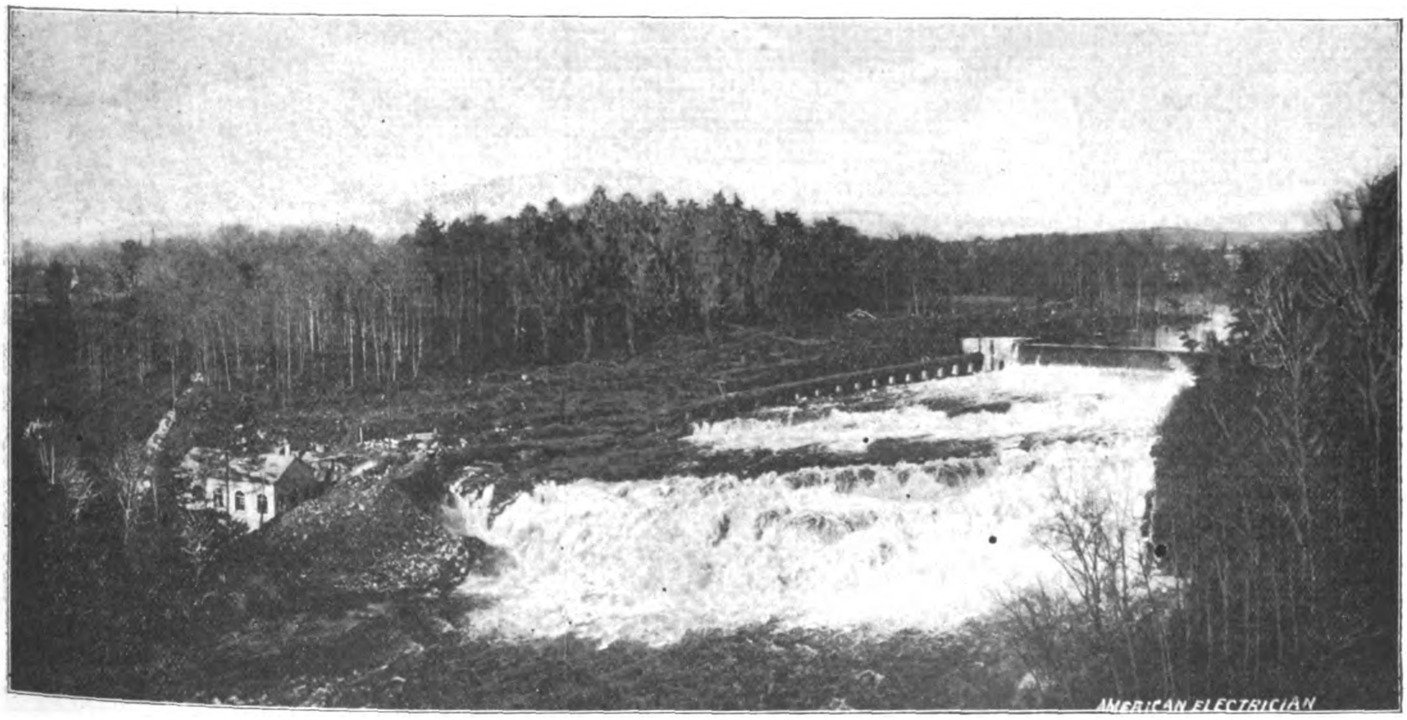

FIG. 6.—GENERAL VIEW OF DAM, FLUME AND POWER HOUSE.

bines by face couplings. The generators are of 2400 volts potential, and will deliver their rated output at 300 r.p.m. at 94 per cent efficiency under continuous service of any nature, no part showing a rise in temperature of more than 40 deg. C. above that of the surrounding atmosphere. The armatures are of the slotted type, wire wound; the frequency is 60 cycles, there being twenty-four poles.

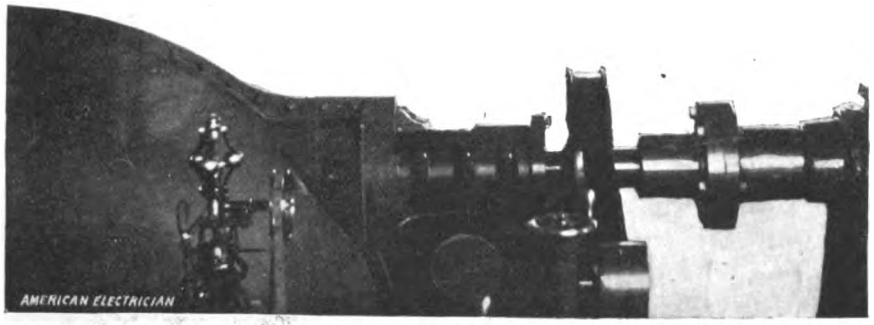

FIG. 7.—ONE OF THE TURBINES.

The field frames are cast from a special grade of iron, insuring high permeability. They present the usual characteristic of Westinghouse apparatus—that of beauty and symmetry in design. Laminated poles are used, insuring high efficiency, close regulation and cool running under trying conditions of service. The bearings are of liberal proportions, self-oiling, there being two oil rings to the bearing. The fields divide through the center in a horizontal plane, such being necessary in the direct-connected type of generator.

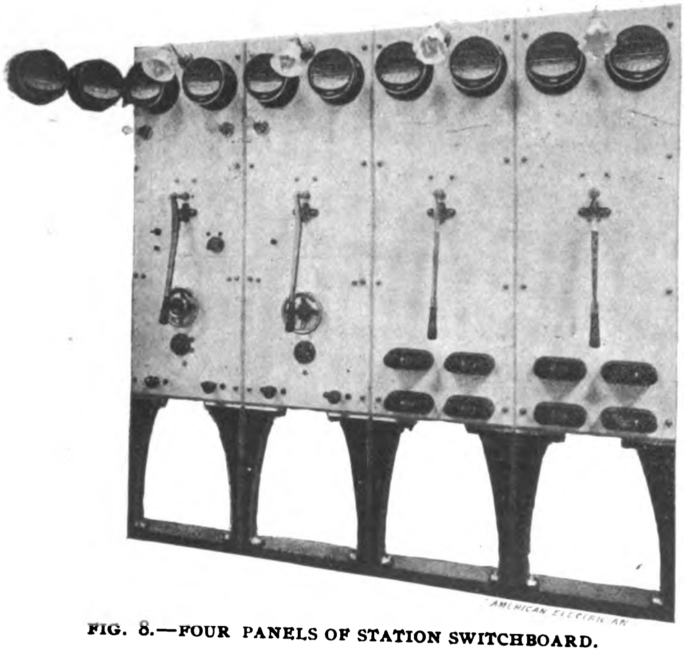

FIG. 8.—FOUR PANELS OF STATION SWITCHBOARD.

The armature core consists of a cast steel spider, having upon its periphery a number of projections, which are turned off to the proper radius, after which operation they are centered and carefully dovetailed upon a machine suitable for the purpose. The armature stampings, which are of specially annealed steel, are then manually built up on this spider, their projections fitting into the slots, dovetailed fashion. When the proper number of laminæ are obtained, they are forced in closer relation by pressure, and so retained by means of steel rings fastened together from each side of the core. Four collector rings are provided, which convey the current to the brushes, 93.7 amps. being the normal current per phase.

Four No. 1 wires carry the current from each alternator to the switchboard, and No. 4 wires convey the exciting current between switchboard, exciter and alternators.

The generators are securely fastened to the foundations by means of anchor bolts provided for the purpose, and are designed with such a factor of safety that they will withstand a speed equal to that of the wheels when traveling at the spouting velocity of the water under 72 ft. of head.

In view of the fact that there were a large number of direct current motors in use in Dolgeville, it was found necessary to provide a 250-k.w. rotary transformer. This machine delivers direct current at 600 volts potential, running as an alternating current motor, self excited, the fields having a compound winding. The speed of this machine is 600 r.p.m. On the direct current side there are twelve brush holder arms, two carbons to the arm. The carbon holders are of the swivel type, being a late design of the Westinghouse Company. The rocker arm is readily adjustable by means of a worm and bevel gear, which device renders the movement self-locking.

Bar winding is used on the armature, and is of the same general type as is found on the Westinghouse railway generators. The open type of winding and apertures in the armature core insure excellent ventilation.

For the purpose of starting the rotary and bringing it up to speed, a two-phase type "C" induction motor of the same general design as those largely in use at Buffalo and Niagara Falls, has its rotating secondary keyed to the shaft of the rotary. The primary of this motor rests upon a bracket fastened to the frame. Current for the induction motor and also for the alternating current end of the rotary is obtained from the alternators through a pair of static transformers, each of 125 k.w. capacity. These converters are the self-cooling oil type, and receive current at 2400 volts, transforming to any one of three e.m.fs., 405, 430 or 455. By this means any change in the direct-current power circuit by virtue of increased or decreased load can be met.

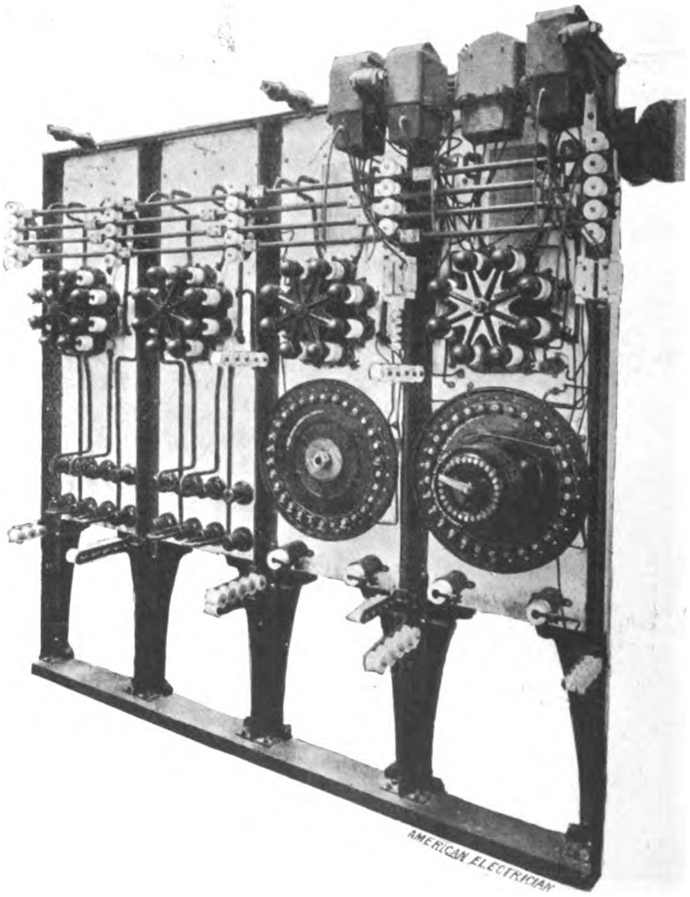

FIG. 9.—REAR VIEW OF ALTERNATING CURRENT PANELS.

Fig. 8 shows four panels of the station switchboard. The two panels at the left control the alternating current generators. Each panel is of Vermont marble, 65 ins. x 24 ins. x 2 ins. resting upon cast iron standards. Upon each generator panel is mounted a pair of ammeters of the round pattern, a pilot lamp, two field plugs, a four-pole, double-break plunger type switch and voltmeter receptacle. Panel No. 1 contains in addition one combination A. C. & D. C. rheostat, ground detector receptacle and push with lamps; panel No. 2 has synchronizing lamps and A. C. rheostat, the switchboard having been designed to operate the generators in multiple. Upon a swinging bracket to the side, one voltmeter for each generator is mounted. These are also of the round pattern, and have a range of 0 to 140 volts.

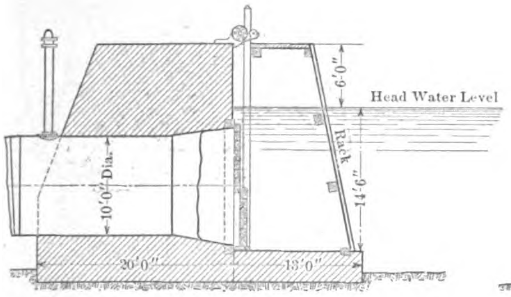

FIG. 10.—SECTION THROUGH HEAD GATE.

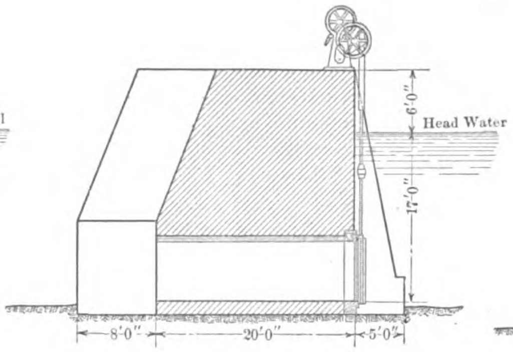

FIG. 11.—SECTION THROUGH WASTE GATE.

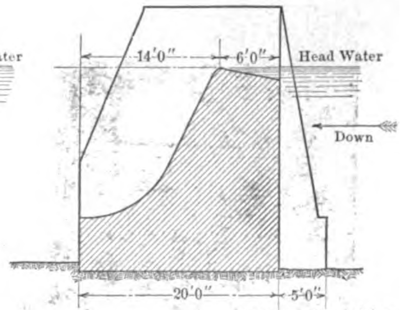

American Electrician

FIG. 12.—SECTION THROUGH BODY OF DAM

The feeder panels, of which there are two, each contain a pilot lamp, four-pole double-break, plunger type switch, four lignum vitæ fuse blocks, using aluminum fuses, and two ammeters of the round pattern. Special attention is called to this board on account of its neat appearance, simplicity for alternating current work, and the fact that there are no metal parts on its face which can be charged in any way by the current handled by it. The combination rheostat controls the exciter voltage and also the fields of the alternating current generator. The exciter rheostat is mounted directly on the back of the board, while the face plate only of the A. C. rheostat is so mounted while the rheostat proper stands upon the floor back of the board. This auxiliary piece of apparatus is of the ironclad type, built up of columns consisting of iron ribbon wound in coils with mica between the layers, each coil so formed having its own terminals admitting of any combination in series or parallel.

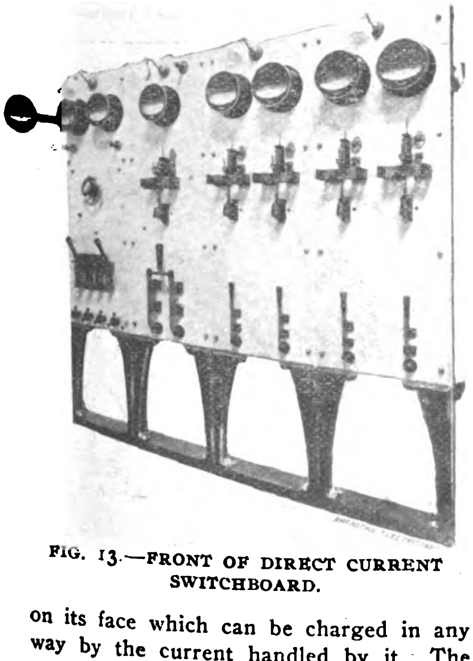

FIG. 13.—FRONT OF DIRECT CURRENT SWITCHBOARD.

Fig. 9 gives a rear view of the A. C. panels, showing the method of supporting the conductors. At the top of the board are the converters for use with the voltmeters and ground detectors.

The plunger type switch shows eight terminals. These are accounted for by the fact that the switch is four-pole, with two terminals or plunger receptacles connected in series in each leg of the two-phase circuit, making it a double-break switch. The breaking of a circuit in such a form of switch is caused by the arc blowing itself out through an aperture provided in the airtight chamber within which the plungers work. This type of switch, as perfected by the Westinghouse Company, successfully breaks its circuit when fully loaded, even though there be a heavy lagging current. They have added much in the way of facilities for handling power circuits using an alternating current.

Figs. 13 and 14 give a good idea of the front and rear of the direct-current board. This board is a continuation of the alternating current panels, each panel being of the same size. The first panel to the left is for controlling the rotary transformer. At the bottom of this panel are four plugs for throwing in the induction motor, thereby starting the rotary. Two lamps upon this panel indicate when the machine is at synchronous speed, at which time the four-pole quick-break switch is thrown, and the plugs withdrawn, relieving the small motor, which remains out of circuit. The hand wheel operates the field rheostat of the rotary. Two A. C. ammeters and a swinging D. C. voltmeter complete the rotary panel.

The second panel is the load panel for the D. C. end of the rotary, containing a double pole switch, circuit breaker and ammeter. The last two sections of this board represent feeder panels, each of two circuits of 200 amps. capacity. At present these feeder panels supply current to three independent circuits, each circuit of No. 0 wire. All leads between the switchboard, dynamo and transformers are carried beneath the floor in a brick lined conduit of ample size. They are supported upon porcelain insulators, attached to wooden cross-pieces, which latter are placed at intervals of 3 ft. This conduit will be covered with a glass plate 1 in. in thickness, and extending its entire length, thus keeping in view at all times the wiring of the circuits.

As previously stated, the original plant supplied current at 110 volts for commercial lighting. This system is now abandoned, and with some changes in the wiring, together with the necessary transformers, the A. C. generators are doing that work. One of the A. C. feeder panels is used for the purpose of controlling the lighting circuits. The remaining A. C. feeder panel will be used for the circuit going to the step-up transformers which will supply current to the transmission line for use in Little Falls.

For the commercial lighting and power work, the Dolgeville Company has adopted the Shallenberger wattmeter. This meter is shown uncovered in Fig. 15. It measures energy in kilowatt hours, and is inclosed in a substantial metallic case, which prevents injury and tampering. On account of the fact that the torque of such a meter is directly proportional to the power passing, one of these meters will start on less than one-half of 1 per cent of its rated load, and no amount of induction can affect the accuracy of the readings. No constants are used in calculating the energy registered, inasmuch as it reads direct.

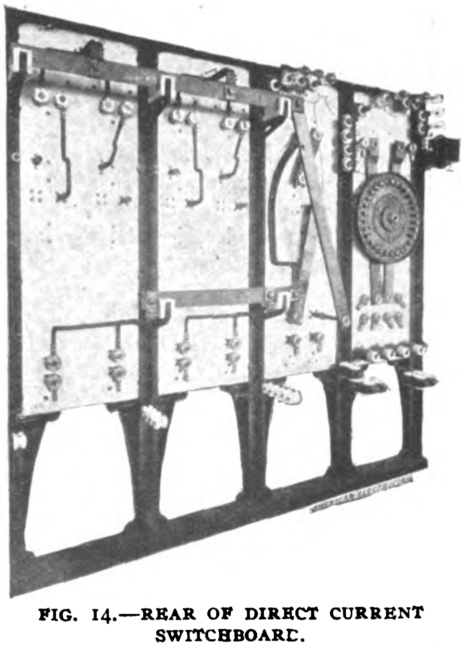

FIG. 14.—REAR OF DIRECT CURRENT SWITCHBOARD.

At present the plant is furnishing current for about 2000 lights and 350 h.p. in motors, and is reported to be working in excellent fashion.

The Transmission Line.—This will be 8 miles in length, extending from the power house to Little Falls, N. Y. The poles are 25-ft. cedars, with 7-in. top, furnished by the Kerby Dennis Company, of Marinette, Wis. They have already been set, numbering fifty to the mile. There will be one cross-arm per pole of yellow pine, 8 ft. x 4¼ ins. x 3¼ ins., well braced. No. 4 hard-drawn copper bare wire will be strung upon porcelain insulators and pins furnished by Mr. Fred M. Locke. This insulator and pin are shown in Fig. 16. The insulator is 5¼ ins. in diameter, and made from three shells of vitrified china fused together with glaze, thus affording a solid insulator of the strongest kind, both electrically and mechanically. The pin is ½-in. steel with a locust top boiled in paraffine, and a porcelain base. By the use of these an arc or static discharge will not burn them off. The sleet and moisture repelling character of insulator and pin when carrying current is therefore carried down to the cross arm; and it is estimated that the arcing distance is increased thereby, corresponding to an increase of 10,000 volts in potential.

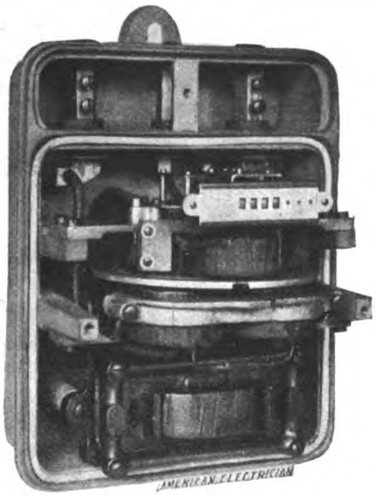

FIG. 15.—SHALLENBERGER WATT METER.

The line will carry 600 h.p. at present, at a potential of 10,000 volts, secured by means of two Westinghouse self-cooling oil type converters, which receive current at 2400 volts, two-phase, and transform to 10,000 volts, three-phase, this method being known as the Scott method of transmission. At Little Falls will be installed two Westinghouse lowering converters, which will receive the current at 9500 volts, three-phase, and transform to 2200, two-phase, ready for distribution for power purposes. The converters mentioned have an efficiency of 98½ per cent.

The transmission line will be transposed three times between the power house and Little Falls, so that each leg of the three-wire circuit will be on the same side of the line for one-third of the distance. No telephone line will be strung on the poles of the transmission line, as one already exists on a separate line running on the opposite side of the railroad. It should also be noted that the high tension line follows the tracks of the Little Falls & Dolgeville Railroad almost the entire distance.

For lightning protection the high tension circuit will be provided with Wurts lightning arresters; three being placed at each end of the line, one for each leg of the circuit. These are of an improved pattern, as manufactured by the Westinghouse Company for transmission work at high potentials. They are each mounted in a rack resting upon glass insulators and provided with choke coils. The loss in the line at full load will be 5 per cent.

In General.—The hydraulic part of the plant was designed by Mr. A. C. Rice, superintendent and chief engineer of the Stilwell-Bierce & Smith-Vaile Company, of Dayton, Ohio. The electrical part of of the work was laid out by the writer.

The Dolgeville Electric Light & Power Company have absolute control of the High Falls water power, and nominal control of rights which will enable it to develop and market 17,000 additional h.p. The facilities for storage are of the best. The headwaters of the Auskerada form a perfect network of lakes, whose area will aggregate 10,000 acres, which is ample for the complete utilization of 20,000 h.p. The natural drainage of the stream through a thickly wooded country above Dolgeville is 260 square miles.

Within the limits of 2½ miles above Dolgeville, and 2½ miles below, the stream has a fall of 412 feet, which is divided up into eight different power sites. A plant immediately below the present installation will obtain 84 ft. of head, and next below 65 ft. The situations are ideal for cheap developments.

The Little Falls market for power is a good one, and there are others not very far away, to which will be sent in the near future power from the Auskerada. Already Little Falls has observed the value of electric power, and subscribed for 300 h.p., which will soon be ready for use.

The officers of the Dolgeville Company are, E. R. Wanckel, president; N. A. Snell, secretary; W. S. Armstrong, treasurer; Alfred Dolge, W. S. Armstrong, N. A. Snell, executive committee.

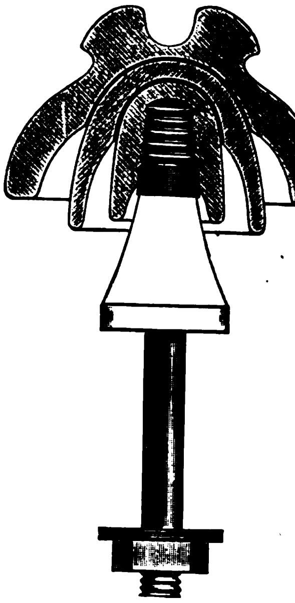

FIG. 16.—HIGH VOLTAGE INSULATOR.

ELECTRIC FAN MOTORS—1898 MODELS.

COINCIDENT with the opening of the commercial fan motor season—which precedes, by several months, the season of use—we print this month illustrations, together with brief descriptions, of the 1898 models of the principal manufacturers of this indispensable modern convenience.

The improvements made since last year present no innovations of a startling nature, but relate principally to perfection in details, increase in efficiency and better appearance. In this last particular the improvement in some cases is quite marked, both with respect to finish and shape.

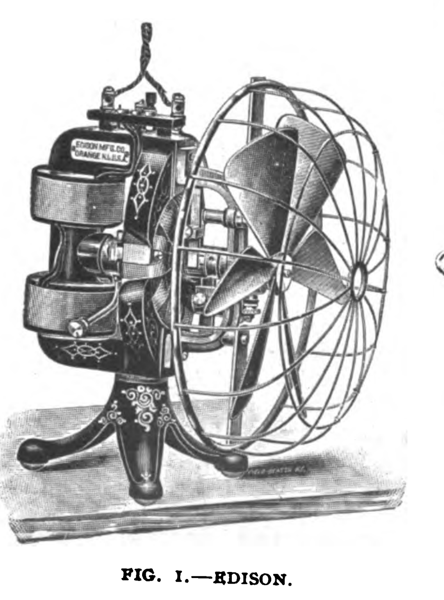

FIG. 1.—EDISON.

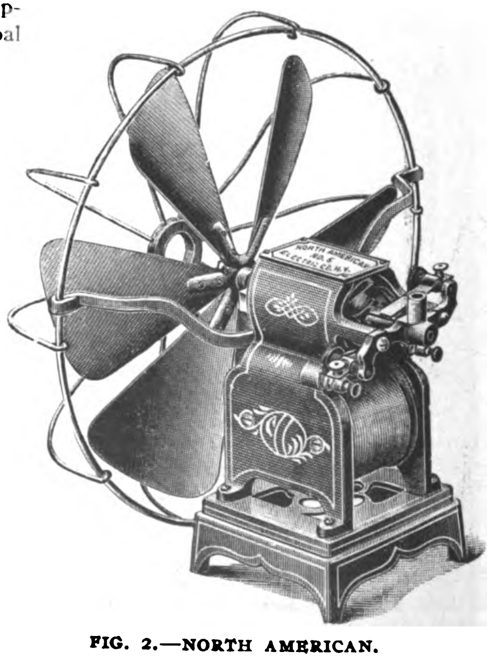

FIG. 2.—NORTH AMERICAN.

There has undoubtedly been a considerable advance in efficiency, particularly in alternating current motors. Now that the ammeter is apt to be applied to test claims as to current consumption, it is a wise business policy to strive after the highest efficiency, even at a sacrifice that might not be thought to be warranted in the absence of competition. We believe that most fan motors of the present day have efficiencies that compare very favorably with those of large power motors, taking into consideration the dependence of efficiency on size. and this is true not only of electrical but also of mechanical efficiency. In the latter respect there has been an advance through the introduction of ball bearings and niceties of fitting borrowed from the bicycle industry. Attention has also been given to the proper proportioning of the size and pitch of fans to the power of the motor—a point that formerly received little attention. It is interesting to note that in fan-work there has been a complete solution to the single-phase induction motor problem, several motors of this type being described in the following columns.

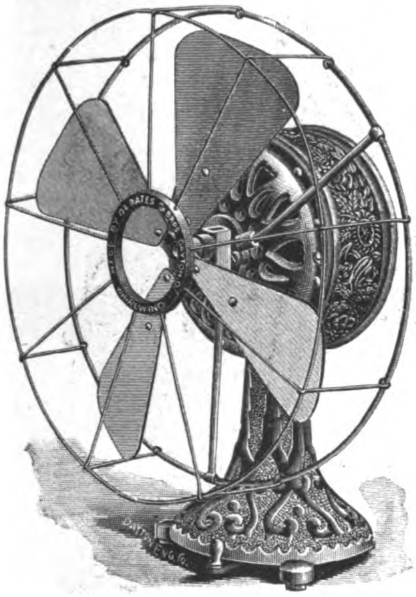

FIG. 3.—BATES—D. C.

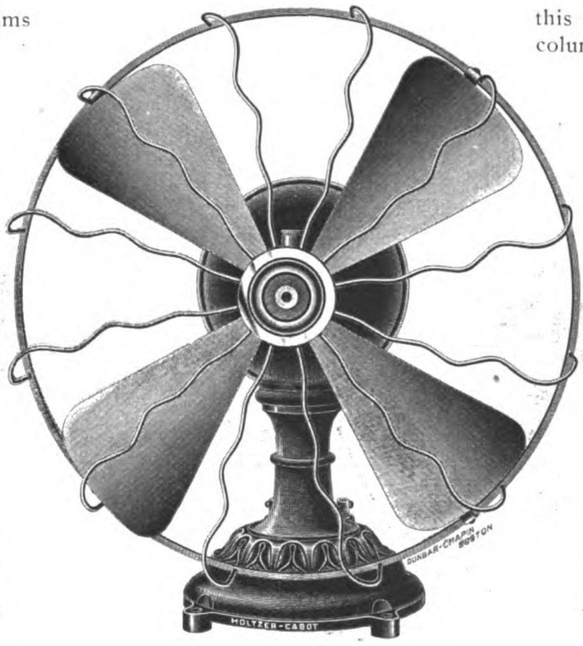

FIG. 4.—HOLTZER CABOT—D. C.

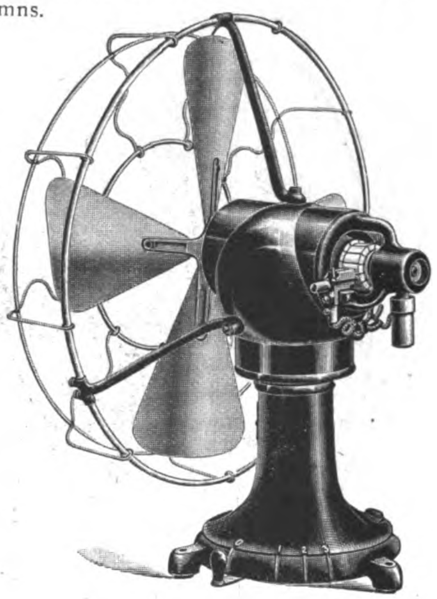

FIG. 5 —HURRICANE—D. C.

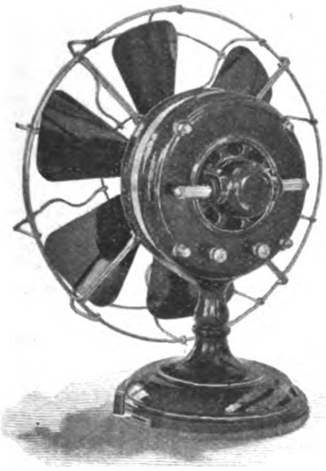

FIG. 6.—GENERAL ELECTRIC—D. C.

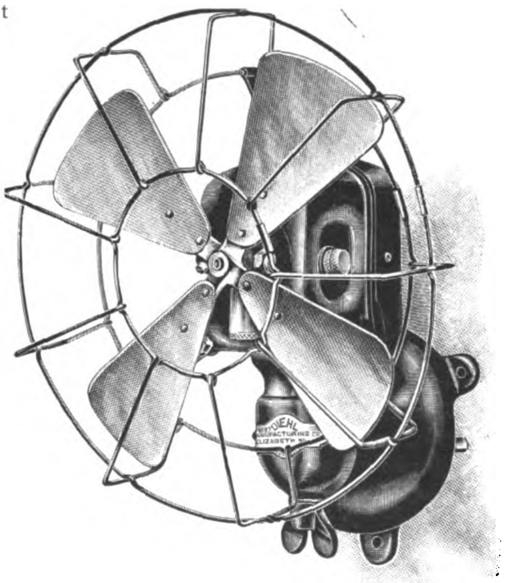

FIG. 7.—DIEHL—D. C.

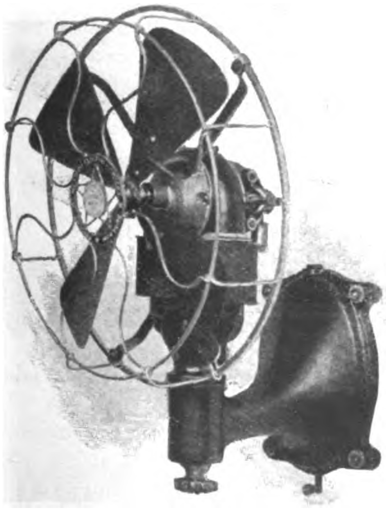

FIG. 9.—WESTERN ELECTRIC—D. C.

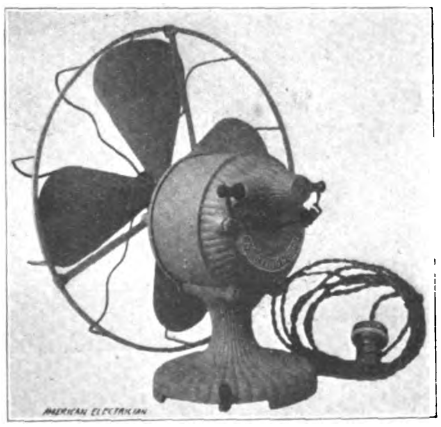

FIG. 10.—WESTINGHOUSE—D. C.

Fig. 1 shows a 9-in. battery fan running at 850 r.p.m. and taking 1.75 amps. when operated with four Edison-Lelande cells. When this type of motor was first placed on the market, some four or five years ago, the same cells ran the fan for 100 hours before needing renewal. By last year the design had been so materially improved that the

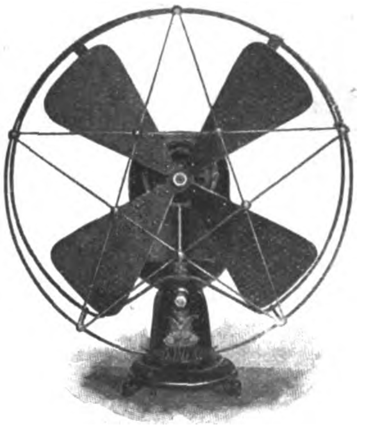

FIG. 8.—ROTH—D. C.

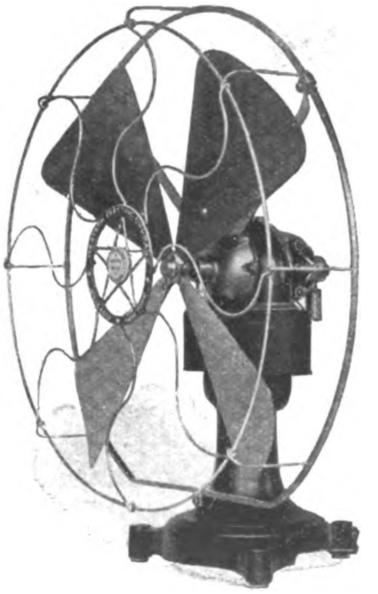

FIG. 11.—WESTERN ELECTRIC—D. C.

same battery would run the fan for 125 hours, the speed being increased to 800 r.p.m. In the 1898 model shown the economy by the use of ball bearings has been increased one-third over that of the 1897 model, and 70 per cent over that of the 1896 model, the speed of the fan being also increased to 850 r.p.m. This same motor is made for a 110-volt direct current with a 12-in. fan and guard, and furnished with a 3-speed switch, enabling speeds of 1000, 1200 and 1400 r.p.m. to be obtained.

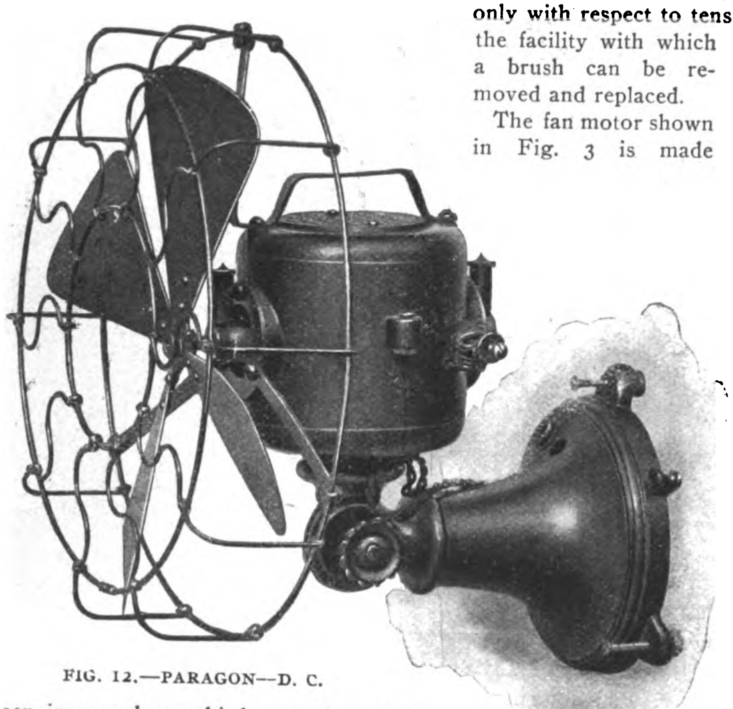

FIG. 12.—PARAGON—D. C.

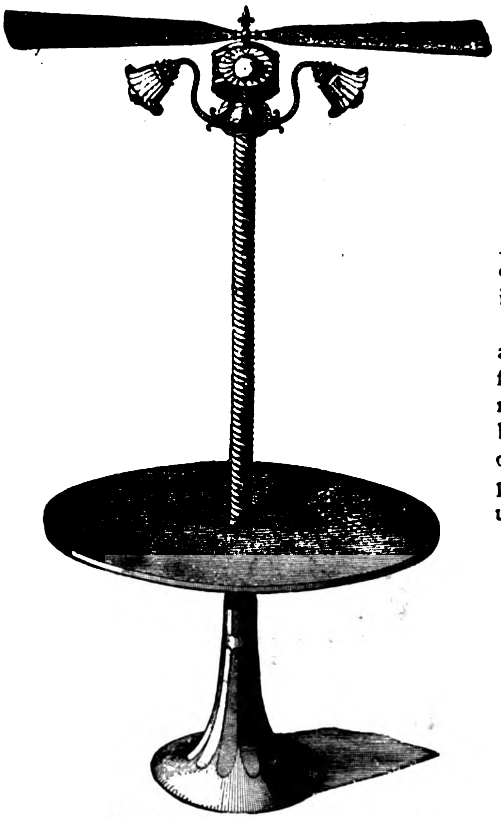

FIG. 14.—WESTERN ELECTRIC—D. C.

The motor in Fig. 2 is a 10-in. battery fan motor designed for four 2-volt cells. Simple brush adjustment is one of the claims made for this type of motor, not only with respect to tension, but also from the facility with which a brush can be removed and replaced.

The fan motor shown in Fig. 3 is made for 110 and 220-volt circuits and is also wound for 250 volts to run two in series on a 500-volt circuit. The consumption of current is .5 amp. on a 110-volt circuit for a 12-in. fan, or about equal to the current taken by a 16-c.p. lamp. There are three speeds, 1100, 1400 and 1800 per minute, except in the case of the series fans, which have but one speed. Instead of being japanned, the metal parts are given an oxidized-copper finish, and all bright work is polished and lacquered.

The fan shown in Fig. 4 has 16-in. blades and is made for 110 volts only. Both the fields and armatures are laminated, and the motor is fitted with self-feeding carbon brushes. The motor may be run at any one of four speeds, the switch being completely inclosed in the base. Oil is not used as a lubricant, the motor being provided with grease cups which require but one filling during the entire season. The shaft is made of crucible steel and the bearings of phosphor bronze, both highly polished and fitted to gage.

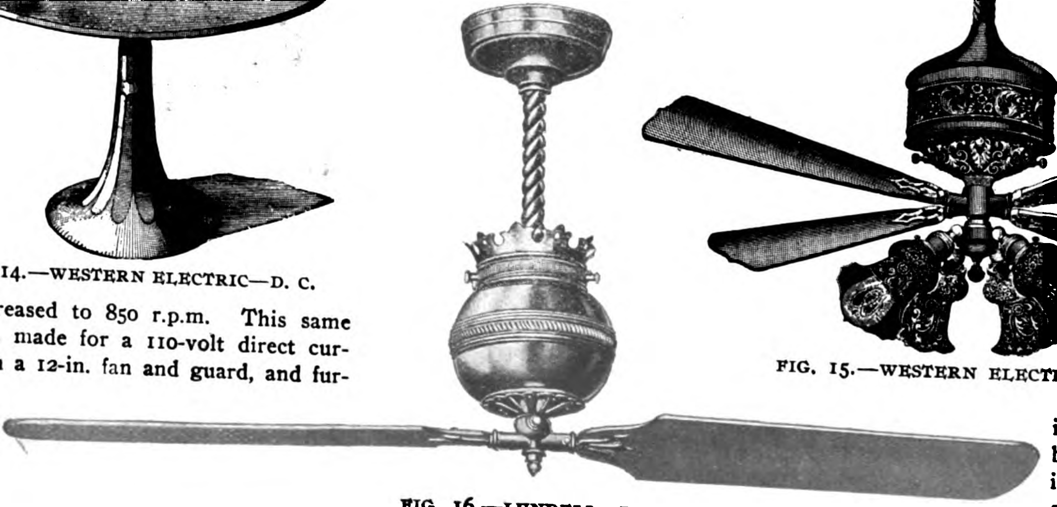

FIG. 16.—LUNDELL—D. C.

The motor shown in Fig. 5 is of the consequent pole type, and the armature is entirely inclosed except at the commutator end. By unscrewing the front bearing, the armature and commutator are easily removed. The bearings are provided with an automatic oiling arrangement which entirely prevents spraying of oil. The brushes are of flat carbon, and make end contact at a slightly obtuse angle to the commutator.

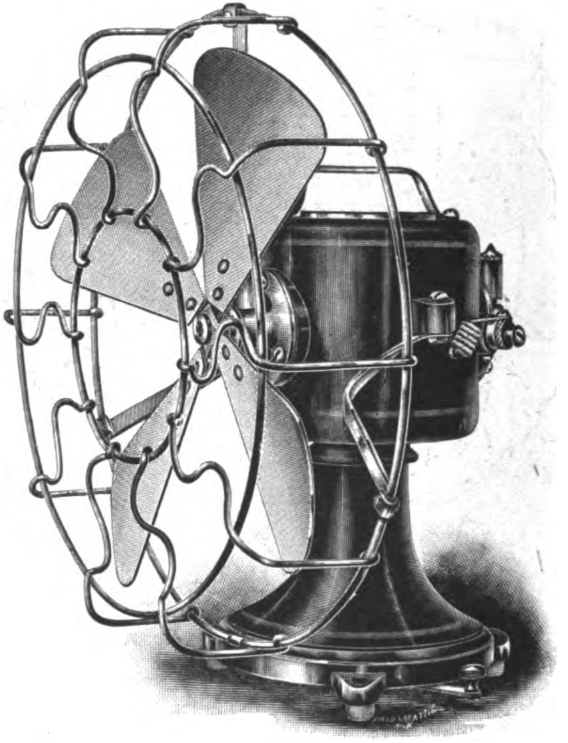

FIG. 13.—PARAGON—D. C.

The constant-current type of fan motor of Fig. 6 has but a single long bearing similar to that of the alternating current fan of the same manufacturer. The commutator is completely inclosed, and the carbon brushes are incased in small tubes which are readily unscrewed for inspection. A regulating switch provides for variations in speed. This motor is also mounted on a swivel frame which enables the

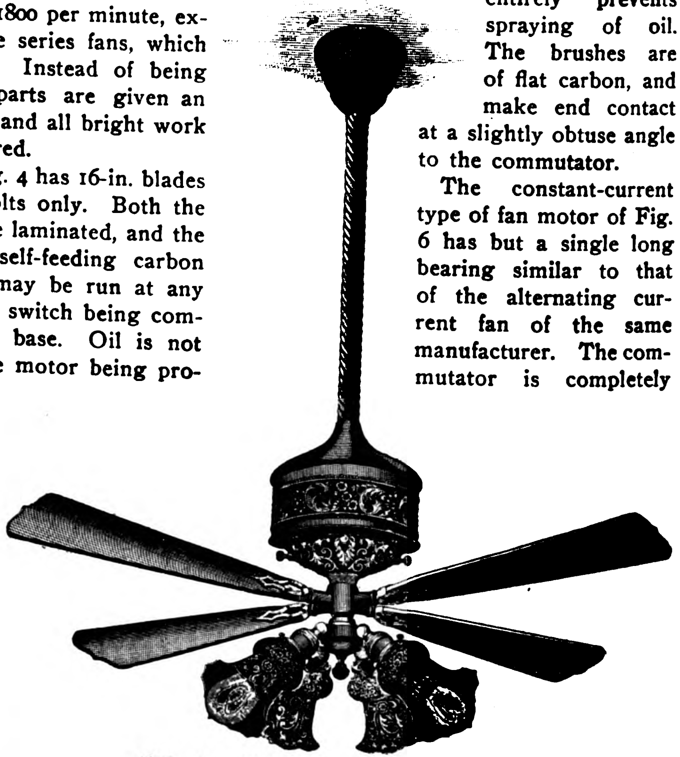

FIG. 15.—WESTERN ELECTRIC—D. C.

LIBRARY

fan to be tilted at any convenient angle.

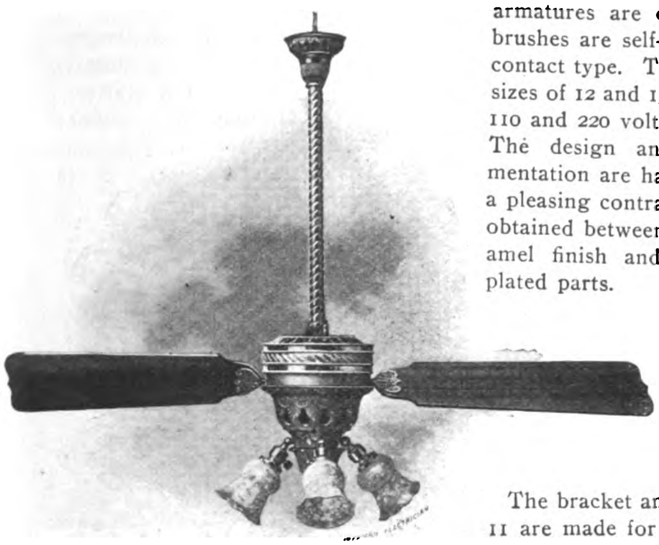

FIG. 17.—HUNTER—D. C.

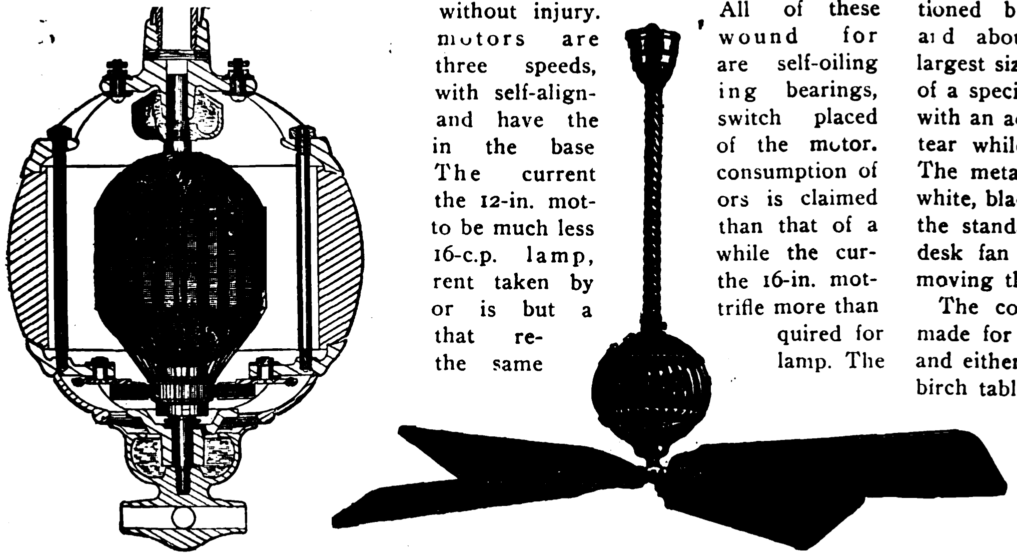

FIGS. 19 AND 20.—ROBBINS & MYERS—D. C.

The type of motor shown mounted as a bracket fan motor in Fig. 7 is made in two sizes—1-12 h.p. with 12-in. blades running normally at 1850 r.p.m.; and 1-6 h.p. with 16-in. blades running normally at 1500 r.p.m. By means of a switch two other speeds may be obtained. This bracket type of fan may be adjusted and clamped at any desired angle to the side wall, the adjustment being effected by means of the wing nut shown, at the bottom.

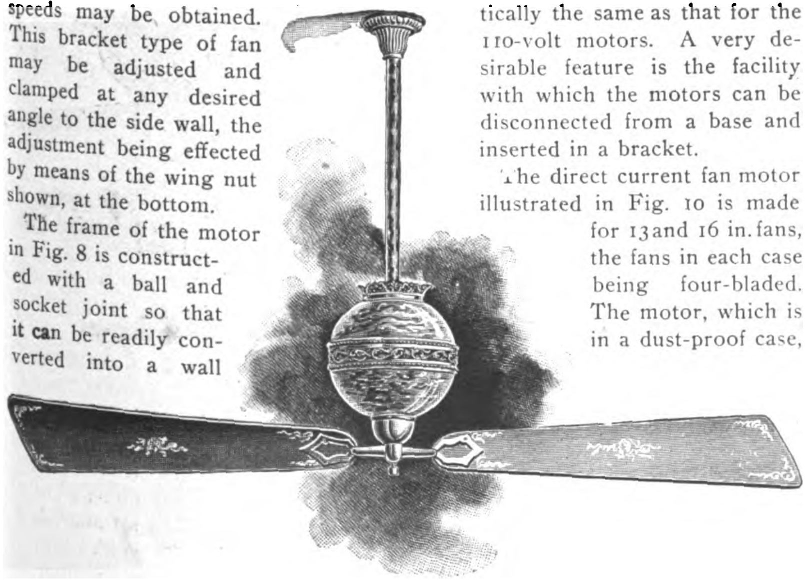

FIG. 21.—BACKUS—D. C.

The frame of the motor in Fig. 8 is constructed with a ball and socket joint so that it can be readily converted into a wall or bracket fan, as desired. Each motor is provided with a porcelain switchboard placed in the base, with a suitable regulating rheostat by means of which three different speeds can be obtained. The armatures are of the ring type, and the brushes are self-feeding and of the end-on contact type. The fans, which are made in sizes of 12 and 15 ins., are wound to run on 110 and 220 volt circuits. The design and ornamentation are handsome, a pleasing contrast being obtained between the enamel finish and nickel-plated parts.

The bracket and desk fans of Figs. 9 and 11 are made for 110, 220 and 500-volt circuits. On 500-volt circuits three 110 or two 220-volt motors may be operated in series, and the 500-volt motor can be operated on a 600-volt circuit continuously without injury. All of these motors are wound for three speeds, are self-oiling with self-aligning bearings, and have the switch placed in the base of the motor. The current consumption of the 12-in. motors is claimed to be much less than that of a 16-c.p. lamp, while the current taken by the 16-in. motor is but a trifle more than that required for the same lamp. The energy required for the 220 and 550 volt motors is practically the same as that for the 110-volt motors. A very desirable feature is the facility with which the motors can be disconnected from a base and inserted in a bracket.

The direct current fan motor illustrated in Fig. 10 is made for 13 and 16 in. fans, the fans in each case being four-bladed. The motor, which is in a dust-proof case, has laminated iron field magnets with two field coils. By throwing the fields in series, a slow speed is given; throwing them in multiple gives a high speed and cutting out one field gives an intermediate speed.

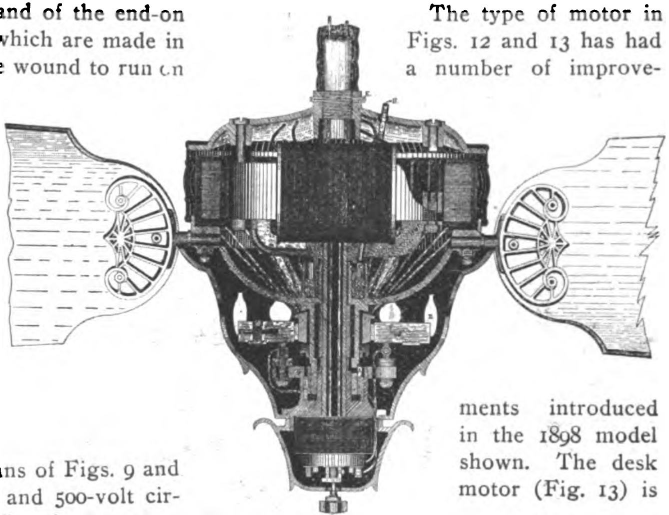

FIG. 18.—DETAILS OF HUNTER MOTOR.

The type of motor in Figs. 12 and 13 has had a number of improvements introduced in the 1898 model shown. The desk motor (Fig. 13) is made for 12, 14 and 16 in. fans, the consumption of current of the first mentioned being that of a 16-c.p. lamp, and about 50 per cent more for the largest size named. The brush holders are of a special design, using flat brushes and with an adjustment to follow the wear and tear while keeping the tension constant. The metal surfaces are finished in green, white, black, blue and maroon, green being the standard. The handle shown on the desk fan is a convenient attachment for moving the motor from place to place.

The column fan shown in Fig. 14 is made for two speeds, 150 and 175 r.p.m., and either with or without a polished, red birch table about the column. The motors are furnished with a switch, and the lights controlled by a switch placed on the under side of the table.

The ceiling fan of Fig. 15 is so made that the chandelier attachments can be readily put on as shown, every motor being wired ready for the sockets with lead wires

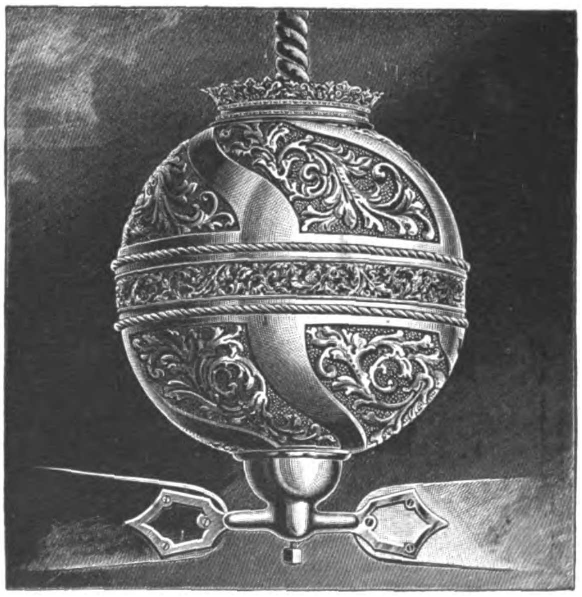

FIG. 22.—BACKUS MOTOR CASE.

coiled in the top of the switch box when not in use. With four blades 6 ins. in diameter and 8¾ ins. wide, the fan runs at 175 and 185 r.p.m. If fitted with two blades, the speed is 210 and 215 r.p.m. These fans take but a trifle more current than that required for a 16-c.p. lamp. The motors are furnished with self-oiling and self-aligning bearings and are perfectly balanced. The switch for change of speed is placed in a neat switch box on the under side of the motor case.

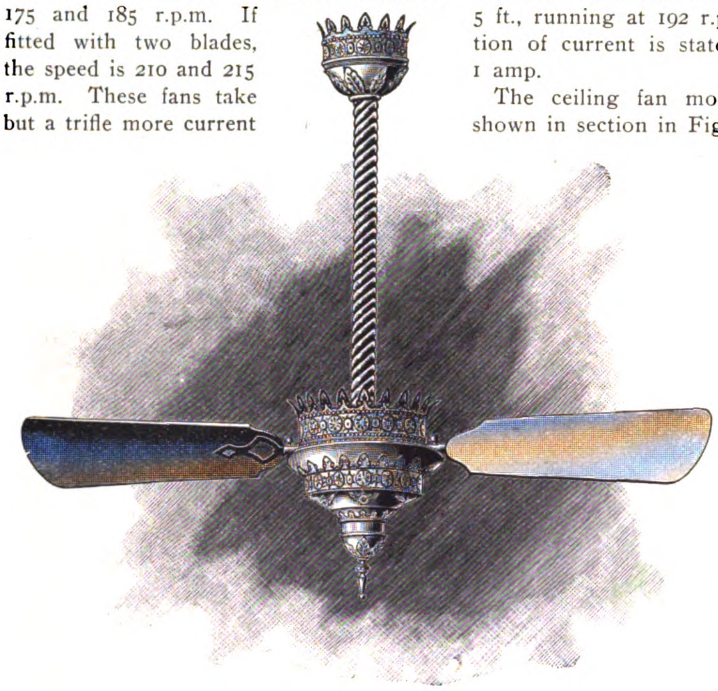

FIG. 23.—DIEHL—D. C.

The ceiling fan shown in Fig. 16 is made for circuits having voltages of 115, 165, 220, 250 and 500. The sweep of the blades is 56 ins. and their width 9 ins. The motor, which is of 1-6 h.p., is the well-known ironclad Lundell type, with cylindrical self-feeding carbon brushes and self-oiling and self-aligning bearings. On a 115-volt circuit the consumption of current is given as 1.1 amps., and ¼ amp. on 500-volt circuits.

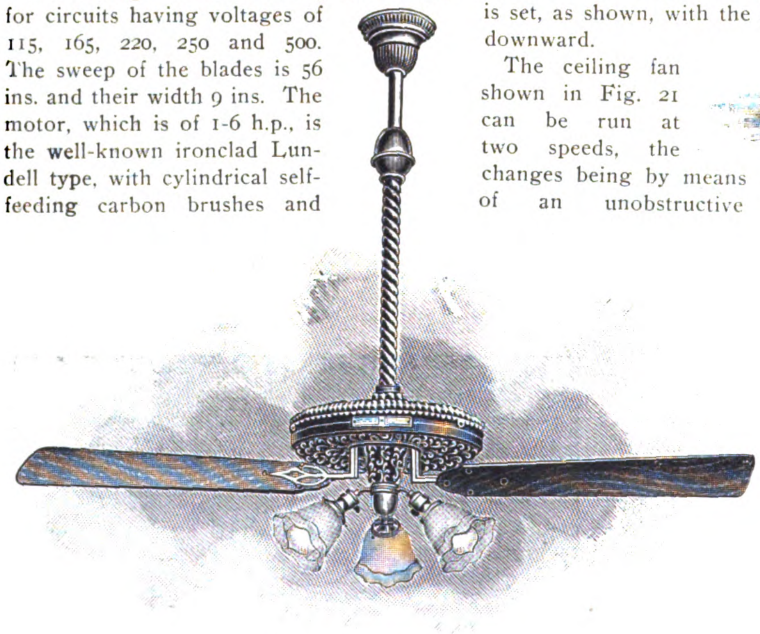

FIG. 25.—EMERSON—A. C.

The ceiling fan illustrated in Fig. 17, and shown in detail in Fig. 18, is for direct current circuits, and can be given two speeds by means of the switch shown. The armature is of the toothed type and the fields are of soft steel. The two bearings are widely separated, thus insuring smooth running, and enabling the air gap to be reduced to a minimum by obviating any chance of the armature striking the pole pieces should the bearing become worn. The bearings run in a bath of oil, which does not require renewal during a season's service. With the blades, whose sweep is 5 ft., running at 192 r.p.m., the consumption of current is stated to be less than 1 amp.

The ceiling fan motor of Fig. 20 is shown in section in Fig. 19, from which a clear idea of the construction can be obtained. The yoke of the motor consists of an iron rim to which two pole pieces are attached at diametrically opposite points. The entire weight of the armature and fan plates is borne by ball bearings which run in oil. Carbon brushes are used and the armature is set, as shown, with the commutator end downward.

The ceiling fan shown in Fig. 21 can be run at two speeds, the changes being by means of an unobstructive switch at the bottom of the fixture. The finish of the brass motor case is in mother of pearl or light onyx body, with a gilt border or crown, a nickel stem and plate holder. Fig. 22 shows another type of motor case made by the same manufacturer, which is finished in oxidized brass or silver, full nickel, or old ivory and gilt.

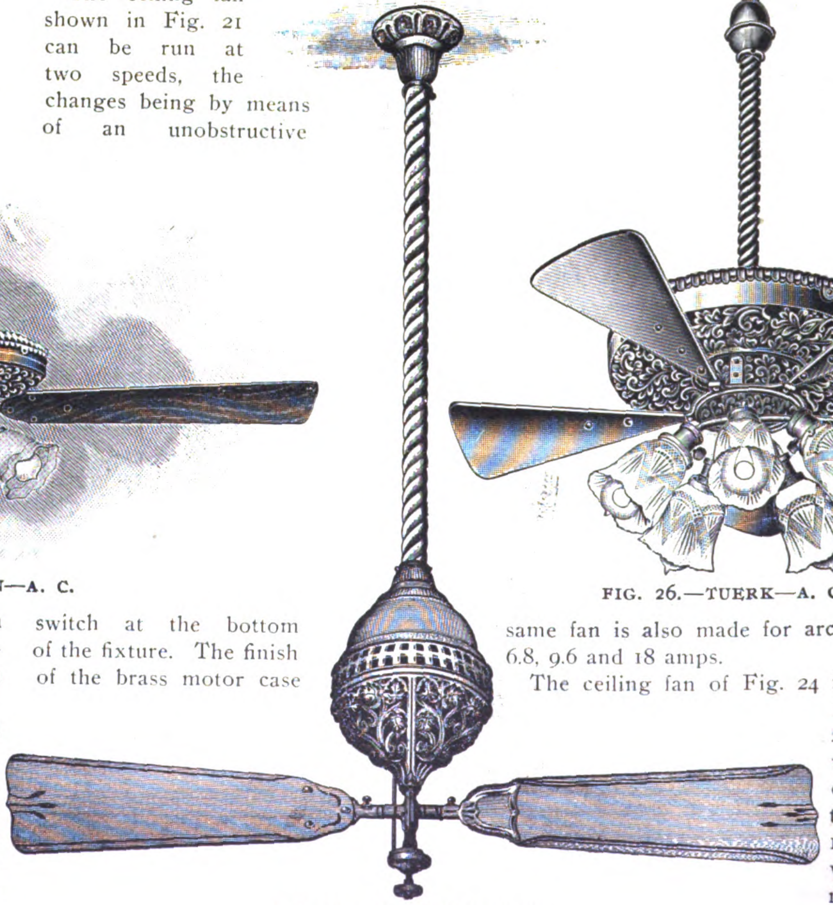

FIG. 27.—EMERSON—A. C.

The motor of the ceiling fan illustrated in Fig 23 is wound for direct-current lighting, power and street railway circuits, in the latter case being operated singly or in series of two, three or four fans. The same fan is also made for arc circuits of 6.8, 9.6 and 18 amps.

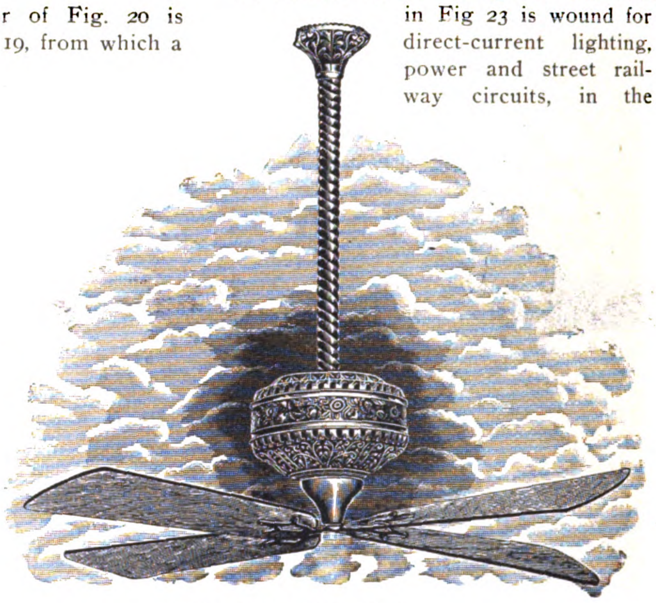

FIG. 24.—BATES—D. C.

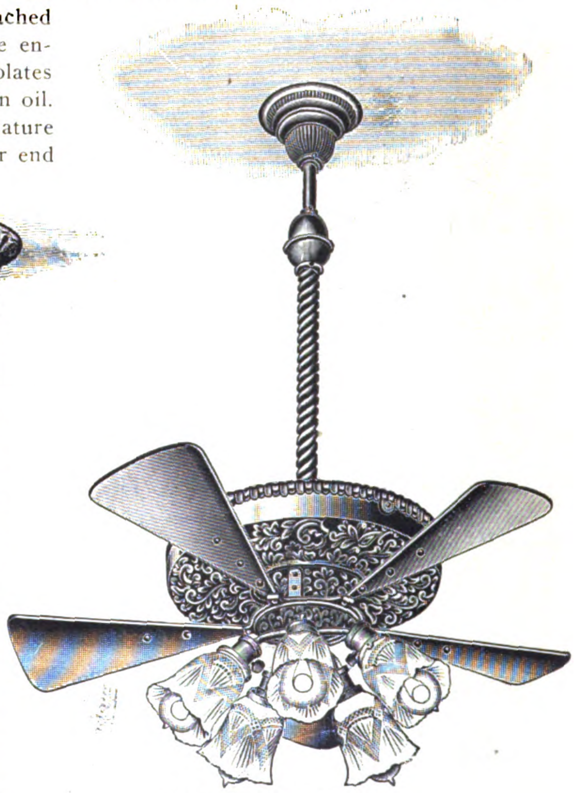

FIG. 26.—TUERK—A. C.

The ceiling fan of Fig. 24 is made for 110, 167, 220, 250 and 500 volts, direct current, those of 167 and 250 volts running three and two in series respectively on a 500-volt circuit. A similar type of fan is made by the same manufacturers for alternating current circuits.

ALTERNATING CURRENT FAN MOTORS.

The ceiling fan motor shown in Fig.25 is a slow speed induction motor for 60-cycle systems. The current consumption of this machine running at the highest speed (210 r.p.m.) is 125 watts. A second speed is also provided of 150 r.p.m., the current consumption at which is 100 watts. The same fan is also made with a current consumption of 150 watts at higher speed. The ceiling fan shown in Fig. 26 is adapted for the higher frequencies of 125 to 133 cycles per second. As an indication of the advance in fan motor design, the manufacturers state that the above fans are from 1-3 to 40 per cent more efficient with respect to the amount of air set in motion than the ones manufactured by them last year. The only wearing part in the above fans is a simple ball bearing running in oil, the fan thereby being also made noiseless.

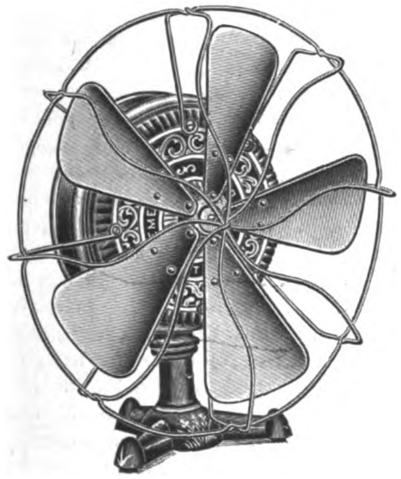

FIG. 28.—GENERAL ELECTRIC—A. C.

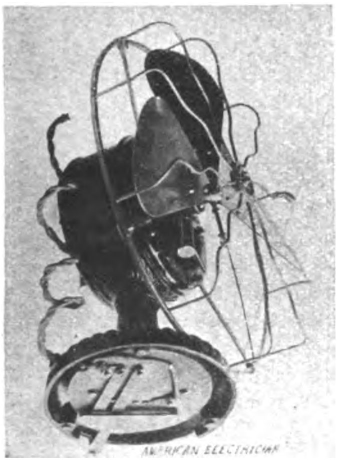

FIG. 32.—WESTINGHOUSE—A. C.

The alternating current ceiling fan motor of Fig. 27 is furnished for 60, 125 or 140 cycles, and for 52 or 104 volts. By an ingenious device the angle of the blades can be so shifted that the air may be blown downward toward the floor or upward toward the ceiling. In this type of ceiling fan reduction in speed is obtained by the introduction of leather-faced friction wheels, which enable the motors to be rotated at a slower speed than that of the armature, thus permitting the use of the highest speed and highest efficiency type of alternating current motor.

Fig. 28 shows an induction alternating current motor, the armature being illustrated in Fig. 31. The cast-iron frame supports a single long bearing, and to the frame are bolted soft iron laminations which make up the field core, being provided with inwardly projecting teeth to form the poles on which are placed the field coils. The armature is also built up of soft iron laminations assembled on a brass spider, but has no insulated wire; bare copper rods run through the core and are riveted into the discs at each side, as shown. Rotation being produced by inductive action, no commutator or brushes are required. This motor is built for 52 and 104 volts and 60 and 125 cycles, and by means of an inductive resistance can be run at any one of three speeds by operating a switch.

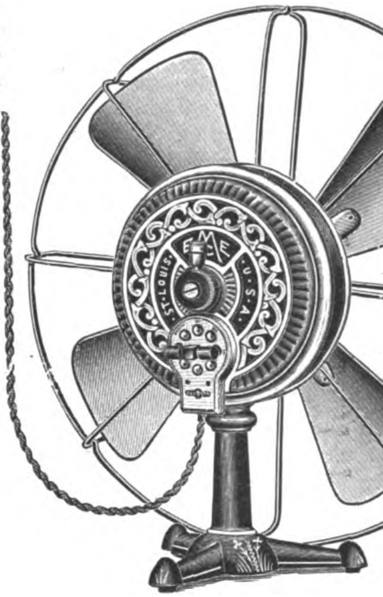

FIG. 29.—EMERSON—A. C.

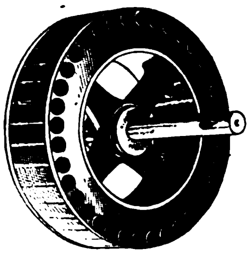

FIG. 31.—ARMATURE OF GENERAL ELECTRIC A. C. FAN MOTOR.

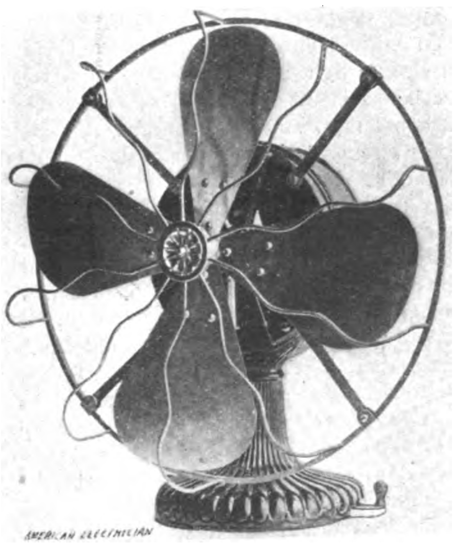

FIG. 33.—WESTINGHOUSE—A. C.

The desk fan illustrated in Figs. 29 and 30 are for alternating currents. The shaft of these fan motors is pressed firmly into the back cover, and is made of ½-in. bicycle tubing, case hardened and ground accurately to size. The armature hub is composed of a larger piece of bicycle tubing, into which is pressed at either end a bushing, reamed to accurately fit the hardened steel shaft. Another improvement is in the switch plate, which is made of porcelain, the binding posts being concealed so as to make it impossible to receive a shock in handling the motor. The 12-in. motor (Fig. 30) consumes from 65 to 70 watts in starting, running at about 1550 r.p.m.; in one position of the switch, this consumption is cut down to 50 watts, while in another it is cut down to about 35 watts, the speed being 950 revolutions in the latter case. The current consumption of the 15-in. motor (Fig 29), is 110 watts on the starting point at about 1550 r.p.m.; in the second position of the switch the consumption is reduced to 90 watts and the revolutions to 1500.

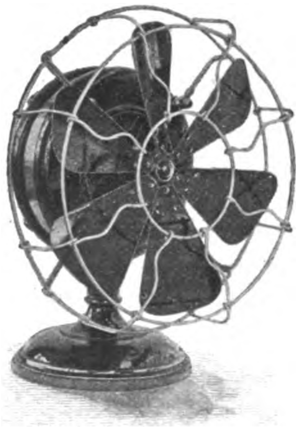

FIG. 30.—EMERSON—A. C.

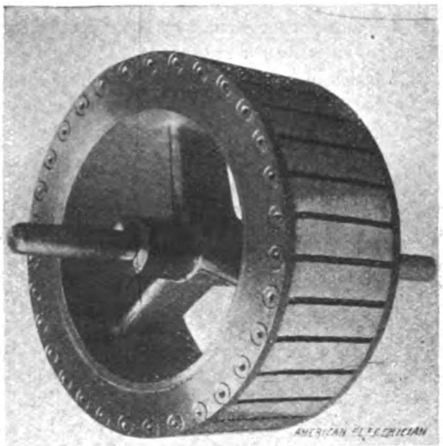

FIG. 34.—ARMATURE OF WESTINGHOUSE A. C. FAN MOTOR.

The alternating current fan motor illustrated in Figs. 32 and 33 is of the induction type, having no collector rings or brushes.

The field is built of thin, soft steel plates, with inwardly projecting teeth to which the field winding is applied. The armature is laminated, being built of steel discs slotted to receive the bar-copper conductors, as shown in Fig. 34. No insulation is used in the armature, and consequently there is nothing to burn out. By means of a three-contact switch located in the base, the motor may be run at full speed, at a moderate speed or it may be cut out of circuit. This type of fan motor is made for frequencies of 60 and 133 and for 50 and 100 volt service. The bearings are self-oiling and self-aligning, thus reducing friction to a minimum.

GETTING EXPERIENCE.

BY * * *

Before the technical schools began to turn out their annual crops of electrical engineers, and, indeed, before there were any technical schools teaching electrical engineering, I determined to learn the subject as thoroughly as I could and to devote myself to its practice. This was in those remote days when the electric railway was the subject of more or less promising experiments, when the electric light was still a sort of curiosity, and a most expensive one, and when the electric motor was regarded an experimental novelty.

How and where to be instructed in the mysteries of electricity was, in those days, a problem of no small order. There were few schools that offered even an apology for a course in electricity, and such as there were confined themselves to the purely scientific side of the subject. There was not a solitary technical course in existence, not a place where a student could learn the practical side of electrical work. The only thing to do was to supplement the lectures and physical laboratory work of the school with a term of service in a shop. In an evil moment I decided on this course.

It was after two years of instruction in the mathematical theory of electricity that I presented myself to the superintendent of one of the few factories then engaged in building dynamos and motors, and asked him to let me work in his shop without pay. He was a courageous man, and consented, but I have always thought that if he had known how amazing green I was he never would have taken the chances that he did.

At that period I knew Gauss' theorem, but I could not have soldered a joint had my life depended upon it. I could talk glibly about ether stress, but a station switchboard appeared to me as a dark and fearful mystery. In this frame of mind I reported for work Monday morning.

My first duties were to take castings off the dray that delivered them at the shop door, groom them with a chunk of emery and send the smaller ones aloft on the elevator. In a few days I was intrusted with a chipping chisel and shown how to cut off various excrescences that would not yield to the emery stone. The next job that fell to my hands was operating a punch press, cutting armature discs. I had an old 12-in. screw driver, with which I was instructed to pry recalcitrant discs out of the die, and during my first hour at the machine I managed to cut it into three neat pieces, to the everlasting ruination of the die.

By slow steps I was promoted to the winding room, where a pervasive atmosphere of shellac and rosin enwrapped everything, until a new insulating material was brought in that smelled worse than all the other scents of the shop combined. Here I learned the technic of the soldering iron, complex methods for clothing an armature core in its winding and many other useful and interesting things. The fine art of armature winding is disappearing in these days of slotted cores and machine-made coils. Then we had smooth cores and all the winding was hand work. To make a neat end on a surface-wound Siemens armature is a really difficult piece of work, and one calling for no little skill and experience. To balance such an armature calls for heaven-sent genius.

When I had worked my way through the various departments of this shop, I concluded to try to learn, in the same way, something about electric lighting. I commenced my labors in a station in a Western city by shoveling coal from the railway cars into a chute. This is excellent exercise, and as it affords an unlimited opportunity for meditation and reflection, very beneficial experience. There were times before I finished with that station when I would have given a good deal to get back my old job of coal shoveling. As stoker, oiler, dynamo attendant, switchboard man and, in the absence of the superintendent, general *charge d'affaires* about the station I absorbed very much that I could have learned in no other way; but I think my most illuminating experience was gained in a brief season of work outside, as lineman, trimmer and wireman. During this time I contracted the pliers habit, a vice to which young electricians are prone. At first, proud of the pair of pliers, which is the outward and visible sign of their calling, they soon find themselves so dependent upon this instrument, and so apt to put it to all sorts of uses, that they can hardly dress in the morning without it.

Of all the laborious work connected with an electric light station I believe trimming arc lamps is the hardest. We had single carbon lamps, and those on the all-night street circuits had to be re-trimmed about midnight. It is not only hard labor but very dangerous labor to go up on an icy pole on a stormy night, and blinded by the blazing arc, turn the switch, throw out the hot points, reach around behind for a new pair, put them in and straighten them in the dark, and then throw the switch and climb down again. It doesn't sound hard, but the total height to which a trimmer climbs in a day's (or night's) work is generally over 1000 feet, and this is vertically upward, with a heavy bag of carbons and tools as impediments. Add to this the dangers of shocks and falls, and it will be seen that the trimmer earns his pay.

We had a few motors, all of them series machines, working on the daylight arc circuit. This was a fairly heavy circuit, the voltage running up to over 4000. To treat an ailing motor with this voltage "lying 'round loose," and a probable ground somewhere, required nerve, if the man who did the job understood the conditions. Generally he did not, and was none the worse for his ignorance, though I remember some narrow escapes. We had a motor in a second story printing office, back of which was a tin-roofed shed. The wires to the motor were about eight feet above this shed. One day when the motor was in trouble, Lanigan, the head wireman, was sent to its rescue. His first move was to put a "jumper" across the two wires outside the building, and to do this he mounted on the roof of the shed. Happily the roof was dry, but the usual ground was on the circuit, and when Lanigan undertook to "skin" the wire for attaching the jumper the yell he let off was heard three blocks. I have never understood how he escaped death, anyhow. His invariable custom was to attach the house leads, in an incandescent wiring job, to the leads on the pole outside, and to work his way into the building with everything "alive." One day he got a shock from an arrangement of this kind that knocked him off the top of a high step-ladder into a bin of oysters that were awaiting canning. It was the custom to send oysters (opened) in bulk from the coast and can them in our town, after proper disinfection. The accident I mention damaged Lanigan somewhat, but didn't hurt the oysters.

There was one night, a windy night, with a wet snow, when somebody started up an arc circuit "upside down"—that is, with the current going through the lamps so that the short carbons were positive. In an hour or two the lower carbon holders were blazing up in a magnificent pyrotechnical display of green fire. That was the night that I resigned my position as trimmer.

The real excitement in those times, however, was a fire. This was long before the days of conduits, and pole lines carrying twenty or thirty circuits of arc wires and a few heavy incandescent feeders were quite common. The firemen were desperately afraid of these wires, and men that would face any kind of danger from fire or falling walls, balked at orders to go among them or throw streams of water near them. On occasions of this sort some of us had to go up the poles and cut the wires, and it took a steady hand and considerable trust in Providence to do it. There was not much monotony about central station work in those days.

The experience gained in this way is of a sort that is always useful to the engineer. It is rather a hard school, but there is no better. Given a foundation of instruction in scientific electricity, so that he may understand what he sees, the student who is willing to soil his hands with hard work will learn practice very rapidly. There are many young men who could have entered our station and calculated efficiencies, drops, capacities, everything—who would have been utterly helpless in the presence of a heavy short circuit and a blazing switchboard. I am convinced that I learned more in the year I served without pay, more that has been valuable and useful to me since, than in any other year of my life.

ELECTRICAL DECORATIONS.

How to Produce the Effect of a Waving Flag.

BY C. R. PERSONS.

The switch here described is one that was used during the National holidays last July in the main court of the Palace Hotel of San Francisco. It operated a very handsome American flag, which was composed of over 320 miniature lamps. The flag in question was placed on the face of the third-floor balcony, and was admired by hundreds while it was in operation. The entire arrangement was the work of Mr. Edgar Gribble, chief electrician of the hotel, who very kindly furnished the writer with the data, etc., the accompanying sketches.

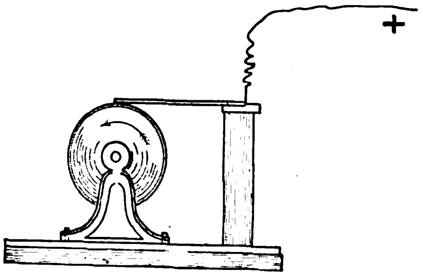

FIG. 1.—SIDE VIEW OF SWITCH.

Before describing the switch and flag, I will state that the Palace is illuminated by over 6000 16- and 32-CP lamps, in addition to which standard lamps, many hundreds of small 3- and 4-CP lamps are used in decorative candelabra in the grill rooms, parlors, etc., the latter are connected five in series.

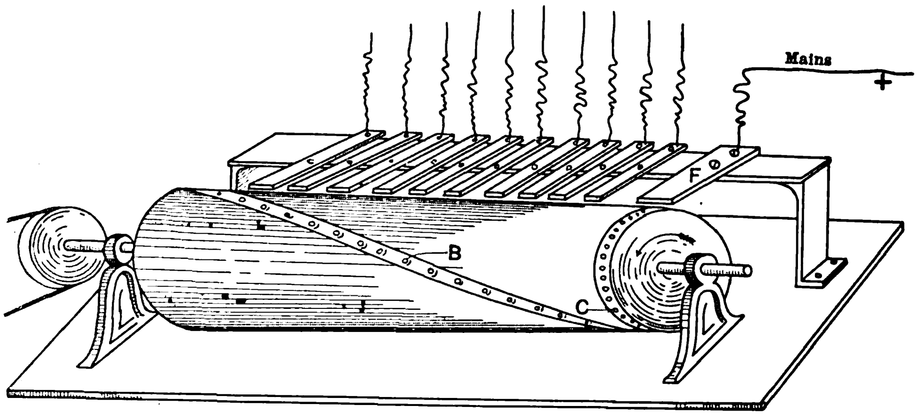
The hotel formerly had its own electric plant, but at present current at a voltage of 120 is supplied by the underground mains of the San Francisco Gas & Electric Company. The hotel management has placed a large and well equipped laboratory at the disposal of its electrical staff, and here during spare moments Mr. Gribble and his assistant arrange many of the novel effects for the benefit of the hotel patrons. During the late International Christian Endeavor Convention in July, the house was the headquarters of the United Society of C. E., and as a compliment to them, Mr. Gribble arranged a large electric monogram of the C. E. emblem. Over 600 miniature lamps were used, the C. E. being formed of yellow and the background of purple lamps. Purple and gold were the Convention colors, and the effect was extremely brilliant.

Returning to the subject of this article, the list of materials to be used in the construction of a flag-switch is as follows:

One sheet 1/16-in. copper, 20 ins. X 6 ins.; 1 strip 1/16-in. spring brass, 138 ins. X 1/4 in.; 2 bearings; 1 piece of hardwood, 14 ins. X 24 ins. (1/2-in. stock); 1 cylindrical piece of wood, 20 ins. X 6 ins.; 2 pieces of 3/4-in. steel (or iron) shafting, 6 1/2 ins. long; 2 or 3 dozen copper washers; 2 or 3 dozen brass screws, and an assortment of iron screws; 1 piece of tough asbestos cloth large enough to cover the cylinder mentioned below.

The above list will probably cost $2 or $3, and most all of the material can be usually found in the scrap heap of any electric-light or power station.

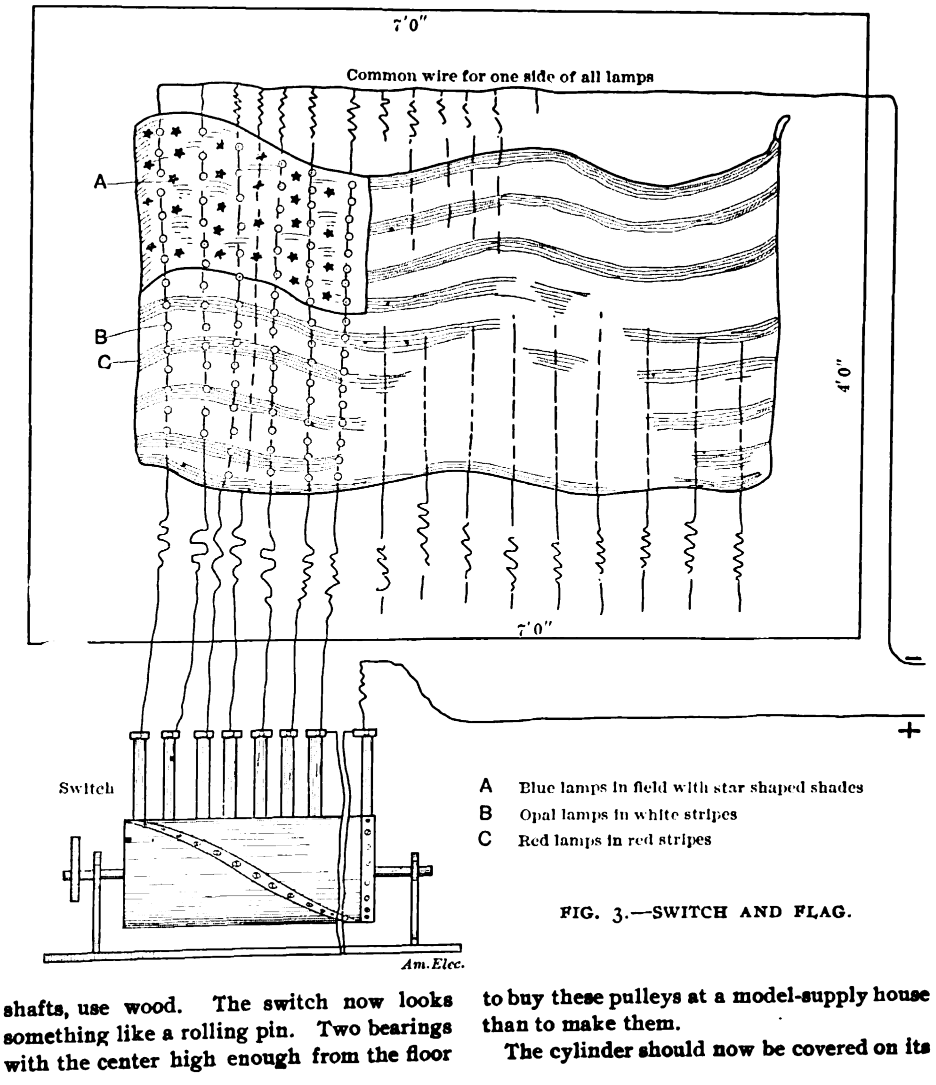
The cylinder of wood will first receive attention. It will be best to have it trued up on the lathe in the planing mill, and also have each end bored to the depth of 4 or 5 ins. so that the pieces of shafting may be driven in tight, one in each end. The writer would suggest that unless the person making the switch has had experience in wood-work, it would be better to have the turning and boring done at the mill, and this is all the machine work to be done.



B One of the 1/16 copper contact strips
C Brass or copper collar around end of cylinder
F Main copper contact brush

FIG. 2.—COMMUTATING SWITCH.

If it is not convenient to use steel for the shafts, use wood. The switch now looks something like a rolling pin. Two bearings with the center high enough from the floor to allow the cylinder to revolve freely, are mounted on the hardwood base-board. These bearings may be purchased at any model-supply house, or can be very easily made by using two pieces of hardwood and boring the upper end of each with a hole large enough to take the 3/4-in. shaft. A piece of brass tubing should be driven into each hole for the shaft to revolve in.



A Blue lamps in field with star shaped shades
B Opal lamps in white stripes
C Red lamps in red stripes

FIG. 3.—SWITCH AND FLAG.

At one end of the cylinder the shaft is allowed to protrude about 3 ins., and about 1 1/2 ins. at the other, and a pulley, either grooved or flat-face, is tightly keyed on to the 3 in.-end of the shaft. The pulley can, of course, be made of wood, but a brass or iron pulley would look neater. It will be much cheaper to buy these pulleys at a model-supply house than to make them.

The cylinder should now be covered on its face with either asbestos, or any good fireproof insulating paint. A ⅜ in. × 18 in. copper strip should be cut from the sheet of copper and be fastened spirally around one side of the cylinder (see Fig. 2). On the other side of the cylinder another copper strip should be placed, both of these strips being securely fastened by screws countersunk so that a smooth sliding contact can be easily made with the spring contacts, also shown in Fig 2.

To get the correct shape of the two contact strips, it would simplify matters to cut them out of pasteboard and when the shape has been made exactly right, to cut the copper strips from the pasteboard patterns. A frame of hardwood is also made, which should be long enough to carry all the brass spring circuit contacts, and high enough so that when the contacts are screwed on they will press firmly and evenly on the copper strips on the cylinder.

One end of the cylinder is covered with a brass or copper collecting ring with a face of 1 in., and both of the copper contacts connected electrically with this ring. A stout 1/16-in. spring copper brush with a 1-in. face is fastened to the frame, and must be arranged to press firmly on the brass ring, in the same manner that brushes press on the commutator of a dynamo.

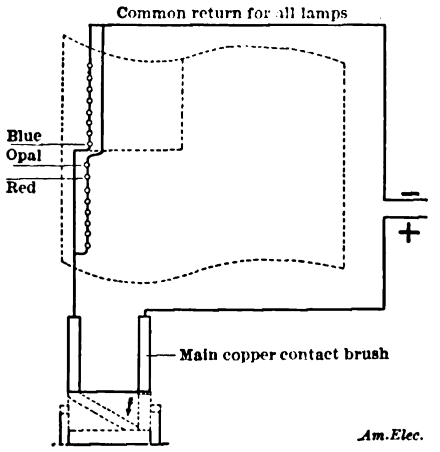


FIG. 4 —DIAGRAM OF CONNECTIONS.

The sketch, Fig. 2 shows, without further explanation, the general appearance of the switch and the arrangement of the parts. The brass contacts are made from the long strip of spring brass, and two holes for screws are drilled in one end of each, the other end being bent slightly so as to make a more binding contact on the copper. One of the screws on each strip is used with a washer to fasten the circuit wires to. The strips are each about 9 ins. long by ¼ in. broad and 1/16 in. in thickness, and are placed so that they will all strike the center of the cylinder, as shown in Fig. 1.

To prevent sparking, on the side of each of the copper contact strips nearest the rear frame, a small groove must be cut in the face of the cylinder, which groove need only be ⅛ in. deep and ½ in. wide; it should be slightly curved and must follow the strips from one end of the cylinder to the other. The grooves will cause the brass contacts, when they break the circuit, to spring in to them so suddenly that only a slight spark will follow. The cylinder must have no end play and should move easily. Oil cups may be screwed into bearings, or oil holes may be left for lubrication. The American flag is made as follows:

Procure several ½-in. white or sugar-pine planks, 12 or 14 ins. in width, and fasten them together by battens on the rear side, thus forming a surface 9 ft. × 5 ft. Of course, this depends on the size of flag desired, as the larger the surface, the more lamps will be required and the more current will be consumed. The flag in the Palace courtyard was 6 ft. long and 4 ft. broad, and 320 lamps were needed to give a proper effect.

An American flag having the appearance of waving is painted on this surface, using paint without gloss. The rest of the surface not covered by the flag is stained a dull black.

Small lamp receptacles can be very easily made, or may be purchased to fit the small lamps to be used on the flag. Connect these in series as indicated by the maker (eight is the usual number so connected). Use red lamps on the red strips, opal (not clear) for the white, and for the blue field, use blue lamps with a star-shaped white shade. Be careful to make the flag according to the latest type of "Old Glory," or every schoolboy in town will be laughing at you.

The method of connecting the flag and switch is shown in Fig. 3. All the wiring should be done on the rear of flag. Make the common return for all lamps of No. 10 B. & S. gage and of No. 14 for the circuit wires.

The operation of the switch is very pretty, and is as follows: As the spiral-shaped copper strip comes around, it makes connection in regular order with the first brass contact piece; the lamps then light up, and as the revolution continues the second circuit is lit up, each section going out as the other one lights up, and so on. Finally, the sign is rapidly illuminated until the whole flag is lit up, the large contact piece touching nearly all the circuits at once. One end of the strip shown in Fig. 2 should be broader at one end than at the other; the broad end allows the lamps last lit to stay illuminated the longest.

The shape of the copper contacts causes the flag to light up each section from the pole end, and the lights chase across the flag rapidly from left to right, producing the exact effect of a flag waving in the wind.

The writer, of course, has left many little ideas to the reader's good judgment, and very likely many other ways may be suggested in which this switch can be used. The motive power is a small electric or water motor belted to the pulley. If the motor runs too fast or slow, gear wheels of the proper pitch will give any desired speed.

In the sketches shown I have only drawn a few circuits, the total number depending on what use the switch is to be put to. The cylinder at the Palace Hotel was arranged for twenty-three circuits, and there was space left for ten extra circuits. If the reader objects to painting his flag on the board surface, there is no objection to making it of silk or satin. Whatever it is constructed of, *it must be arranged in wavy lines.*

It is not necessary to use costly rubber-insulated wire to carry current to the flag; as the circuit wires running to each section of flag are of the same polarity, any annunciator wire may be used. Bunch the wires in a neat cable, wrap the cable with tissue paper and then carefully tape it. The paper gives additional insulation, and if it is desired to use the wires again for bell work, they are not soiled.

In the Palace design each section was composed of sixteen lamps arranged eight in series across the mains, the method of connecting being shown in Fig. 4. But one of the brass spring contacts is shown, as all the other sections are similarly arranged.

◆

ELECTRICAL SIGN SWITCHING.

BY GEORGE T. HANCHETT.

Electric signs have now come to be a popular method of advertising, and in order to utilize them to their fullest extent it is often desirable to be able to switch them in and out in various ways. Nothing is more likely to attract the attention of the passerby to the advertising sentiment than suddenly flashing it before him in brilliant lights, and this effect can be varied in scores of ways. Such sign manipulation requires an intermittent switch system, and many such have been devised, most of them requiring a motor to drive a rotating cylinder or similar device.

A few expedients are herewith shown which, though they may be readily criticised with regard to durability and convenience, have the merit of great cheapness and adaptability. The first of these methods is a very simple one, and can be arranged to give any combination of progressive switching that can be conceived.

A rectangular pan is provided—one of agateware will answer, or one may be made of wood, and is fitted with an iron tube at its base, as shown in Fig. 1. To this tube is connected a piece of rubber tubing, two or more yards in length, the other end of which is connected to a glass reservoir, which can be conveniently made with a bottle, the bottom of which is perforated with a single hole. This hole may be conveniently drilled with a hard steel drill moistened with a solution of camphor in turpentine. Instead of using the drill, a hole may be bored with a rattail file, the end of which has been snapped off. The file is used after the manner of an awl, and is moistened with the solution before mentioned. It is hardly necessary to say that care and patience are essential.

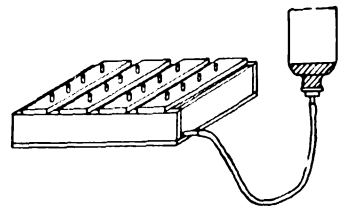

FIG. 1.—MERCURY SWITCH.

The bottle carrying its rubber tubing is connected to a frame, whereby it can be readily raised or lowered. If the machine is to be continuously driven by power, a crank and connecting rod will give the necessary reciprocating motion, and if manipulated by hand, a simple windlass will suffice.

The apparatus is filled with enough mercury to raise or lower the level of that liquid in the pan ¼ or ½ of an inch, and consequently the pan, the tubing and the reservoir should be selected of the smallest possible sizes that will give the necessary results, for the mercury is expensive.

Across the pan are secured hard rubber or fibre strips, which may be fastened with small screws at the edges, and in these strips are bored holes, 1-16 of an inch in diameter, so that they will fit a short piece of iron rod with a pointed extremity, as shown in Fig. 2. Each rod is fitted with a binding screw, such as is shown in the figure. This screw serves to secure the connecting wire. If desired, a second screw may be provided to secure the iron rod and allow its length to be varied, but it is more convenient to use non-adjustable binding posts, as described below. The sign lamps are all connected with one terminal to one of the mains, the other terminals being connected each to one of these binding posts over the mercury bath.

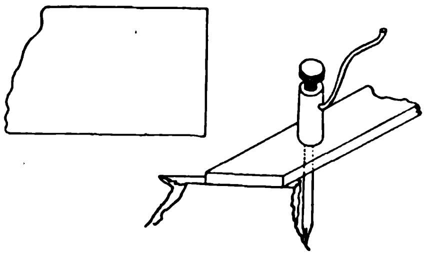

FIG. 2.—DETAILS OF MERCURY SWITCH.

It will be found convenient, though a little more work at first, to provide standard non-adjustable binding posts of different lengths, and mark them 1, 2, 3, etc., in the order in which they will meet the surface of the mercury as the latter rises. Let us suppose that we have a sign in which we wish to switch in each lamp successively, thus giving the apppearance of tracing the letters in fire. We simply connect the lamps in the order in which they are to be switched in respectively to binding posts 1, 2, 3, 4, etc., which binding posts, if the apparatus is well made, can be placed in any of the prepared holes. Raising the tank *A* will raise the surface of the mercury and make the contacts in the required order. The main terminal which feeds the mercury bath may be the pan itself, if the latter is of sheet iron, or it may be a loop of iron wire lying in the bottom of the pan. Iron should be used for all the metal contact with mercury, for the reason that it does not amalgamate with the latter.

It seems at first an expensive method to use a mercury tank and raise the level of the mercury rather than to lower the contacts into it, but it will be found that a mechanical device which could squarely and accurately lower a frame of contacts into a pool of mercury, would cost more and be more liable to be unsatisfactory. Each of these contacts should not carry more than ½ ampere.

It can be easily seen that with a suitable assortment of binding posts, any combination can be obtained. In spite of the possibilities in electric sign switching, many advertisers seem to prefer the simple expedient of alternately switching the sign off and on, and motor driven switches of various kinds are employed. A small motor, which must inevitably run at a high speed, is usually utilized, and invariably necessitates a complicated reduction in gearing, by a train of pulleys or gears.

A simple expedient which will work for 10 amps. or less is shown in Fig. 3. It consists of a supply reservoir, a tantulas cup, and a suitable receptacle for catching the intermittent overflow. The liquid is highly acidulated water, and in the tantalus cup are placed two terminals, consisting of broad lead plates, not more than ⅛ of an inch apart, and as large as possible. These two terminals are interposed in the lamp circuit. When the cup is empty the circuit is open, and while it is filling the circuit is closed, provided that the terminals are in the bottom of the cup.

If the terminals are raised to ½ the maximum depth of liquid, the period of illumination will be proportionately diminished, and thus any period can be obtained. The frequency of the cycle of events can be regulated by regulating the flow of the stopcock.

The only care that the apparatus will require is occasionally refilling the upper reservoir from the lower one. If the tanks are of suitable capacity, the apparatus will run for a given period and then stop altogether. Thus 120 cupfuls of acidulated water may be placed in the upper reservoir, and the stopcock set to flow at the rate of one cupful in two minutes. On closing his store at at 6 P. M. the proprietor may thus arrange his sign, which will operate for four hours, and when the streets begin to be deserted, at about 10 P. M., it will automatically shut itself off; and, obviously, by suitably arranging matters, the sign can be set to shut itself off at any hour desired.

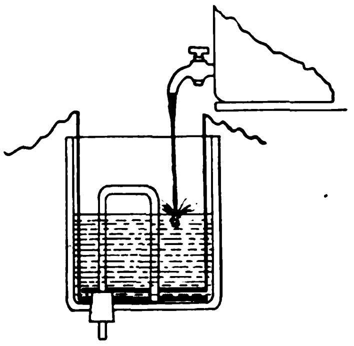

FIG. 3.—TANTALUS CUP SWITCH.

This arrangement as described would have the disadvantage that there would be a chance that the last cup of liquid would not reach the crest of the siphon, and would therefore remain in the cup, leaving the sign permanently in circuit. This may be obviated by placing a second set of contacts in the supply tank in series with the first. When the level of the supply tank had sunk below the contacts, the circuit would be broken and the hour at which this would occur could be regulated by raising or lowering the contacts in the tank.

A third set of contacts in the lower tank would make the device still more automatic. These contacts being in series with the sign circuit, it is plain that the latter could not operate till the level in the lower tank had reached a certain height, and that this time would be determined by the height of the contacts. This would enable the operator to start the flow and leave the sign, say, at 6 o'clock, and at 7 it would begin to run intermittently, according to the rate of flow and the height of the contacts in the tantalus cup. At 10 the sign would automatically shut itself off. This arrangement would be much appreciated by advertisers.

If these contact plates are properly made and the acid is proportioned for maximum conductivity, the drop will be found to be 2½ volts per set of contacts with 10 amperes flowing; therefore, the sign will have to be composed of lamps which are designed for a pressure of 7½ volts less than the voltage of the supply mains. The only objection is that this arrangement is the same as Edison's objection to a battery—it is wet. For this reason, and also for the reason that it generates to a certain extent corrosive gases, it should be placed in a cellar or in some similar locality where its presence will not be obnoxious or its manipulation troublesome.

ARMATURE WINDINGS AND CONNECTIONS.

BY PROF. ARTHUR L. RICE.

MULTIPOLAR WINDINGS AND TWO CIRCUIT CONNECTION.

NOTE.—In the March issue, the upper figure on p. 102 is Fig. 6—Four pole wave winding—the lower is Fig. 5—Four pole lap winding.

On multipolar armatures, as on bipolar, there are generally two or more layers of conductors. The majority of multipolar machines are at present built with formed coils, Fig. 1, and these coils are laid on one after another, one side of a coil—that is, one conductor on the connection diagram—being in the bottom of a slot under one pole, and the other side in the top of another slot in the corresponding position under an adjacent pole. Care must be taken, therefore, that a conductor in the bottom layer always joins to a conductor in the top layer, so that the coils may lay into place properly. For a 4-pole machine, with 48 conductors in two layers, and 24 commutator bars, the pitch for a lap winding may be taken as 11 back and 13 front, Fig. 2. The connection will then be as given in Table I.

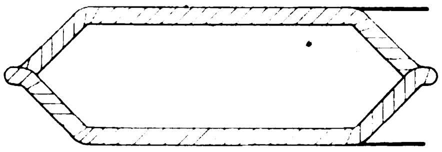

FIG. 1.—DRUM-FORMED COIL.

TABLE I.—MULTIPOLAR LAP-WINDING CONNECTIONS.

Bar	1	to	conduct'r	1,	back	to	conduct'r	12,	front
"	24	"	"	47	"	"	"	10	"
"	23	"	"	45	"	"	"	8	"
"	22	"	"	43 etc.					

As the even number conductors are all in the botttom layer, and the odd number in the top, the condition for proper laying of coils will be fulfilled. By tracing out the direction of the E. M. Fs., they are found to be in series, and it is also found that the brushes will go on at bars 1, 7, 13 and 19. In laying on the coils, conductors 2, 4, 6, 8, 10 and 12 must be put in place in the bottom of the slots before 1 can be placed; then coil 14-3 would be put in place, and so on in order around the armature. If the winding be examined it will be seen that the connection drops back one bar and one slot at each connection, instead of advancing as in other cases considered; this is because the front pitch is larger than the back, and the winding is called "retrograde" winding; the previous ones were "progressive" windings. There is no particular advantage in either type over the other.

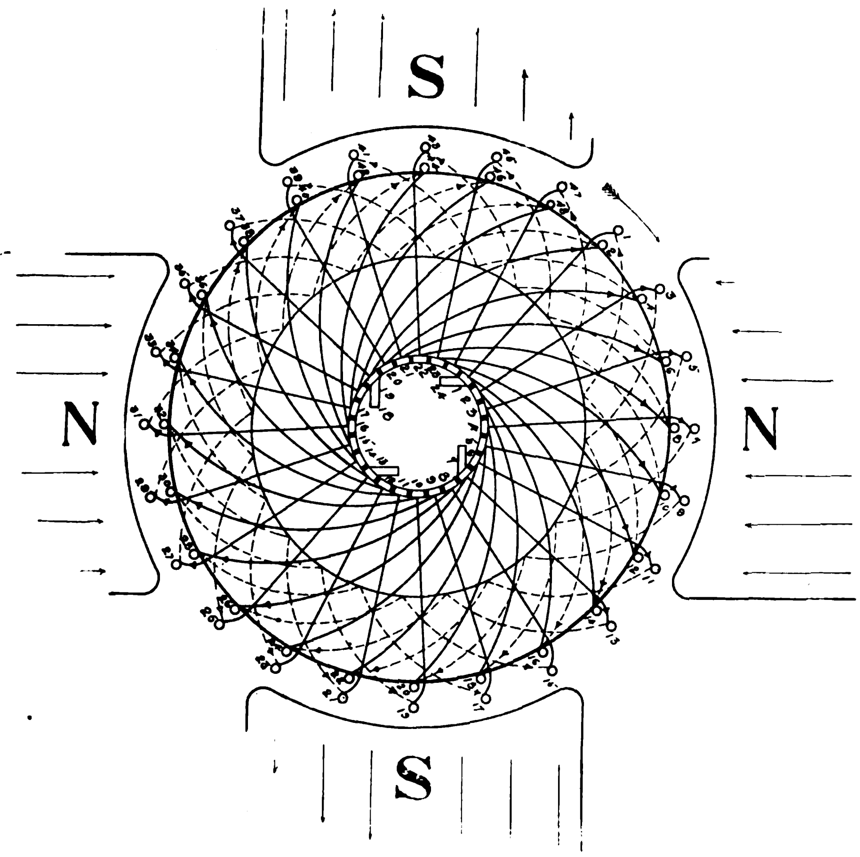

FIG. 2.—TWO-LAYER, FOUR-POLE LAP WINDING.

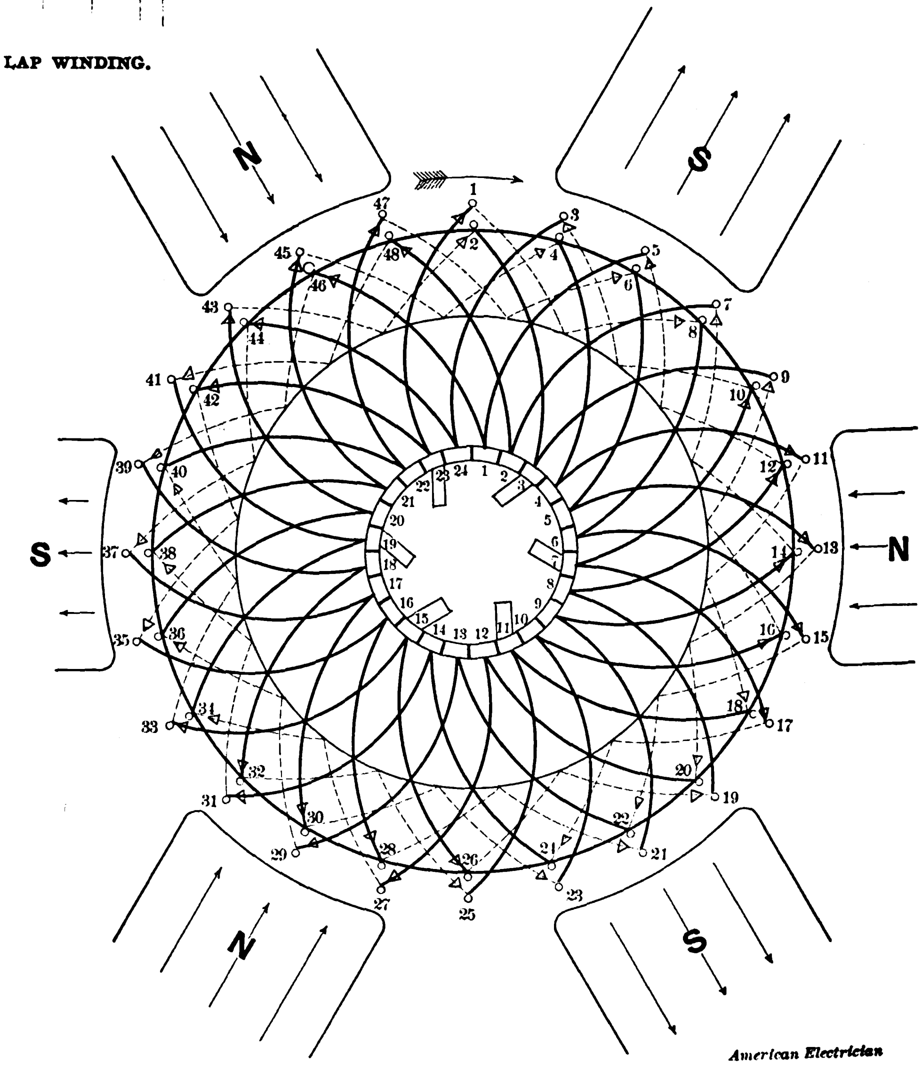
The winding for a machine having six, eight or more poles is the same in principle as for four poles. If it is to be a lap winding with as many circuits in parallel as there are poles, the number of coils must be divisible by the number of poles, that is, the conductors divisible by twice the number of poles, and the average pitch is best taken as the quotient of the conductors divided by the poles, though the front and back pitch may be taken at any two values whose average is the quotient thus found; generally the numbers next above and below the average are chosen. For a wave winding, the condition already stated must be fulfilled. If the armature is to have two layers of conductors, it is always best to connect a conductor from the under layer to one from the upper to form a coil, whether formed coils are used or not.

For illustration of a multipolar wave-wound armature with two layers, a six-pole machine with 48 conductors will be used, the machine to have six parallel circuits. By our condition for wave winding,

$48 + 6 = 54 = 6 \times$ pitch; pitch $= 9$, or,
$48 - 6 = 42 = 6 \times$ pitch; pitch $= 7$.

hence 9 or 7 may be the average pitch; let 7 be chosen. Also connection will be so made as to equalize the length of the connecting leads—that is, conductors which are to be connected on the front will both be joined to a commutator bar half way between. The connection will then be (see Fig. 3) from conductor 1 to conductor 8 in a coil; 8 is to be joined to 15, and bar 6 is nearest of any to being half way between, so that the lead from 8 goes to bar 6; thence the connection is to conductor 15, to conductor 22, to bar 13, to conductor 29, to conductor 36, to bar 20, to conductor 43, to conductor 2, to bar 3, and so on. By examination of the direction of E. M. Fs., it is found that the brushes go on bars 3, 7, 11, 15, 19 and 23; those on 3, 11 and 19 would be joined by a common connection to one main leading from the machine; those of 7, 15 and 23 to the other. Note that in going from one brush to another—for instance, from the brush on bar 3 to that on bar 7—eight conductors are joined up; this is one-sixth the whole number, so that there will be six circuits in all, as was intended.

The tendency in present day practice is toward high voltages. For direct current machinery, which is most commonly used in connection with isolated plant lighting systems, the limit is set by practice at



American Electrician

FIG. 3.—TWO-LAYER, SIX-POLE WAVE WINDING.

about 220 volts for three-wire and 110 volts for two-wire systems. For these voltages a multipolar dynamo or motor will generally be wound with as many parallel circuits as there are poles, according to the methods just described. When a circuit is to be used entirely or mainly for power transmission, it is better to use higher voltages, and 500 volts are commonly adopted. It is desirable to keep the speed low for the 500-volt machines and this means using a large magnetic flux or many conductors in series in each circuit.

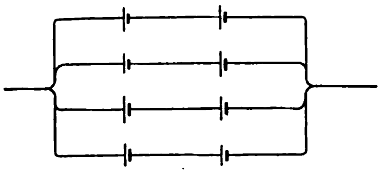


FIG. 4—FOUR-CIRCUIT BATTERY CONNECTION.

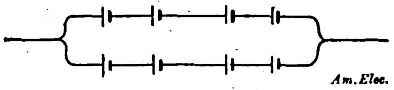

Am. Elec.

FIG. 5—TWO-CIRCUIT BATTERY CONNECTION.

From the manufacturers' standpoint it is necessary to be able to use the same frames for machines of all voltages; since the magnet cores will be worked well up to the saturation point when used for 110 or 220 volt machines, it will not be possible to increase the flux materially, and therefore the number of conductors in series must be increased in direct proportion to the voltage. This might be done by using many turns of small wire in each coil, and keeping the parallel method of connection. The use of many turns per coil makes the winding difficult and costly; also the space occupied by the coil for the high voltage armature must be about the same as that used for the low voltage coil if the same size armature is to be used; for many turns this means smaller wire, which is mechanically bad and uses up more space for insulation. On both accounts, increasing the turns per coil is an undesirable procedure.

There is one possibility left; to connect more coils in series and have fewer parallel circuits. This is analogous to the connection of coils in series or parallel for a battery. Suppose eight cells of two volts each are to be connected so as to give an e.m.f. of 4 volts, the connection would be as in Fig. 4. If it is desirable to get 8 volts, the cells will be connected with twice as many in series, and half as many parallel circuits as in Fig. 5. Since there must always be an even number of parallel circuits, four or six pole dynamos can be connected only as two-circuit machines in the series form; eight-pole machines might be connected with eight, four or two circuits; but, in practice, the two-circuit is the one used almost without exception.

The Gramme ring armature may be connected in the two-circuit form for multipolar machines, but must fulfill this condition; 2 x number of coils, plus or minus 2 = number of poles x average pitch.* Unless this condition be fulfilled the winding will re-enter upon itself before all the coils are connected.

Suppose that it is desired to wind a Gramme ring armature for a dynamo having four poles, and the design calls for 22 active conductors: $2 \times 22 + 2 = 4 \times$ pitch; $44 + 2 = 46 = 4 \times$ pitch: Or $2 \times 22 - 2 = 4 \times$ pitch; $44 - 2 = 42 = 4 \times$ pitch. In neither case would the pitch be an even number as neither 42 nor 46 is devisible by 4. But if two conductors be wound into a coil, the active coils to be connected are $22 \div 2 = 11$, and the condition becomes, $2 \times 11 + 2 = 4 \times$ pitch; $22 + 2 = 24 = 4 \times$ pitch, pitch $= 6$; or $2 \times 11 - 2 = 4 \times$ pitch; $22 - 2 = 20 = 4 \times$ pitch, pitch $= 5$; and either 5 or 6 may be used. Let 5 be chosen. There will be 11 commutator bars, as many as there are coils. The diagram is shown in Fig. 6.

For the sake of equalizing the length of leads, connections are made from each of two joined coils to a bar half way between. Conductors 1 and 2 are joined into coil I; 3 and 4 into II, and so on. The pitch of coils is to be 5, so I joins to VI, the leads going to bar 4; from VI the connection is to XI through bar 9, and so on as shown in Table II.

A coil under an S pole is joined in series with one under an alternate S pole and one under a N pole to one under a N pole. This is the principle followed in all two-circuit windings for multipolar machines. By tracing the direction of the e.m.fs. it is found that brushes are to go on bars 1 and 9. Since there are but two circuits, only two brushes will be needed. It will be noted that the path through coils III, VIII, II, VII, I and VI has six coils, while that through IX, IV, X, V, and XI has only five; with so few coils as are on this armature, serious unbalancing of resistance would be produced by this arrangement. The e.m.fs. generated would be equal since coil III is between poles and is not generating.

In practice no machine would be built with so few coils and, with a large number, no serious effects would follow the use of one more coil in one circuit than in the other. If, however, more conductors are wound up in one coil than in another, a peculiar result follows, especially in multiple-circuit Gramme ring, and in lap-wound drum armatures where the ends of a coil are joined to adjacent commutator bars. The coils having the larger number of turns will have a greater self-induction than the others, hence will require the brushes set with more lead to prevent sparking. If the machine is so wound that the coils are alternately large and small, blackening of every other bar will be produced; because if the lead be right for the larger coils, the smaller ones will spark, while if it be right for the smaller coils, the larger ones will spark.

6	VIII.	11	II.
5	VII.	10	I.

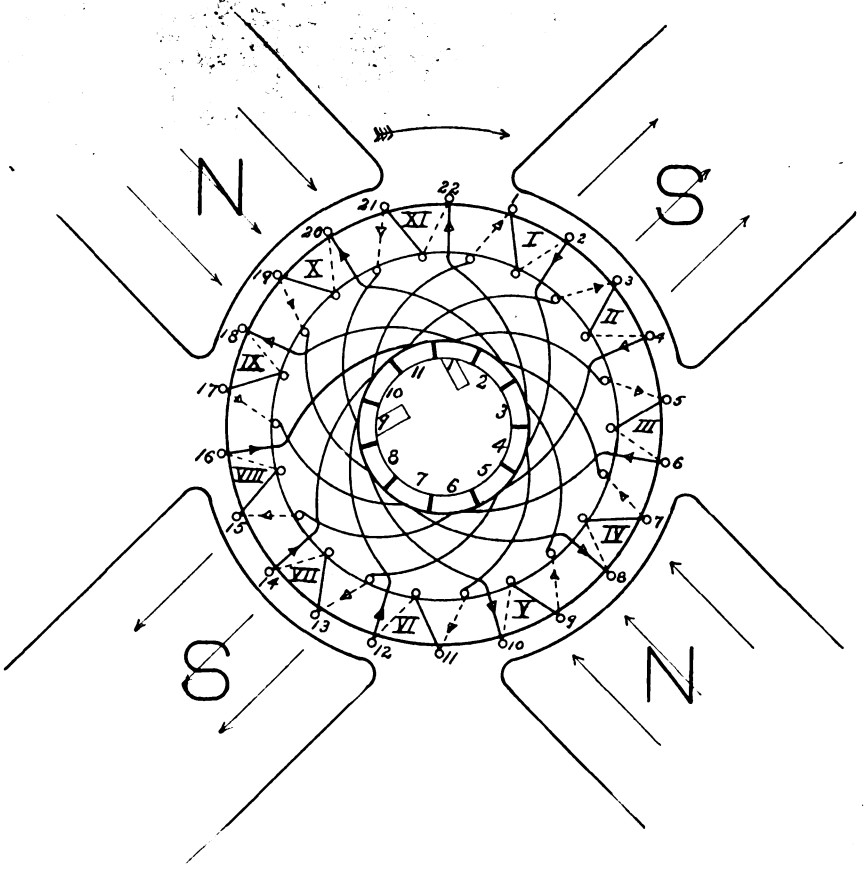

FIG. 6.—FOUR-POLE TWO-CIRCUIT GRAMME RING WINDING.

To return to Fig. 6 there are approximately half the conductors on the armature joined in series in each path; therefore the e.m.f. generated will be twice that produced if only one quarter the conductors had been joined in series. On the other hand, the armature can carry only one-half the current with the two-circuit connection that it could with the four-circuit. The same coils might be connected into either a four-circuit armature, for 230 volts and 50 amps., for example, or into a two-circuit armature for 460 volts and 25 amps. If 500 volts were desired, either the speed must be increased somewhat—but not probably beyond allowable limits—or the coils must be made of a few more turns of somewhat smaller wire.

---

* More briefly, $2C \pm 2 = ny$ (In the March number the equation for wave wound multipolar drum armatures should have been $C \pm K = ny$.

THE USE OF ELECTRICITY FOR TURNING LOCOMOTIVES AND CARS.

BY I. G. RAWN.

Gen. Superintendent. B. & O. S. W. R. R

A source of much annoyance and no little expense is the turning of locomotives and cars at divisional points and terminals. Workmen are not especially employed for this service, but engine wipers and helpers about the engine house are called upon each time the turn table is used. The number of men that usually assist in this work is four, two at each end of table, and the time they lose from their regular duty is considerable, as they are frequently in the pit under an engine, in the engine house or on top of the engine or at some other inconvenient place to get away from when called; their movements are also apt to be slow, and they frequently engage in conversation when meeting, which takes up time that should be devoted to other purposes.

Our general master mechanic estimates that it costs 12 cents to turn each engine by hand. Observing these delays and the expense attending them, the writer about two and one-half years ago devised a plan for turning the 60-ft. turn table at Chillicothe, O., by means of an electric motor. This motor was applied to an old car wheel by means of cast iron spur gear wheels, so as to reduce the speed. The car wheel and motor were attached to a frame which was hinged to the girder of the turn table, the car wheel bearing on the circular rail or the track of the turn table. It was found that the weight of the frame, motor and car wheel was sufficient to give necessary adhesion, so that the tractive force would easily turn any engine. On trial we found that the heaviest engine could be turned completely around in fifty-six seconds.

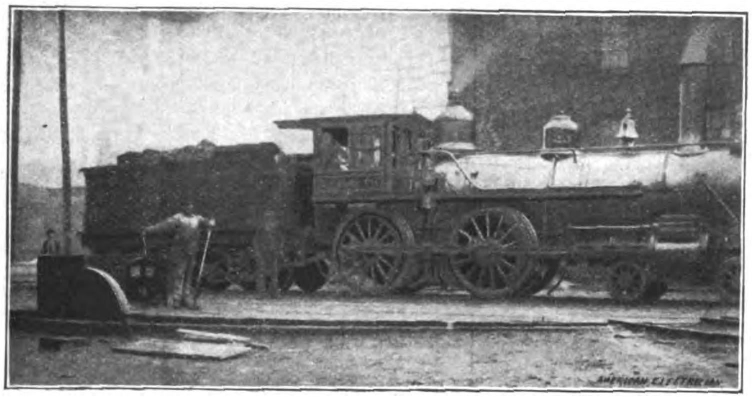
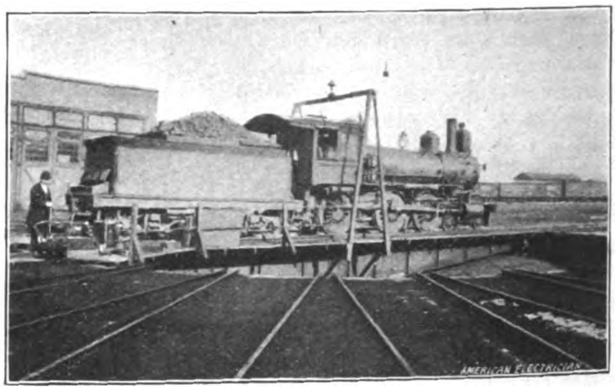
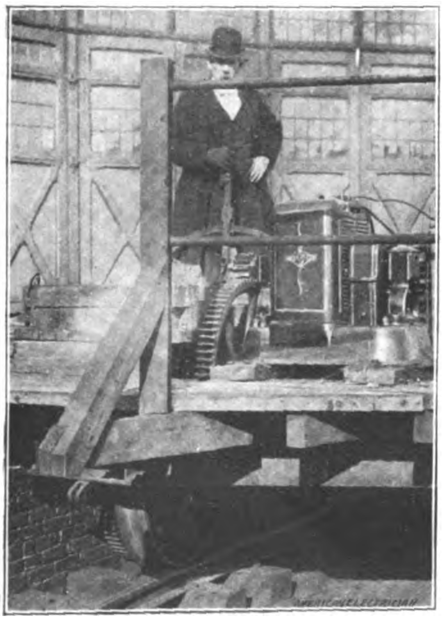
DETAILS OF TURNTABLES.

The current is carried to the motor by an overhead wire which is connected directly over the center of the turn table by two brass rings, insulated with hard wood, so that a perfect contact is always given, thus furnishing a good conductor for the current to the motor. The current is controlled by a rheostat so that the motor can be run in either direction, and at such speed as may be desired; this is done by a single lever, which is moved back and forth. The cost complete, including motor, did not exceed five hundred dollars, and after two and one-half years' use, the device seems just as good as when constructed, and has given such good satisfaction that it was decided to operate the turntable at Park Street, Cincinnati, Ohio, in a similar manner, except that the current is taken underground and connection made around the center cone of the table, so that all wiring is concealed, thus presenting a neater appearance. A motor of from 5 to 7½ h.p. will furnish sufficient power.





ELECTRIC TURNTABLES.



OPERATING GEAR, ELECTRIC TURNTABLES.

The electric power is purchased from the Union Depot Company at meter rate; the cost of this power for four months, viz., May, June, July and August, has been $29. All of the electrical equipment has been furnished by the Triumph Electric Company, of Cincinnati, Ohio.

This turn table is used on an average of fifty times each day, thus making a cost of less than one-half cent for each time the table is turned, while if it was operated by hand, using the figures of the general master mechanic (12 cents for each engine), it would cost $738, which shows a saving of $709, no cost being allowed for repairs; the repairs, however, will never be very expensive.

We have just completed a plan for equiping the turntable at Shops, Ind., with a device similar to the one in use at Chillicothe, Ohio, and will have it in operation in a few weeks. I think even a better showing can be made there than at Park Street, Cincinnati, as more use is made of the table.

COLUMBIA UNIVERSITY ELECTRICAL ENGINEERING SOCIETY.

The Electrical Engineering Department of Columbia University has been well supplied with facilities in the new buildings at Morningside Heights. The laboratories, lecture and other rooms of this department are on the south end of the engineering building, which flanks the laboratory on the west. In the sub-basement are located the storage battery and photometer rooms, the former containing a battery of 70 cells to be used for efficiency and output tests, and also as a source of steady and potential current. The photometer room is equipped with the necessary apparatus for determining the candle power of arc and incandescent lamps, as well as other sources of light. In the basement are situated two machine laboratories, shown in cross section and plan in the accompanying illustrations, the larger containing the direct current machinery, while the smaller accommodates the alternating current apparatus. In the former, a 50-h.p. high speed steam engine drives two lines of shafting carrying pulleys controlled by friction clutches, to which various machines are belted, the arrangement being such that two dynamos of 30 k.w. each can be connected to the engine; or either or both of the two machines may be used to drive the line shaft, the current being obtained from the electric light and power plant of the University. The various dynamos belted to the line shaft include examples of 115, 230 and 500 volt constant potential generators, constant current arc lighting machines and other typical machines. Several types of stationary and railway motors and motor dynamos are also placed in this room. Machine hand tools are provided in one corner of this laboratory for making and repairing apparatus, adjustments, etc. Complete sets of ammeters and voltmeters to speed indicators, transmission and absorption dynamometers are available for testing the various dynamos and motors. In the other machinery laboratory the alternating current apparatus is placed, including single and polyphased generators, induction and synchronous motors, as well as various types and sizes of transformers. Each generator is driven by its own electric motor, thus enabling its speed to be independently regulated. On the third floor are located the experimental laboratory and research room, containing a very complete equipment of galvanometers, standard cells, resistances, and, in fact, all manner of instruments used in measurement and research. A most important feature is the large and reliable supply of electric current afforded by the central power plant of the University. This consists of boilers of an aggregate capacity of 2000 h.p., two low-speed engines directly connected to dynamos of 275 h.p. each, and two high-speed engines directly connected to two dynamos of 100 h.p. each. Special conductors lead from this station to all the laboratories as well as the lecture rooms of the electrical engineering department, thus enabling an ample supply of current for experimental work to be obtained. In addition to the above laboratories, the student of electrical engineering receives instruction in the physical laboratories which occupy four floors of the Physics Building, and in the mechanical engineering laboratories, both of which are exceedingly complete in their equipment and facilities.

COLUMBIA UNIVERSITY ELECTRICAL LABORATORIES.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

Roller Bearings.—Some tests made upon roller bearings for the motor cars of the Liverpool elevated railway show, according to *Engineering*, excellent results. Each bearing carries eight rollers each 1⅝ ins. in diameter and 7 ins. long. The starting resistance on a level was found to be one quarter to one sixth that shown by ordinary bearings, while on a grade of 1-140 it was diminished 40 per cent.

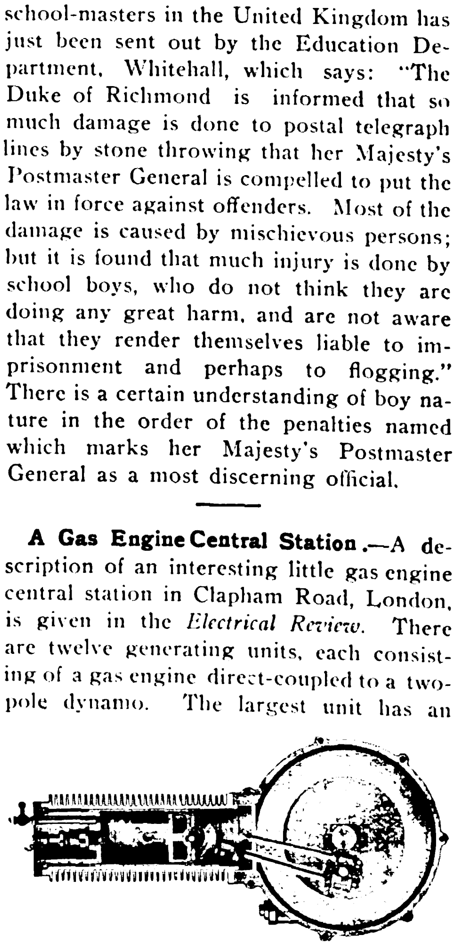
Light Accumulators.—A new type of accumulators for traction purposes has been brought out in England, says *La Revue Technique*, which is remarkable for its lightness. The negative elements are thin sheet-iron plates coated with lead. The electrolyte is a mixture of the sulphates of cadmium, magnesium and zinc. An element weighing only 8.16 pounds is said to have given 33 amp. hours discharge, the e.m.f. meanwhile falling from 2.4 to 1.9 volts.

Submarine Cables—The total number of submarine cables in the world is 1459, of which 1141 are coast and river cables belonging to governments. The total length of cable is 162,938 miles. Of this 143,024 miles are owned by corporations, 70 per cent of these companies being English. In time of war it has always been the custom for messages to pass without question through neutral States. During the recent war telegrams between Turkey and Greece were forwarded through Austria, direct communication being interrupted. In the war between China and Japan there was no interruption in the telegraphic service between those countries.

Ringing Church Bells Electrically.—Electrical machinery has been applied to the ringing of heavy bells at the church of St. George, Berlin, and the installation is briefly described in the *Electrical Engineer*. A shaft carrying three drums, upon which are wound the bell ropes, is turned by a 10-h.p. motor. The drums turn freely on the shaft, to which they may be clutched by a friction disc arrangement. The bells are of the swinging variety. When the motor is started and a bell drum clutch is worked by hand the bell swings as its rope is wound up, until at a certain point the clutch is released and it swings back and rings. This operation is then automatically repeated and the bell continues to ring as long as the motor runs. One man can attend the three very large bells in this way.

Stone Throwing and Telegraph Wires.—It appears that the British small boy is not unlike his American cousin in his stone-throwing proclivities. A circular to school-masters in the United Kingdom has just been sent out by the Education Department, Whitehall, which says: "The Duke of Richmond is informed that so much damage is done to postal telegraph lines by stone throwing that her Majesty's Postmaster General is compelled to put the law in force against offenders. Most of the damage is caused by mischievous persons; but it is found that much injury is done by school boys, who do not think they are doing any great harm, and are not aware that they render themselves liable to imprisonment and perhaps to flogging." There is a certain understanding of boy nature in the order of the penalties named which marks her Majesty's Postmaster General as a most discerning official.

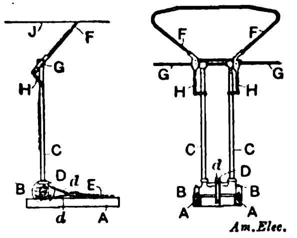
A Gas Engine Central Station.—A description of an interesting little gas engine central station in Clapham Road, London, is given in the *Electrical Review*. There are twelve generating units, each consisting of a gas engine direct-coupled to a two-pole dynamo. The largest unit has an output of 25 k.w. and the smallest of 2 k.w. Current is distributed in the immediate neighborhood at 110 volts, a storage battery being used to steady the voltage and tide over the peak of the load. Much the most interesting feature of the plant is the type of engine used. This is an Otto



SECTION OF GAS ENGINE CYLINDER.

cycle single-cylinder machine, the piston being geared by a sort of screw gear to the wrist pin so that it rotates once about its own axis for each two revolutions of the engine. In this way, ports in the piston are brought opposite proper intake and exhaust openings at the right moments. The piston is made very long. and is so arranged that the ignition of the gas takes place inside it, the cylinder walls not being exposed to the ignition temperature. The section of this novel gas motor shown here renders further description unnecessary.

A German Trolley.—In a recent bulletin of the Verein fur die Förderung des Local- und Strassenbahnwesens is given an illustrated description of a new form of the Siemens bow trolley. A frame *A* mounted on the roof of the car carries two bearings *B* in which the fork *CC* is hinged. This is furnished with a grooved pulley *D* around which are wrapped in opposite directions two metallic ribbons *d*. The free ends of these are attached to the spiral spring *E*, which is in turn attached to the frame *A*. By this arrangement the fork *CC* is kept always vertical, except in emergencies, when it has the necessary ability to deflect out of the way of obstructions. The bow *FF*, which bears on the trolley wire, is mounted, as shown in the illustration. When the car is reversed this bow engages with the trolley wire and is carried over to the corresponding position on the other side of *CC*. This trolley arrangement has been working for some months on the Chaux de Fonds tramway in Switzerland, and the success it has met with there has determined its application on several other lines in the neighborhood.



A GERMAN TROLLEY.

Safety Accumulators.—At a recent meeting of the St. Petersburg Electrical Society a novel form of accumulator was described by M. F. A. Jeremin. To obviate the undue formation of sulphate and the falling out of the filling composition of the plates, he fills the cell and the spaces between the plates, which are more widely separated than usual, with crushed glass. The sulphuric acid solution is somewhat stronger than the usual proportions and the cells, after filling, are hermetically sealed.

The Centennial of the Battery.—In 1899 there will be held an international electrical exposition at Como, Italy, to celebrate the hundredth anniversary of the invention of Volta's pile. Sig. E. Jona, in an article in *L Elettricita*, proposes that this should be made a special exhibition of batteries of all forms. For a long time the battery was the only source of electricity, and despite the perfection of dynamos, has yet many useful applications. By bringing together all the various types of batteries and properly classifying them, an exhibit of great interest would be secured. It would also be possible, he thinks, to thus amass a battery of perhaps 100,000 cells or more, with which a number of valuable and interesting experiments might be made. It seems rather unfortunate for the proposed exposition that its date falls between that of the Turin fair this summer, and the great show at Paris in 1900, and this suggests the thought that we might possibly dispense with a few of the international expositions that are being exploited every month or so.

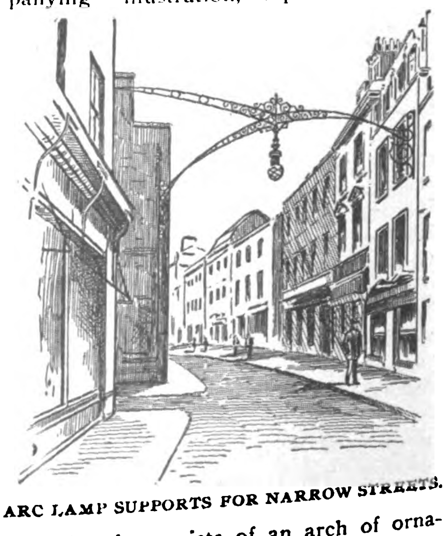
An Argentine Transmission Plant.—*La Inginiera* (Buenos Ayres) describes the fine electric light and power plant for Cordoba, Argentina. Power is derived from the falls of the Rio Primero, near Dique de San Roque, 13.6 miles distant. A tunnel 11 ft. in diameter and 295 ft. long through a hill connects two extremities of a great bend in the river. Water is taken from the tunnel to the turbines in an iron pipe 6½ ft. in diameter. The total available power developed is 5000 h.p. Current is transmitted to the city at 10,000 volts, three phase, the pressure being raised to this figure by transformers at the station. At the city limits it is reduced to 2000 volts and distributed in the usual way to customers.

The Tides as Motive Power.—An interesting little plant in which the rise and fall of the tides is used as motive power for the generation of electricity is described in *L'Electricien*. Near Ploumanach, on the northern coast of France, where the tides have a daily range of 39 ft., a small fish pond separated from the sea by a dike is arranged with gates so that at high tide the water flows in and fills it, the gates closing automatically when the tide recedes. The machinery of an old grist mill is used to operate a small dynamo, which charges a storage battery and furnishes light for the fish industry there. Another wheel in the same mill works an ice-making machine, the whole being under the charge of one man. It is stated that the total daily expense for generating about 2,000 h.p.-hours is only $2.

Measurements of Magnetic Field Intensity.—M. E. Bouty, in *Comptes Rendus*, describes a novel method for measuring the intensity of a magnetic field. A liquid conductor, which may be ordinary hydrant water, is made to flow normally to the lines of force of the field to be measured. The constant e.m.f. induced between the upper the lower surfaces of the steam is measured by a capillary electrometer and, from the known velocity and dimensions of the stream of liquid, the field intensity is calculated. For comparative measurements it is unnecessary to know the size or velocity of the stream so long as these are constant, which gives the method a practical value. The nature of the liquid used makes no difference in the result, and hydrant water, being readily obtained in large quantities and under pressures that will give high velocities or flow, is the best for practical use. The greater the velocity the greater the delicacy of the method. For very strong fields, where the sensitiveness of the electrometer is needlessly great, a standard condenser of two or three microfarads may be charged by the induced e.m.f. and discharged through a ballistic galvanometer. The only precaution necessary for comparative measurements is the thorough insulation of the electrodes in contact with the two surfaces of the stream. The polarization of these electrodes introduces no difficulties in the measurement.

A Dry Accumulator.—An electric miner's lamp of novel design is described in *L'Elettricita*, it being worked from two small cells of storage battery carried by the miner. The plates of this battery are built upon thin sheets of lead, which are provided with numerous projections to better secure the active material. This consists of a paste of finely powdered oxide of lead, mixed with a solution of india rubber, a solution of ammonia sulphate and some inert porous matter, such as powdered pumice, mica or mineral wool. The electrolyte is sulphuric acid. The inventor avoids the inconvenience that would follow the use of a liquid, without sensibly increasing the resistance of the cell, by the use of a paste made by boiling paper in sulphuric acid with small quantities of caustic potash and alcohol. The resulting material is dried and pulverized. When it is mixed with the electrolyte it swells and forms a semi-solid plastic mass.

Arc Lights in Narrow Streets.—At Dover, Eng., where the streets are very narrow and crooked, a novel form of arc lamp support has been devised and used with great satisfaction. As shown in the accompanying illustration, reproduced from *Lightning*, it consists of an arch of ornamental iron-work thrown across the street and supported from the buildings at either side. Where streets intersect the arch is in three parts, the lamp being over the in-



ARC LAMP SUPPORTS FOR NARROW STREETS.

tersection of the street centers and illuminating the streets equally in all directions. Alternating current is used, the supply circuits being underground. Where the lamps are mounted on poles the transformer is in the base of the pole. For the lamps suspended from arches it is installed in a manhole.

Permanent Carbons.—A Russian patent has been granted for the manufacture of permanent arc lamp carbons. They are composed of the purest carbon mixed with finely powered silicon carbide, some adhesive material such as molasses being used. A mixture of 90 per cent of carbon and 10 per cent of silicon carbide is said to be a good composition, though the proportions can be varied indefinitely. The electrodes can also be made with a core of the carbide, or the latter may be combined with any conducting material, such as carbon, to form the core. Since silicon carbide can only be produced by the action of a temperature approximately that of the arc, it contains no volatile ingredients and has the highest resistance to oxidation of all known substances. It develops a very intense light and, according to *L'Elettricita*, seems to promise excellent results. As the carbide is not a conductor, it is not possible to use it as an arc lamp electrode except in combination with carbon.

Death by Electricity.—There seems to be a wide variance of opinion as to the way in which powerful electric shocks produce death. Dr. W. S. Hedley, in a rather learned article in the *Electrical Review*, after stating the various theories on the subject, concludes that death by electricity can be accomplished by various physiological mechanisms. First, and perhaps oftenest, it may be by sudden arrest of respiration; it may also be brought about by sudden and primary stoppage of the heart action. In either case the result is not improbably due to physiological death of the centers of respiration or circulation, from chemical or other changes therein which present methods of observation do not permit us to recognize. The view, however, that death from electric currents is due to action upon the structure of the heart itself is very influentially held, and has never been disproved. The treatment recommended for those apparently killed by electric shock is artificial respiration, begun early and continued long. In proper hands the administration of nitrite of amyl may be productive of good results.

Resistances for Starting and Reversing Shunt Motors.—In a long article in *Elektrotechnische Zeitschrift*, Herr E. Egger describes a method for the control of motors which is said to be in very successful operation. The object of the method is to do away with the heavy starting current while the motor is accelerating and to reduce commutator sparking to a minimum. A series coil on the field, acting in the same sense as the shunt winding, is put in circuit in starting the motor. This increases the field strength and the starting torque and diminishes the starting current. When the motor is stopped, the armature is short-circuited in the strong field due to both coils, acting as a magnetic brake, and the discharge current of the shunt is minimized by the self induction of the series winding. Data of tests of this system in a building having six electric elevators show that the use of the auxiliary series winding reduces the starting current to almost one-half of that required before its adition to the motor. The first part of the article is a reply to a recent article by Menges upon the same subject, but contains nothing of special interest.

Prevention of Sparking.—A discussion in the German technical press of methods for the avoidance of sparking in the switches when stopping shunt motors has brought forward a number of novel ideas. The following simple and ingenious method is described by Herr J. Fischer-Hinnen in *Elektrotechnische Zeitschrift*: The shunt is connected across both the starting resistance and the armature, as shown in the diagram, and is consequently always short-circuited by the armature. At the moment of cutting out the motor the current due to self-induction in the shunt is closed through this path, and no arc whatever is formed at the switch. The effect of the resistance in circuit with the shunt is, of course, to slightly increase the speed of the motor, but it is pointed out that this only amounts to about 2 per cent with a properly proportioned resistance. The same arrangement can be used with series motors, which is a great advantage from the manufacturer's point of view.

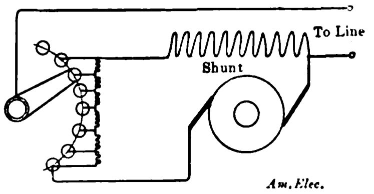


DIAGRAM OF MOTOR CONNECTIONS FOR SPARKLESS OPERATION.

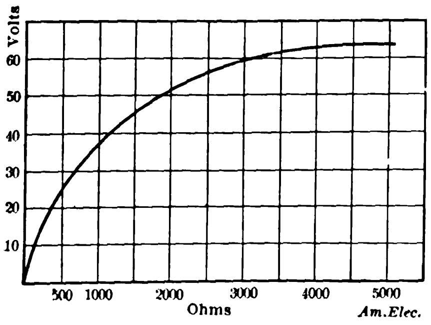
Chloride Accumulators.—An elaborate illustrated account of the process of manufacturing chloride accumulators appears in the *Electrical Review*. The principal interest centers in the making of the spongy lead negative plates. It is needless to say that no chloride of lead appears in the finished plate, its use being in the preparation of the spongy lead for the pellets of the negative plate only. The chloride is manufactured from litharge, which is dissolved in acetic acid and precipitated as chloride by hydrochloric acid. The precipitate is compressed to remove the excess of acid, dried, and subsequently melted in large iron pans lined with fire brick and containing a stratum of melted lead at the bottom. The molten chloride is cast into pellets for the plates, and these, while still hot, are set in a steel mold and melted lead forced in around them under a pressure of 150 lbs. per square inch. After the plates thus formed are scraped and trimmed they are set up alternately with rolled zinc plates in a bath, the result being that the chloride pellets are decomposed, leaving pure spongy lead in the grids, and the zinc reduced to its chloride. A thorough washing and exposure to a stream of hydrogen, which insures the complete reduction of the chloride of lead, leaves the finished plate ready for the attachment of the connecting cross bars.

Electric Mail Delivery in High Buildings.—At Geneva, a novel system for delivering letters in high apartment-houses is about to be tried. *L'Elettricita* describes it as follows: On the ground floor is arranged a cabinet having as many compartments or boxes as there are floors in the house. Depositing a letter in any box makes a contact that sets ringing a bell on the corresponding floor. This bell can only be stopped by removing the letter. The same current that rings the bell opens a valve connected with a water tank in the top of the house. Here are located cylinders attached by cords and pulleys to the letter-boxes below, and so arranged that when they are filled with water their weight serves to haul up the letter-box and its contents to the proper floor. When the box arrives, it is automatically dumped into another stationary letter receptacle, and at the same time the cylinder is discharged of its water. The letter-box then descends by its own weight to the ground floor and all is ready for the next visit of the postman.

Carbides of Sodium and Potassium.—In a communication to the Académie des Sciences, M. Henri Moissan stated that it is not possible to make the carbides of potassium and sodium in the electric furnace. M. Berthelot has already shown the existence of compounds having the formulæ C_2HNa and C_2Na, which are formed by the action of heat on sodium in an atmosphere of acetylene. The metals of the alkaline earths also form similar compounds under similar circumstances, according to M. Moissan. His conclusions in regard to the alkaline carbides are that both sodium and potassium form intermediate compounds, or acetylides, under the action of cold acetylene of the liquid gas, either at atmospheric or higher pressure, the compounds being C_2KH and C_2NaH. Upon being heated these decompose, acetylene being disengaged and the carbides, C_2K_2 and C_2Na_2 remaining. At a higher temperature the carbides are dissociated into the metal and carbon. The same phenomena may be observed with the carbides of the metals of the alkaline earths, but these require much higher temperatures. The conclusion is drawn that at the temperature of the electric furnace the carbides of sodium, potassium and magnesium are dissociated, and that these carbides cannot, on this account, be made in it.

Accumulator Mail Wagon.—For a month or more some of the mails between the general post office and Paddington Station, in London, have been carried in an electric mail wagon. Six round trips, a total of 35 miles, are made daily on one charge of the battery. Forty cells are used. each 6½ ins. square and 10 ins. high and containing eleven plates. The battery weighs 1456 lbs and has a capacity of 172 amp. hours at 30 amps. discharge. It is carried in a tray slung under the wagon. One motor, Lundell two-pole type, of 3½ h.p., is used. The armature has two windings and two commutators, and there are also two series field windings. Control is given by grouping these in five combinations, thus: (1) all the windings and a resistance in series; (2) the same with the resistance cut out; (3) two field windings in parallel and the armature windings in series; (4) the fields in series and armature windings in parallel; and (5) the field windings in parallel connected in series with the armature windings in parallel. The motor is connected through a differential gear and sprocket chains to the two rear wheels. These have a diameter of 3 ft. 6 ins. and are rubber tired. The *Electrician* says that the wagon has given punctual service and is very satisfactory.

E.M.F. of a Telephone Magneto.—Some experiments on the voltage of telephone calling magnetos are described in *Elektrotechnischer Anzeiger*. The magneto was of the usual form, having three steel permanent magnets of horseshoe shape, each ¾ in. wide, 4-10 in. thick and 5 ins. long. The pole pieces were of soft iron, 2¾ ins. long, their section being such as to embrace an arc of a circle. The armature core was of soft iron, having the usual double-T cross-section. The armature winding was of wire 0.15 millimetre in diameter (about No. 35, B. & S. gage), of which enough to bring the resistance up to 500 ohms. was wound on. Its coefficient of self induction was 2.7 henrys when the coil lay parallel to the lines of the field and 7.3 henrys when it was perpendicular to them. The driving mechanism consisted of a handle and two gears multiplying the speed 3.8 times. The magneto was one used by the Antwerp Telephone Company in its regular service. Measurements made with the armature making 15 turns a second showed that the magneto gave 65 volts on open circuit, its voltage rising with the non-inductive resistance in the circuit as shown by the curve. In this the ordinates show the volts and the abscissæ the resistances in circuit. No figures of the current output are given, and no indication of the shape of the current wave, which must be very different from the sine form.



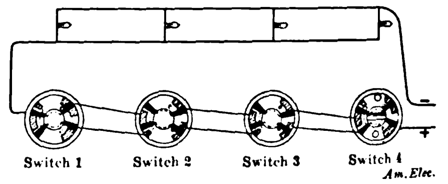
CURVE OF VOLTAGE OF A TELEPHONE MAGNETO.

Electrolytic Searchlight Mirrors.—In a paper read before the Institution of Electrical Engineers, Mr. Sherard Cowper-Coles describes a very rapid and cheap process for making parabolic or other curved reflectors by electrolytic means. A convex matrix of glass is prepared, of the precise form desired, and its surface polished and thoroughly cleaned. This is then silvered by the ordinary tannic acid and sugar process, a very thin and brilliant film of silver resulting. Upon this film copper is plated, very slowly at first in order not to destroy the exceedingly delicate silver coating, until its thickness is sufficient for mechanical strength. By placing the glass matrix in warm water the different expansion rate of the glass and copper loosens the metallic coating, which may be stripped off, the brilliant film of silver adhering to its inner surface. To prevent the tarnishing of the mirror which would immediately follow its exposure to the vapors of the arc, a coating of some non-tarnishable metal is electro-deposited upon it. Palladium is best for this purpose and easily plated. The palladium coating is not as brilliant as the silver, but remains unaltered after exposure to moist air and the fumes from the arc. The great advantage of mirrors of this sort over those made of glass and silvered on the back is that they may be penetrated by a rifle bullet without material injury to their reflecting power, where a glass mirror would be shattered to bits by such an experience. As the same matrix may be used over and over the process is also very cheap.

Volunteer Corps of Electrical Engineers—The English journals contain a set of rules for the government of the volunteer corps of electrical engineers connected with the military service of that country that would form an excellent basis for the organization of a similar corps in America. The English corps is recruited from an excellent class of artisans and engineers, and the officers and engineers of high standing, Dr. John Hopkinson being the major commanding. The corps wears the uniform of the Royal Engineers (Volunteers) and is armed with the Lee-Mitford rifle. Training is given to recruits in two branches, military work consisting of infantry drills, etc., and technical work including every application of electricity to war, except telegraphy. Each member must spend eight days each year in a defended port under training, which embraces signaling, fitting, loading, priming, and connecting up submarine mines and torpedoes, and a certain amount of boat work, knotting, splicing, etc. Enlistment is for three years, and non-efficient members are dropped at the end of the first year. Members are put to no expense, as the allowance made them covers the cost of their uniform, etc. The corps is said to be in a flourishing condition.

The value of such a body of trained electricians in time of war would be almost incalculable. The applications of electricity to warfare are nearly all of the defensive sort, and the possession of a corps of experts in such matters might prove of enormous importance to a country maintaining a defensive campaign or guarding a threatened coast. The value of such a volunteer organization to this country would be greater than to almost any other, because of the number and importance of the unprotected cities on our coasts, and the vital need for rapid and intelligent work should it be necessary to defend them. In no country would it be easier to enroll a body of competent electricians and electrical artisans. Already there is in existence a small corps of this kind attached to the National Guard of the State of New York, but it is only the beginning of what should be a far-reaching and efficient organization.

A Universal Switch.—It is frequently desired to control incandescent or other lights from any one of several places. as for example the case of lights in a stair hall, which could be conveniently lit by a switch on the ground floor and extinguished by one at the head of the stairs. No little ingenuity has been expended in the effort to perfect devices of this character, but one of the simplest and neatest that have yet appeared is described in *L'Energie Electrique*. The diagram is self explanatory, any one of the four switches operating to either light or extinguish the lamps and always leaving the system in order for subsequent manipulation. By using a relay switch in place of the lamps heavy currents can be handled, the individual switches being hardly larger than a lamp socket. Of course, any number of these switches can be used on one circuit without interference.



UNIVERSAL SWITCH.

Counter E.M.F. of the Arc.—A number of novel points of view are contributed to the literature of this subject by Mr. Walter D. Jameson in a letter to the *Electrical Review*. He criticises Blondel's method (an attempt to measure the e.m.f. between the carbons a very short time after the rupture of the main current) and postulates that if any counter e.m.f. persisted after the interruption of the main current for a definite time, say one *n*th second, then if, in the case of an alternating arc, the frequency be increased to *n* cycles per second the resistance due to the counter e.m.f. would decrease until it vanished, a manifest absurdity. If the persistence of the e.m.f. is a definite fraction of the time of the impressed e.m.f. it would tend to make the e.m.f. curve of the supply current "peaky," and introduce a harmonic into the curve. The contrary is well known to be the truth, the arc tending to flatten "peaky" curves. A new hypothesis is offered to explain the actions observed. It is that carbon, which is a tetravalent element, or one having 4 atoms in its molecule, at ordinary temperatures, becomes divalent at the temperature of the arc, each molecule splitting up into two others of two atoms each. Under these circumstances the formulæ for electrolytic action give a potential difference of 40.316 volts at the terminals of a 10-amp. arc, and this was very nearly the observed voltage in the case cited by the author. An experiment upon an arc with iron electrodes showed an exact agreement between the observed voltage, 27.18 volts, and that calculated under the above hypothesis, iron being like carbon a tetravalent element at ordinary temperatures.

A Three-Phase Railway.—An installation of an electric railway operated by three-phase currents and using induction motors has been undertaken and nearly completed under conditions of exceptional difficulty. The line extends from Zermatt to the Gornergrat, in Switzerland, a distance of 5.7 miles and in this short length rises 5248 feet. The heaviest grade is 20 per cent. A rack rail of the Abt system is used throughout the entire length of the road. Power is generated by three high-pressure horizontal shaft turbines of 250 h.p. each at 400 r.p.m., direct-connected through elastic couplings to three-phase generators of the fixed armature type. These machines furnish current at 5400 volts with a frequency of 40 cycles per second. This high tension current is transmitted over lines of three wires, each slightly smaller than No. 3 B. & S. gage, to two transformer sub-stations on the line of the road, at each of which is installed two sets of three 30-kw. single-phase transformers, the whole substation having a capacity of 180 kw. There is also a transformer outfit of the same capacity at the generating station. The line is fed from these at a pressure of 540 volts. Feeders of No. 0 wire are used on two sections of the line. Two trolley wires and the rails form the circuit, the trolley wires being suspended 16 ins. apart over the center of the tracks. Chicago rail bonds are used. The rails are of the Vignole pattern, were necessary, as shown by the map, which is taken, as are the figures given here, from *Le Genie Civil.* The principal point of interest about this installation is the motors. There are three locomotives, each equipped with two 90-h.p. induction motors. The two motors are entirely independent, each actuating one pair of wheels. Their speed of 800 r.p.m. is reduced by a double reduction gearing, the normal speed of the locomotive being a little less than five miles per hour. Control is effected by resistance inserted in the secondary or rotor circuit of the motors, collector rings being provided for this purpose. The locomotives start under full load with a current consumption no greater than that normally taken at full speed. They start a fully loaded train from rest on the heaviest grades with no difficulty. A most elaborate system of electric brakes and hand brakes is provided, but the motors become generators and restore energy to the line at speeds only slightly above synchronism, and fully loaded trains weighing 31 tons have descended the road with no other retardation than that afforded by this action, and at a speed but little greater than the normal ascending speed. Although the road has not yet been completed for its whole length the part of it that is in operation is entirely successful, and shows that for this sort of work the three-phase system is admirably adapted.

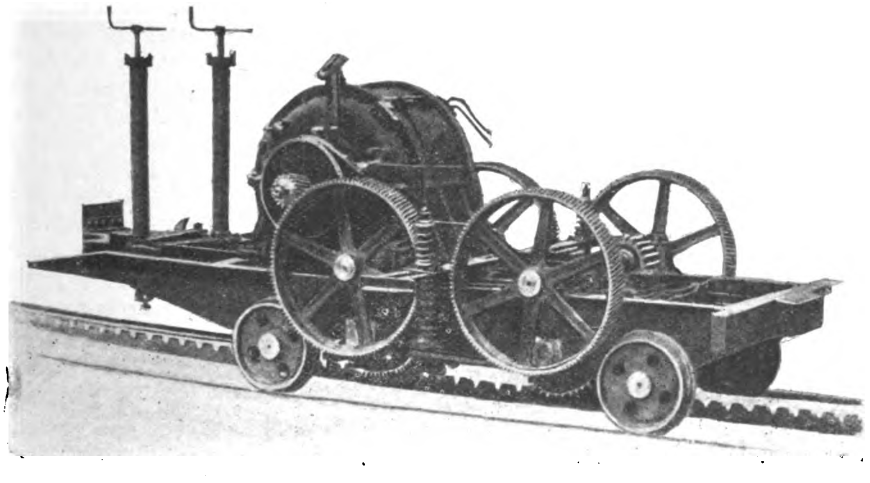
MAP AND PROFILE OF ZERMATT-GORNERGRAT RAILWAY.

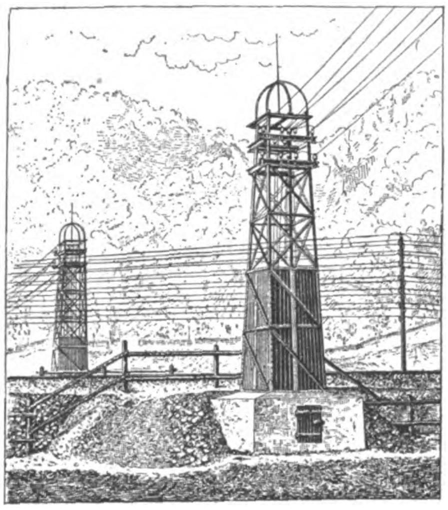


THREE-PHASE LOCOMOTIVE TRUCK, ZERMATT-GORNERGRAT RAILWAY.

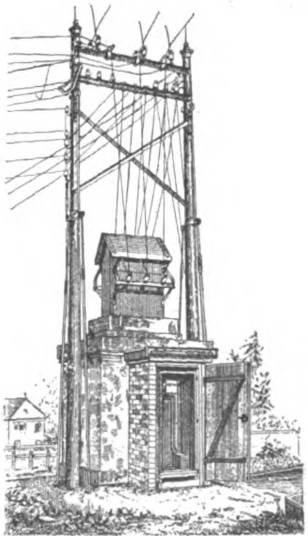
Polyphase Motors for Traction.—In a lengthy editorial the *Electrician* sums up the case against the induction motor and advocates the direct current motor for street car work. It says that the great difficulties of a double overhead wire circuit and of limiting the voltage drop in the earth return have not been sufficiently considered. In Europe the objections to a single overhead wire have retarded the development of electric traction, and the opposition to a double wire system would be prohibitive. Great trouble would be caused by induction from an alternating system in which one conductor is 20 ft. or more from the others. The power-factor of an induction motor is only 0.85 at full load and the transmission efficiency for a given output of the motor would be only about 73 per cent of that of a direct-current motor at full load. The average power of the motors in service is only about one-third of their rated power and the average transmission efficiency of the polyphase system would be only about one-third to one-half that of the direct-current system. The sub-stations in an alternating system would have to be of a sufficient capacity to meet the maximum load that would be likely to occur in the section that they feed, and hence the fixed losses of transmission would be relatively large. Of the various methods of speed control suggested none seem to be satisfactory. The rheostatic method requires collector rings and these need attention and inspection. The controller would be large and complicated and there would be difficulty in dealing with the arcs at the contacts, since magnetic blowouts are not reliable with alternating currents. Control by the "concatenation" two-motor method, where the stator of one motor is fed by currents induced in the rotor of another, is dismissed on account of the troubles due to the increased self-induction of the system, decreasing the power factor and diminishing the maximum torque. A variable voltage transformer on the car diminishes this defect, but this method is unsuited for city working where long runs must be made at low speeds. The commutator of an ordinary car motor costs only $20 to $30 and runs some 100,000 miles before wearing out. The conclusion drawn by our contemporary is that the polyphase motor will not replace the present commutating machine, but that the continuous current system will be greatly developed.

Unfortunately for these arguments they are largely based on incorrect assumptions. Nothing is said about the ease of working polyphase conductors in a conduit, nor is any mention made of the possibility of using a considerable drop in the track returns without causing serious electrolytic disturbances. As railway systems extend the direct current and feeder system must give way to the alternating even if the direct current motors are retained and the line fed through rotary converters. Here, however, is the opportunity of the polyphase car motor, and while it is true that at present the speed regulation methods proposed are not entirely satisfactory, the urgent need for better ones will almost certainly result in their appearance. Nobody proposes to immediately supersede the commutator motor, but it cannot be denied that its commutator and that of the generator are the weak points of the present system, and that the induction motor possesses the inestimable advantage of being as "simple as a grindstone." The sub-stations where the voltage is lowered for the motors need not be very large, since they may be interconnected and an excessive load occurring at any point distributed among several of them.

Power Transmission Lines in Switzerland.—Among the numerous Swiss installations for the electrical transmission of power, that in the neighborhood of the Lake of the Four Cantons presents some of the most interesting features, both on account of its magnitude and the novelty of the methods employed. The generating station is at Schwyz, where a natural fall of the river Muota is used as a source of power. Five horizontal turbines of 600 h.p. each are direct-coupled to three-phase alternators giving 8000 volts directly. The precautions against the destruction of the wheels by sand and gravel in the water, like the rest of the hydraulic features of the plant, are of the highest order and are very fully described by M. Henry Martin, in *Le Genie Civil*, from which the accompanying illustrations are taken. Perhaps the most interesting part of the installation is the line work. This is all aerial, bare copper wires being used throughout for both primary and secondary voltages. The lines extend to sixteen towns at present, and later will be built to Lucerne, 22 miles away. The longest line now operated is about 10 miles in length. Pine poles of various lengths are used, the insulators being of porcelain, double petticoated, 6 ins. high and 4 ins. in diameter and weighing about 5½ lbs. These are attached to the pole by a hook-shaped iron bracket which goes through the pole to a nut on the opposite side. Each pole tip carries a cast iron head from which a copper point projects, the whole being earthed through a stout bimetallic wire. At crossings over ordinary roads a double pole is planted at each side and a net of stout steel wires constructed from pole to pole under and about the three high tension conductors, so that if one of them breaks it cannot possibly fall into the road. At railway crossings a still more elaborate arrangement is used. Towers are built on each side of the tracks and a tunnel under the railway connects them. The conductors come down through the central part of the towers and are led through the tunnel on insulators attached to its masonry roof. The lower parts of the towers are of iron plate. Sub-stations are uniform in construction, and consist of a vaulted structure of concrete, about 8 x 10 ft. in plan and 8 ft. high. This is surmounted by a sheet iron chimney for the conductors. On each side of the structure is erected a pole, the two being connected above by an iron beam carrying the insulators. Three transformers are in each sub-station, their connections being the usual triangle. They are wound to give 240 volts in each phase of the secondary. A peculiarity of this installation is that lights are operated from one side of the three-phase system, this being consequently unbalanced. The transformer from whose secondary lights are to be fed is, of course, larger than the other two in the same sub-station, and is provided with a terminal from the middle of its secondary coil. The lighting circuits are three-wire, with 120 volts between each side and the neutral. The whole installation, complete with water power developments, station, lines, and rights of way cost only $160 per h.p. Power is sold at prices ranging between $26 and $56 per year, and 16-c.p. incandescent lamps are supplied with current at $4.40 a year.



HIGH-TENSION LINES CROSSING A RAILWAY.



A SWISS TRANSFORMER SUB-STATION.

Steel for Permanent Magnets.—In a recent contribution to *Comptes Rendus* Mme. Sklodowska-Curie describes a number of experiments undertaken to determine what varieties of steel are most available for making permanent magnets. Bars 20 c.m. long and 1 c.m. square were used and measurements were also made upon closed magnetic circuits in the form of rings. The bars were heated in a helix of platinum, made incandescent by an electric current and tempered in water. The magnetism thus induced was removed by a magnetized needle. The conclusion reached was that the quality of magnet steel is determined by the intensity of the residual magnetization in a closed magnetic circuit, and by the coercive field necessary for the demagnetization of the specimen. Of steels with varying proportions of carbon, those having about one-half of 1 per cent are best for magnet making. The presence of small quantities of various metals was found to have little effect upon the residual magnetization of a closed ring, but frequently increased the coercive field, and hence, better fitted the steel for use as a permanent magnet. Silicon, boron and manganese in small quantities were found to have practically no influence on the quality of the steel, while an admixture of a little nickel, chromium or copper seemed to improve it. The best steels, however, were found to be those containing small proportions of tungsten and molybdenum. The coercive fields necessary for demagnetization vary in the proportion of sixty for carbon steel, seventy-four for tungsten steel and eighty-five for molybdenum steel.

Electrical Drainage—A rather primitive installation for the drainage of the delta of the river Memel, in Prussia, is described at length in *L'Elettricita*. The district drained comprises about 45,000 acres, for the most part lying about 3 ft. below sea level, and protected by dykes. There are six pumping stations operated from a central generating station, steam being the motive power. Three-phase currents at 5000 volts are generated by two inductor-type dynamos of 160-kw. each, direct-connected to compound engines. Two exciters, each capable of furnishing current for both main dynamos and the station lights, are employed, one being driven by a small engine and the other by a synchronous motor connected with the main circuit. At the sub-stations, which are all alike, the pumping arrangements are very primitive, but very satisfactory for the work required of them. The water is raised by a large paddle-wheel running in a concrete setting (almost precisely a breast wheel, but reversed and acting as a water lifting machine). The average lift is only 3 ft., and the maximum lift 6 ft. The wheel is 26 ft. in diameter by 5 ft. 6 ins. face, and is provided with a cast steel countergear meshing with the pinion of a reducing train connected with the motor. This is of 75 h.p., of the synchronous variety, and takes the line voltage of 5000 direct without transformation. The motors work at 590 r.p.m. and the paddle wheels at 2.6 r.p.m., delivering at that speed 3600 cubic feet of water per minute. When it is desired to start up one of the pumping stations it is necessary to shut down the central station and connect the line to the motor upon the main switchboard, each pumping station being provided with a separate transmission line. Then the main dynamos are started up slowly, the synchronous motor keeping step with the current as the frequency rises. The whole installation is a curious mixture of old and new engineering methods, but it is probably as satisfactory as a more elaborate plant would be, and has the further merit of having been erected at a very low cost.

Synchronizing Alternators.—It is well known that if synchronizing transformers are improperly connected, the synchronizing lamp may be brightest when the machines are completely out of phase. To determine if the connections are properly made H. E. M. Kensit gives in the *Electrician* the following simple tests:

Referring to Fig. 1, which represents the case where the transformers are across only one coil of each armature, let AA represent double-pole bus-bar switches, and assume machine No. 1 to be running. Disconnect at B and C and connect the transformer terminals B and C to B' and C' respectively. Then if the lamp is bright when machine No. 2 is brought up to speed, the connections as shown are correct. If not, one of the transformers must be reversed.

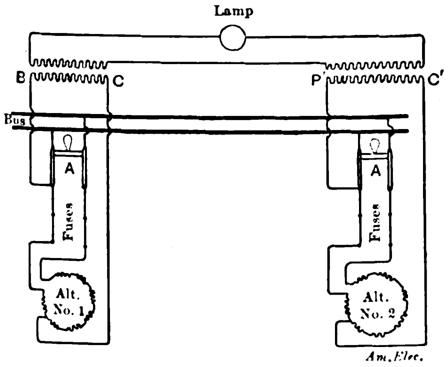


FIG. 1.—SYNCHRONIZING ALTERNATORS.

Fig. 2 shows the case when the transformers are connected directly across the alternator terminals. Take out the fuses of No. 2 and close the switch. If all is right the lamp will be bright. If the lamp remains dark one transformer must be reversed.

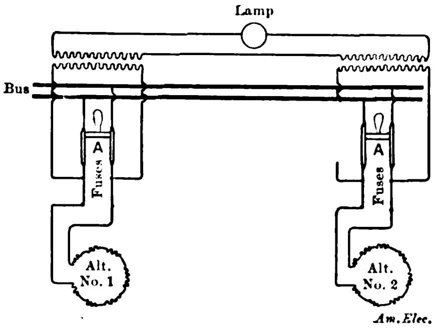

FIG. 2.—SYNCHRONIZING ALTERNATORS.

In cases where the synchronizing transformers are fed off only one coil of one machine and off the terminals of the other, a different arrangement is necessary, as shown in Fig. 3, the temporary use of another transformer being required. This should be connected up as shown by the dotted lines. Disconnect the leads B', C', D', and E' and connect D' to F and E' to G. Then run No. 2 machine up to speed. If the lamp is not bright reverse the high tension leads to the temporary transformer. Then disconnect the leads D' and E' from F and G and secure them in their proper places and connect up the coil B'C'. Now proceed as in the first case and, disconnecting at D and E, connect D to F and E to G. If the lamp is not bright reverse the leads at B'C' and replace the leads at D and E. Having now proved that No. 2 machine is ready for being thrown in by the use of the temporary transformer, and that the transformer fed from one of its coils is in correspondence with the temporary transformer, the latter may be removed and the machines paralleled by means of the switchboard transformers with every confidence. With machines having small self-induction some method of this kind is recommended as decidedly less dangerous than the usual method of trial through a long light fuse.

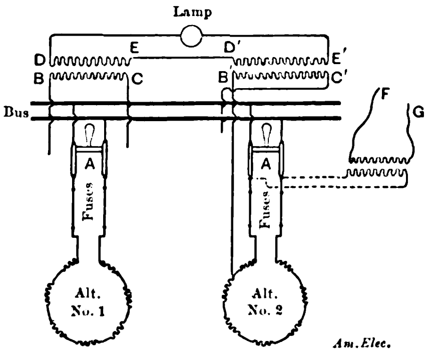

FIG. 3.—SYNCHRONIZING ALTERNATORS.

Electrolytic White Lead.—Up to the present the old Dutch process for making white lead (lead carbonate), writes Mr. Sherard Cowper-Coles in the *Electrical Review*, has held its own as the best, and the excellence of the product resulting has kept it the standard method of manufacture despite its slowness and expense. This process consists of subjecting grids of pure cast lead to the action of acetic and carbonic acid vapors. In a large cubical brick stack a layer of tan-bark is put down and on this are arranged as closely as possible a layer of stone pots filled with dilute acetic acid. Over these are laid several layers of the lead grids and the whole covered with planks. Upon these planks is built up another layer of tan-bark, pots and so on until the stack is full. All ventilating apertures are then closed and the stack left to itself for from 10 to 15 weeks. The process of change from the metallic lead to its carbonate is not well understood. The tan-bark ferments and heats, giving off carbonic acid and volatilizing the acetic acid. When the stack is opened the grids are wetted and rolled to free them of the white lead which has formed on them. The process is necessarily very slow and expensive. A modification which reduces the time of the operation to five weeks is to put the lead, in the form of sheets, in crates with carbon plates to which the lead is connected by tin strips. The warm vapors start an electrolytic action between the lead and carbon, hastening the corrosion of the lead. Another electrolytic process consists in electrolyzing a 10 per cent solution of sodium nitrate in a wooden cell, the anode being pig lead and the cathode copper. The lead dissolves as nitrate while caustic soda forms around the cathode. The mixture of the two solutions precipitates the lead as hydrate, from which the carbonate is made by the action of sodium carbonate or bicarbonate. The process is regenerative and continuous. Another process is to use an anode of lead in a solution of a salt of ammonia and any acid that will produce a soluble lead salt, and of a bicarbonate of an alkali. A soluble lead salt is produced and precipitated as the carbonate by the free carbonic acid liberated at the cathode by the action upon the alkaline bicarbonate of the caustic ammonia there set free. The bath is regenerated by a stream of carbonic acid gas.

WHAT IS ELECTRICITY?

Some of the views expressed in an article in the March issue, entitled "Electricity," not being in accordance with those popularly held, proofs of the article were sent to a number of eminent electrical authorities, with a request for criticism, and below are printed the communications received in reply.

In the article it was stated that the smallest electrical wave thus far measured was 8 ins. This is an error, as waves one centimetre long have been observed, which length corresponds to a frequency about one ten-thousandth less than that of a wave of light.

In referring to the effect of frequency on the resistance of conductors, it was stated that "with very high frequencies electrical energy cannot be transmitted by means of wires, owing to the increase in the apparent resistance of conductors at high frequency." The qualifying word "commercially" should have followed "cannot," and "solid" preceded "conductors." With a frequency corresponding to a wave length of one centimetre, the flow of current would be practically confined to near the surface of the conductor, with the consequence that the drop through a solid No. 0 conductor would be about 7000 times greater than if a direct current of the same value were flowing. By using, however, hollow conductors, this effect is very largely decreased. The effect of circuit inductance was not mentioned, as this may theoretically be neutralized by capacity. Should it not be practicable to do so, the inductive drop, since it increases directly with the frequency, would in itself prohibit the use of high frequencies.

To the Editor of American Electrician:

I have read the proof of the article on what is electricity, and completely agree with the views expressed therein.

Chas. P. Steinmetz.

Schenectady, N. Y.

To the Editor of American Electrician:

I have read the proof of the article entitled "Electricity" with great interest.

It seems to me an admirable presentation of the attitude of scientific men toward the question, "What is Electricity?" and I think that it cannot fail to do good in encouraging a spirit of research into the relations of the manifestations of energy, and in repressing the tendency of untrained minds to philosophize beyond the limits of their possible knowledge.

John Trowbridge.

Cambridge, Mass.

To the Editor of American Electrician:

In accordance with your request, I have read over the proof of the article sent to me, and find the views expressed therein to be sufficiently orthodox. You make therein a number of eminently sensible remarks, such as those in the second paragraph, and the conservative tone of the article is to be commended. The popular idea that the domain of electrical phenomena is more mysterious than that of gravitation and other parts of physics, cannot be too strongly combated.

Arthur Gordon Webster.

Worcester, Mass.

To the Editor of American Electrician:

I think that you answer the question according to present knowledge. A physicist uses the words "light," "sound," "heat," in an objective sense, and also in a subjective sense. In the objective sense, light, sound, heat, are not agents or forces, but forms of energy; in the subjective sense they mean certain sensations, forms of physiological energy. In the case of electricity, the word is not so apt to be used in a subjective sense, as it is not perceived without artificial means, but in the objective sense it means nothing but electrical energy. Those who seek after a "juice," or an agent, or a force, do not understand the modern doctrine of energy.

I think that the terms of the comparison about the No. 0 conductor should be made more clear.

Further advance in knowledge of the constitution of matter and of the ether, and of the nature of molecular and ether motions, is bound to increase skill in controlling and directing the transformations of energy, but, as you show, there are limits which may be more and more approached but cannot be reached, far less surpassed.

Alexander Macfarlane.

South Bethlehem, Pa.

To the Editor of American Electrician:

I have glanced over the galley proofs of your article on "Electricity," and have no criticisms to offer, but I should think, with reference to the last paragraph, that while electrical energy is certainly the reality with which we are all principally concerned, it is quite possible that an electrical charge is an entity, in addition to, and apart from, the electrical energy which accompanies it. In other words, a charged insulating metallic sphere may, perhaps, not only be the focus of electrical energy in the surrounding ether, but may be, possibly, the seat of an entity even if this entity be not a substance. In this sense, electricity might be a reality as distinguished from electrical energy. Thus, if it could be shown that electrostatic flux consisted of a particular kind of stress or displacement in the ether, then the charged sphere would be surrounded by a distribution of this displacement. The displacement itself might be called electricity, while the energy contained in the displacement would be electrical energy. Of course, this is still, unfortunately, all speculation.

A. E. Kennelly.

Philadelphia, Pa.

To the Editor of American Electrician:

In the main I quite agree with the opinions expressed in the article, entitled "Electricity,"at any rate, so far as the practicable possibilities of the immediate future are concerned. I would only add that though much must be discovered, and much investigated before such things can be practically attained, still, I do not despair of the possibility some day, not only of light without heat, and of the electric transmission of power on a large scale without wires, but also even of the obtaining of energy by other means than the oxidation of carbon, or the utilization of water and wind power, say directly from the radiations that come to us from the sun, or from other sources internal or external to the earth. Probably, however, these are matters for succeeding generations, not for our own.

A. A. Campbell Swinton.

London, England.

To the Editor of American Electrician:

I have carefully read the proof of your article and think it is admirably written and covers the subject very fully. I could not suggest any improvements, unless it should be to modify the statement in regard to electrical energy being the "only entirely new form of energy with which man has become acquainted within historic times." The energy liberated by the thunderbolt has probably been known to men as long as heat or light has been known. The only difference, it seems to me, is that man has only recently learned how to economically generate, apply and control electrical energy. But this is equally true of some forms of potential energy, such as chemical energy. It can hardly be said that chemical energy was really known to man one hundred years ago, though the forms of energy resulting from its transformation were well known. I do not think there is any danger of adverse criticism, however, on your statement.

Philadelphia, Pa. C. J. Reed.

To the Editor of American Electrician:

The article in your March issue entitled "Electricity" takes a view of the case which has been held by the writer, in substance at least, for some years past. It is interesting in this connection to call attention to the tendency of human thought to move in a closed current, so to speak, and to explain *A* by referring it to *B*, and then after a while to explain *B* by referring it to *A*.

Throughout the whole course of electrical discovery, as may be seen by reference to Mr. Benjamin's "Intellectual Rise in Electricity," each new discovery was used, either by its discoverer or by somebody else, as the foundation for an explanation (I will not say theory) of some well known phenomena—for example, Gilbert's explanation of the rotation of the earth by magnetic attraction. Of late years it is somewhat fashionable to attempt to explain electrical phenomena by means of other phenomena not heretofore considered electrical, and when the average man asks what electricity is, he wants to be answered, it is matter, it is energy, or some such answer, and he is not satisfied with any other kind of reply. Yet at the same time the ancient idea of explaining other things by means of electricity still retains a hold on the mind of the multitude, as for example, "electricity is life." This brilliant remark was made by Napoleon to his physician, Corvisart, on witnessing an experiment performed by Volta upon a corpse. This practice of constructing reversible or cyclic explanations has not, up to the present time, advanced electrical or other science in any marked degree, yet it has not entirely lost its popularity.

Townsend Wolcott.

New York.

To the Editor of American Electrician:

I received a copy of proof on the subject of "What is Electricity?" and think you are quite right in assuming the attitude you did, and, so far as I can see, the views you put forward are perfectly reasonable.

I have never had any sympathy for the tendency in the popular mind to surround electricity with an air of mystery, more than to so surround the operation of other natural forces, for they are all equally mysterious; in fact, I think, as a matter of philosophy, if the truth were really known to us we should find that electrical actions were probably far simpler than what we regard as purely mechanical ones.

The very simplicity of electrical laws seems to point to the fundamental character of the actions. The ether of space is an electromagnetic medium, i. e., its properties are apparently altogether electromagnetic; and believing, as I do, that the material universe is based in some way upon the ether of space, I am naturally led as a matter of philosophy or speculation to think that if we could see far enough we should find that gravitation, cohesion, inertia, and other mechanical forces and properties, as well as chemical attraction, were, in some way, dependent upon the electromagnetic properties of ether; and if we really understood the meaning, or could form in our minds an image of electrical actions, we should have the key to nearly all others.

This view is not in response to any desire to make all things electrical, or regard them as all based upon electrical manifestations. My own training, in fact, has been fully as much a mechanical training as it has been an electrical one, and for years I had charge of chemical teaching in the High School of Philadelphia. There is no reason why I should be predisposed towards the mechanical, electrical or chemical theories, in preference to each other; but I am growing in the conviction that attempts to explain electrical and chemical phenomena by mechanical analogies or by modes of thought involving particles possessing energy, momentum, weight, mass, etc., may possibly be beginning at the wrong end; for if it should really be true that electromagnetic properties lie at the foundation of mechanical properties and actions, then it would manifestly be absurd to attempt to use the effect to work backward from the more complex to an explanation of the more simple, or to use the more complex phenomena as a basis for the more simple actions, so to speak.

I was pleased to find last summer that Mr. A. E. Kennelly had about come to the same view.

ELIHU THOMSON.

Lynn, Mass.

◆

Condensation in Steam Engines.

To the Editor American Electrician:

I have read with interest the editorial in the March number on "Condensation in Steam Engines," and as the subject is one of importance, a further discussion of some of the points involved may not be without value.

The action of the walls of a steam cylinder in producing condensation of steam depends, as pointed out, on their capacity when at a lower temperature, for absorbing heat from the steam, as during admission, and for giving it up when at a higher temperature, as during exhaust. The amount of such prejudicial action depends, therefore, on the range of temperature between admission and exhaust, and on the particular readiness with which as a substance the walls absorb and reject heat, according as they are cooler or hotter than their surroundings.

There are, therefore, two distinct features to be considered—the range of temperature and the characteristic readiness of absorption and emission. Now, it seems to be the case that once the walls of the cylinder become wetted or covered with a film of moisture, the absorption and emission of heat into and from the metal proceed with much greater readiness than when they are dry. In other words, the passage of heat between metal with a moistened surface and moist steam is much more rapid than between the same metal with a dry surface and dry or superheated steam. In the ordinary steam engine we have, therefore, an action of the walls due to the range of temperature employed, and to the natural capacity for cast iron to absorb and emit heat from and to steam, greatly augmented by the presence of a more or less complete film or layer of water over the surface, arising from the condensation of the first entering saturated steam. In the engine using slightly superheated steam we have the same general tendencies as above, but less augmented, because of the smaller amount of moisture formed. In the engine using steam superheated to such a point that the action of the walls and the thermodynamic action serve only to reduce it to near the point of saturation, no moisture is formed, and the action of the walls is limited to that which can take place between their dry surfaces and the dry or superheated steam.

Superheating must not therefore be unstood as effective as against the fundamental action of the walls, for no matter what the working substance, they will still act as a shunt or by-pass to the condenser, or from another point of view, as a place of hiding into which heat can slip and out of which it can escape to the condenser without doing its share of work. The office of superheating is simply to reduce the readiness with which this transfer is carried on, and there is no doubt that such reduction is real and highly beneficial when the superheating is carried to a point sufficient to prevent the formation of moisture in sensible quantity.

Regarding the application of reheaters to the receivers or exhaust spaces of the h.p. or i.p. cylinders, it seems likely, as pointed out, that their beneficial action will be marked in proportion as they are able to superheat the steam passing through them. With saturated or wet steam at the start, however, it is doubtful if they can be depended on to more than dry the steam, and the result would be simply a decrease in the amount of water present in the various cylinders, with probably little added saving in the thermodynamic actions within the cylinders themselves. For best results the steam should therefore be somewhat superheated at the start, and the combination of initial superheater and reheaters may be considered as giving a general superheating effect, broken up into stages, each stage producing sufficient superheating to prevent condensation in the following cylinder.

In considering the question of saving, it must not be forgotten that the net gain from the reheaters consists of the heat saved in the cylinders less that expended in the reheaters, and that in the final balance the latter must not be forgotten as a part of the expense account.

Ithaca, N. Y. W. F. DURAND.

Electrical Journals.

To the Editor of American Electrician:

As an old telegrapher, I was much interested in the short letter in your March issue from Mr. Edward Caldwell, on early telegraphic periodicals. Fortunately, or unfortunately, in early days while I was with the old American Telegraph Company in its Wall Street headquarters, New York, I had a hobby of collecting all I could on telegraph or kindred electrical subjects, and have to this day preserved much of that period.

As stated, the *Telegrapher* was the pioneer journal in this line, Mr. L. H. Smith, House printing operator, being its first editor. I took a lively interest in it from its inception, contributing many items and securing many subscriptions, though not a member of the Telegraphic Union. I have to-day the original letter from Prof. S. F. B. Morse, who at my solicitation sent his subscription and promised, if a library were started, to add to its archives. The *Telegraphic Journal* was started by a Morse operator, named Jerry Borst. Mr. J. D. Reid seemed to be the editor, and I always suspected that the Western Union Company was behind him, as Jerry, from appearances, inclinations and taste, was about the last man one would expect to go into a literary venture. The death of the Borst paper and the appearance of the *Journal of the Telegraph*, with that most fascinating of writers and gentlest of men, J. D. Reid, as editor, seems to confirm my Western Union theory.

I have copies of nearly every early telegraph or electrical journal, and was the first to issue the *Canadian Electrical News* in this city in 1884—the first paper in Canada devoted exclusively to electrical science but, like many other such ventures, it was ahead of the times and lived but six months. I can supply libraries or collectors with copies.

In those early days I made a collection of original letters and documents on the early history of the electromagnetic telegraph, etc., consisting of a series of letters from those early identified with its development and progress, written in answer to many queries from me, I have arranged the whole loosely in five large quarto volumes, illustrated with some 250 portraits and biographical sketches of all kinds. The letters contain an inside history of this period exceedingly interesting, and from which an interesting volume might be compiled. The letters are from Morse, Gale, Vail, French, Rogers, Wood, Cornell, Pell, Dr. Jackson, House, Hughes, Kendall, Barnes and many others, with portraits of all these people, as well as of Galvani, Volta, Mesmer, Wheatstone, Borelli, Ampere, Ohm and many others. It is such an American history as should a permanent home in the library of some American electrical society, and I might part with it under certain circumstances.

John Horn.

Montreal, Can.

NOTES.

Philadelphia Electrical Exposition.—An electrical exhibition will be held in Philadelphia, beginning June 6 of the present year and continuing one month. The exhibition building is situated on Chestnut Street, between Eighth and Ninth, nearly opposite the Post Office, and extending through to Sansom Street.' Among the features decided upon is an electric fountain, and especial attention will be given to recent electrical inventions and to the exhibits of distinguished inventors. Prof. Wm. D. Marks is director of the Exposition, whose business offices are at 1308 Arch Street.

American Institute of Electrical Engineers.—At a meeting of the Council of the A. I. E. E. on March 23, the following nominees were selected from the proposals submitted by the membership, and will appear on the council ticket that will be sent out previous to the annual election: President, Dr. A. E. Kennelly; vice-presidents, Prof. Robert B. Owens, Mr. William Stanley and Dr. Cary T. Hutchinson; managers, Mr. Herbert Lloyd, Prof. Samuel Sheldon, Prof. George F. Sever and Mr. Charles P. Steinmetz; treasurer, George A. Hamilton; secretary, Ralph W. Pope.

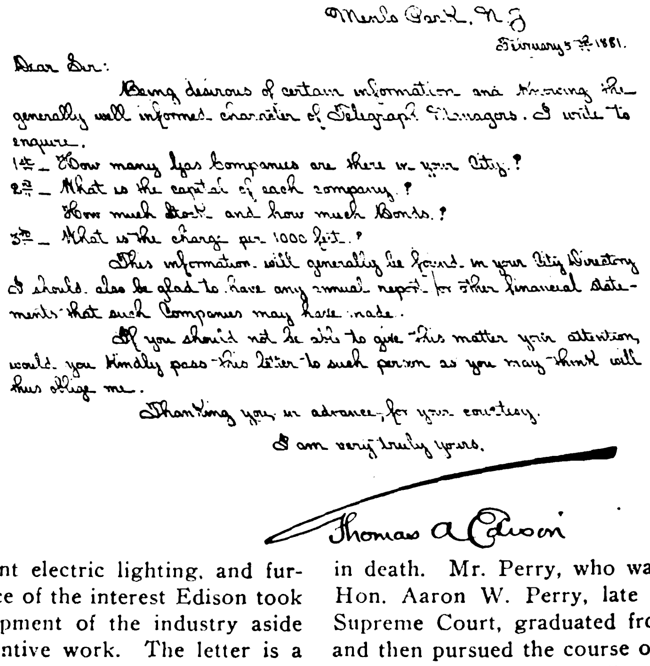
Standard Electrical Diagrams.—A little book containing the report of the Chicago Electrical Association committee on standard diagrams has been issued by that body. This gives the report in concise, convenient pocket-book form for the use of electrical draftsmen and patent attorneys, and for electrical engineers who wish to have a set of the diagrams for reference. To cover the expense of the printing, a nominal price of 10 cents each will be charged. Application for copies should be made to Mr. J. R. Cravath, secretary, Chicago Electrical Association, 825 Monadnock Building, Chicago.

Insulating Compound.—Prof. Fessenden recommends for armature work a compound made by boiling pure linseed oil at about 200 degs. with ½ per cent of borate of manganese, the boiling being continued for several hours, or until the oil begins to thicken. An advantage of this borated oil is that it always retains a slight stickiness, and so gives a good joint when wrapped around wires, etc. Many substances so used are not sticky and let moisture in through the joints. Where a smooth surface is required, it is readily obtained by dusting on a little talc. It can also be given a coat of japan on the outside.

From Over the Sea.—We clip the following kind comment from the editorial page of our London contemporary, *Electricity*: "The fact that we have just received our usual copy of the current number of the *American Electrician* reminds us of the debt which I, in common with so many other of my contemporaries, owe to its pages. One never takes up one of the numbers of this paper without knowing that there is much in it which will be at once interesting and instructive. How the editor manages to secure such practical up-to-date articles is one of those secrets he alone can tell. If any of my readers ever wish to go abroad for scientific information, I could not, if I wished, do better than advise them to subscribe to this monthly periodical."

A Mercury Cutout.—At the March meeting of the Societé Internationale des Electriciens, a new form of switch was described, in which the circuit is opened and closed by mercury. In a box of insulating material are two cavities separated by an insulating partition, the cavities being filled to a certain height with mercury. If a plunger is thrust in each cavity the mercury rises above the top of the partition and closes the circuit; when the plungers are withdrawn, the mercury separates and falls back into the cavities, thus opening the circuit. A number of forms of switches, automatic, cutouts, etc., constructed on this principle, were shown at the meeting, and it was stated that on a circuit of 12 amps. and 3000 volts their use gave excellent results.

A Reminiscence of Pioneer Days.—The accompanying engraving is a reduced facsimile of a letter dating from the early days of incandescent electric lighting, and furnishes evidence of the interest Edison took in the development of the industry aside from his inventive work. The letter is a mimeograph copy, of which the original was written by Edison with his electric pen; the signature is autographic. During the first several years of incandescent electric lighting development, Edison was the guiding spirit in every advance, his inventions being brought forth, not through needs discovered by others, but to perfect a low-tension system of distribution which to-day remains as he completed it. From the above letter it will be seen that his activity also extended beyond the inventive sphere to that of the engineer and the promoter.



Menlo Park, N.J.
February 5th 1881.

Dear Sir:

Being desirous of certain information and knowing the generally well informed character of Telegraph Managers. I write to enquire.

1st_ How many Gas Companies are there in your City?
2nd_ What is the capital of each company?
How much Stock and how much Bonds?
3rd_ What is the charge per 1000 feet?

This information will generally be found in your City Directory I should also be glad to have any annual report or other financial statements that such Companies may have made.

If you should not be able to give this matter your attention would you kindly pass this letter to such person as you may think will thus oblige me.

Thanking you in advance for your courtesy.

I am very truly yours.

Thomas A Edison

Non-Induction of Wire.—The following, signed by Gorham Gray, Boston, appeared in the New York *Herald* as a reply to a letter in a preceding issue, conveying an intimation that the "Maine" disaster might have been due to "induction" from the electric light wires, insulation, it being stated, affording no protection against the danger from "induction": "Noting the remarks of Mr. Miles Pauson in to-day's *Herald*, I beg to say that whether the 'Maine' explosion was from external or from internal contact, it seems to me that no wire insulation can be a safety from induction of current and accidents on land and sea. The wire must and can be self-insulated. No covering can safely avoid accident, although all wire should be in non-contact. As a pipe carries water, so must wire be adjusted to electric current carriage. I believe that our cities and our ships are liable to serious explosions with hardly a knowledge of from what cause, owing to surface electric current wire carriage, and it should be required to be reversed."

Nelson W. Perry.—The death of Mr. Nelson W. Perry, which occurred at Brooklyn, March 27, under distressing circumstances, removed a technical writer who has had few equals as such in this country. While performing some scientific experiments at his house, by mistake he drank from a glass containing poison, and though he subsequently rallied from the effects, a relapse the following day ended in death. Mr. Perry, who was the son of Hon. Aaron W. Perry, late of the Ohio Supreme Court, graduated from Harvard, and then pursued the course of mining engineering at Columbia College. For some time he was professor of chemistry in an Ohio college, and spent a number of years in the mining regions of the West. In

1891 he became editor of *Electricity*, and during part of 1893 was editor of the *Electrical World*; returning to *Electricity* the same year he finally severed his connection with that journal last year. Mr. Perry was one of the few writers on technical subjects possessed of a graceful literary style, which made his writing interesting in reading, no matter how intrinsically dry the subject might be. Always in touch with current scientific developments, his loss as a writer is a most regrettable one, while his wide circle of friends will long mourn his sad taking off in the prime of life.

Another Wizard.—The New York *World*, in its issue of March 20, had a sensational illustrated account of a new electrical invention and inventor, the article carrying the headlines: "Invention's greatest triumph, the making of sunlight," "It gives no heat, is cheaper than gas or electricity, and is so intense and clear that photographs can be taken by its rays," "1,000,000 volts passed through the bodies of four *World* reporters without harming them in the least." A reading of the article discloses that the great invention is vacuum tube lighting, the tubes being of the kind used by Hawksbee in 1709, and the whole exhibition of a kind, though on a larger scale, that could have been gotten up a quarter of a century or more ago in any college laboratory provided with Geissler tubes. Among the demonstrations which startled the reporters was a duplication of Hawksbee's experiment of lighting, by induction, a tube not connected with any wires, and the taking of a photograph "to prove that the light produced was really daylight or a substitute for it"—the reporters probably not being aware that in the photo-engraving department of their own offices, the photographing is done by artificial light. The inventor, John H. J. Haines, we are informed, "has already been hailed by authorities as the probable originator of the light of the twentieth century," and that he has been experimenting with the new light since 1890, five years having been spent on the mathematics and design of his apparatus. The apparatus is stated to consist of two induction coils.

Northwestern Electrical Convention.— For the 1898 summer convention the Northwestern Electrical Association has adopted the plan of engaging the steamer "Northwest," holding short daily sessions on the boat and ending with business and social sessions at Duluth, and a reception and banquet at Superior. The steamer will leave Chicago at noon on Friday, June 10, touching at Milwaukee for delegates who may find it convenient to join the party there, thence proceeding to Mackinac Island for a short stop, enabling a brief inspection of that celebrated resort; thence to Sault Ste. Marie and through the government locks and ship canal; thence to Hancock and Houghton to visit the Calumet and Hecla copper mines; thence past the "Pictured Rocks" and Apostle Islands to Duluth. Two days' stay will be made in Duluth and Superior, then home by rail. The mayors and common councils, the boards of trade and commercial clubs of both cities,have united in a cordial invitation to the association and its guests, and are now preparing for their welcome on arrival, and entertainment during the visit. A "convention hour" each day on the boat will be devoted to discussions by practical men on topics of practical interest to owners and operators of central station plants. It is intended to make the trip a valuable, as well as a delightful, one to all on board. The "Northwest," specially chartered for the occasion, is the largest and finest steamer on the lakes, and is surpassed by no ocean vessel in stanchness and elegance of appointments. She carries a fine orchestra, and has every modern improvement known to passenger boat construction, including an extensive and complete electrical equipment. No one but her officers and crew, and those invited by this association, will be carried on the trip.

Condenser and Induction Coil Insulation.— In making condensers, Prof. Fessenden advises, in a recent Institute paper, that the paraffine be heated at 220 degs. F., about three hours. The paper should also be heated and plunged into the hot paraffine. When made up, the condenser should be boiled for several hours to remove the air. A condenser so made, he says, if perfectly pure cellulose is used (perfectly pure paper is used in practice), and with pure paraffine, will stand 250 volts per thousandth of an inch when the dielectric is less than .01 in., and at a higher rate for greater thicknesses, with which the effect of small defects in one sheet of paper is not so serious. Practically the same remarks apply to the making of induction coils. Here, however, the great difficulty is that the paraffine in cooling is sure to shrink, and will leave hollows inside. The way to get over this is to construct the coil so that when cooling the shrinkage will take place outside, just as if one were making a casting of some metal having great contraction. The coefficient of adhesion also should be less between the walls of the mold and paraffine, than between the wire and paraffine; also the outside should never be let harden first, as then, of course, a hollow space is left inside. Another precaution is to expel all gases by heating the paraffine for some time above the temperature at which the coils are to be boiled. The coils should be boiled above 212 degs. F. for some hours to drive off the loosely combined water. This destroys the mechanical strength of the cellulose, but as the whole coil forms a solid mass this is of no great consequence. Silk should never be used where high insulation is required, as pure cellulose dry and boiled in paraffine is so much superior to it that there is no comparison. With pure cellulose, coils with only 1700 ft. of wire per inch of spark stand perfectly; that is, the spark may be five times longer than the coil. In ordinary use, coils having a spark length 3 1-3 times that of the coil have been run for long periods with no break-downs. Gilsonite mixed with paraffine is recommended as a good insulation for induction coils. The same material in combination with linseed oil also makes a good insulation.

Electrical Exhibition. —An interesting feature of the Electrical Exhibition to be held at the New York Madison Square Garden, during the month of May, will be a telegraphic tournament, which will include a typewriter receiving contest. Mr. Fred. Catlin, the manager of the tournament, hopes to make some new records for speed, both in sending and receiving. One of the remarkable features of the show will be an exhibition by Mr. H. V Pearsell, the well-known New York banker, of a collection of galvanoplastic objects, including reproductions of celebrated works of art, replicas of medals, antique coins, etc. Among the curious items are casts of living snakes and frogs, which are prepared as follows: A snake, for example, is etherized under a bell jar, then placed on a glass plate and posed. Around him is built an enclosure of four square bars, and a thin plaster slowly poured over the snake, the bars confining the cast in a rectangular shape. When the plaster is hard, it is freed from the sticks and glass plate, and the now defunct reptile is carefully removed, tail first from the cast. The plaster cast thus obtained is rendered waterproof by immersion in melted paraffin. A metallic conducting surface is then given to the interior of the cast by moistening the surface of the mold with a solution of silver nitrate and by exposure to sulphuretted hydrogen, which precipitates the silver on the cast. A conducting wire is now fastened around the edge, and the mold is carefully suspended in the depositing bath. A good firm coating takes about three days to form, and then the mold is softened in boiling water, and carefully broken off. Among other curious exhibits, will be the remains of two eagles, some storks and other birds, which had short-circuited high-tension circuits in California, while sitting on the wires, with the result of leaving only their beaks and talons, not a vestige of the bodies or feathers being discovered. Col. Heft, of the N. Y., N. H., & H R. R., has furnished drawings of the three-rail system used on his road, from which a model exhibit is being made. Over a track in the hall a train of cars will run to and fro continually, showing how the current is picked up and delivered to the motor, and how the switches and signals are included in the operation. A committee, which includes Profs. Geyer, Doremus and Loeb, has drawn up rules and regulations for an amateur electrical model-making competition, including small dynamos and motors, galvanometers and other measuring instruments, ingenious applications of electrical apparatus to electrical uses, etc. There will be included a competition of designs and working drawings of electrical apparatus by students and teachers.

Condensation in Steam Engines.

In another column Prof. W. F. Durand gives an admirable résumé relating to the action of the walls of a steam cylinder in producing condensation of steam, and the function of superheated steam in preventing such condensation. As pointed out, there are two factors entering in the general case—the range of working temperature and the conditions of the walls of a cylinder with respect to readiness of absorption and emission of heat. If the walls are wet or damp, they serve as a hiding place for heat, which is absorbed at admission and passes into the condenser after release without doing useful work.

The function of superheated steam is thus evident, being to keep the cylinder walls dry and thus reduce to a minimum their prejudicial effect. As this applies to each cylinder, it follows that for the best results the steam should be initially heated. Indeed, Prof. Durand is of the opinion that if the steam is wet at the start, it is doubtful if there will be any considerable saving from the use of receiver reheaters. It may be added that Corliss early recognized the value of initial superheating, and used a type of boiler in which the amount of this could be controlled within limits by having a greater or less amount of vertical tube surface above the water line.

Among Our Foreign Contemporaries.

With this issue we commence a new department under the above caption which, we believe, will be of much benefit to our readers. It will consist of notes and abstracts from our foreign contemporaries, the matter being confined to subjects of live interest or of direct practical value. Reference will not necessarily be made to the entire scope of the original article, the object being to give in a note the meat of an article, or to extract from it such part or parts as contain information of direct value, irrespective of the object of the writer in including such information. Where thought desirable, comment will be added, or the information extended. In short, the intention is not to give an index to foreign literature, but to select from it only such parts as may be considered of direct value to American readers, and to present it in a form that will make each note complete in itself. Should it happen, however, that a reader wishes to refer to the original article, we shall be glad to supply the indications necessary for him to obtain the number of the journal in which it appeared. The fact that Mr. Charles T. Child will have charge of this department will, we believe, be accepted as an assurance that its value to the reader will be of the highest. We will add that the matter will be compiled from the principal English, French, German, Italian and Spanish electrial and other technical journals, thus keeping our readers in step with electrotechnical progress in practically the entire world.

Fan Motors.

On other pages will be found our annual article on new models of fan motors, containing illustrations of the principal types that are now being placed on the market for the coming season. That there are improvements in efficiency over last year's models can safely be assumed in view of the competition in the field, and the growing use being made of the ammeter—either by the purchaser or the salesman who desires to demonstrate the superior efficiency of his motor. As to mechanical efficiency, no assumption is necessary, the introduction of ball bearings and bicycle fitting vouching for this. In shape and finish there has also been an advance, the machines of the present day being a vast improvement in this respect over those of even a few years ago.

One of the most interesting electrical machines of the day from the technical standpoint is the alternating current fan motor. When first put on the market this consisted of a series wound machine with a commutator. As the polarity of the armature changes with the polarity of the field as the current changes sign, its action was the same as a direct-current motor, except that the turning torque pulsated from a zero to a maximum value each alternation. The present alternating current motor is of the rotary field type; the field, however, not having the constant value of a regular two or three phased motor. The Shallenberger alternating current meter very clearly illustrates the mode of action of the present induction fan motor. The primary coil of the meter induces in a closed coil a secondary current differing in phase, the result being a rotary field which sets in motion a closed ring in the field. Similarly, in an induction fan motor some of the field projections are provided with a closed coil in which a neighboring primary sets up an induced current; the reaction of these poles with the primary poles sets up a rotary field which acts on a closed-circuited armature. If desired, an arrangement may be added to cut out the induced field when the machine gets up to speed, the motor then running as a synchronous single alternating current motor.

What Is Electricity?

In another column will be found a number of comments from authoritative pens, on an article which appeared in the March issue giving a résumé of the present state of knowledge concerning electricity. As the views expressed in the article, while contrary to popular opinion, yet merely expressed the scientific thought of the day, they are, as might have been expected, not controverted in any essential point. Dr. Kennelly brings forth an interesting speculation, but one which seems to be based upon the definition of the word "entity" rather than offering any conflict with present views. The remarks of Dr. Macfarlane on the two ways in which physical phenomena are regarded are suggestive, for it is by a lack of proper distinction between the objective and subjective, or through confounding the two, that the popular misconception concerning electricity has arisen. The views of Prof. Thomson on the relations between the various forces are extremely interesting, as they express the belief that the mechanical forces and properties, as well as chemical attraction, are dependent upon the electromagnetic properties of ether, and that the latter may furnish the key to the elucidation of the so-called molecular sciences.

The answer to the question, What is electricity? is then, that as electricity is but a name, there can be no answer. The true form of the question, and one that may some day meet with an answer is, What is the mechanism whereby mechanical, thermal or chemical energy is transformed into electrical energy? But even should a complete answer be given to the latter question, we know that it would not result in decreasing the cost of any of the present commercial methods of generating electrical energy, for the reason that the present transformations are so nearly perfect as to leave no margin. For example, in the article on another page on the Dolgeville plant, it is stated that the electrical generators are guaranteed to work at an efficiency of 94 per cent—that is, to turn into electrical energy in the exterior circuit 94 per cent of the mechanical energy supplied to the armature shaft. In the 6 per cent loss are included the bearing, air and collector brush friction losses; the electrical energy turned into heat in the windings and connections—that is, the copper losses; the energy lost in eddy currents and in hysteresis, that is, the iron losses. Which of these losses could be reduced by a complete knowledge of electrical action, and would their amount warrant, from the commercial standpoint, any expenditure of thought to attain such knowledge?

Should one be pressed for a reply to the question, What is electricity? he could retort by asking, What is gravitation or heat or light? If informed that "Electricity is but in its infancy," he might ask his informant in turn if he believed that gravitation, heat or light are also only in their infancy. If met with the prophecy that when we know more of electricity there will be marvelous developments in that branch, it would be well to ask if were we to know more of gravitation, should we also expect marvelous improvements in pile drivers and other mechanical machines. In short, let it be understood that instead of electricity being particularly surrounded with mystery, as much is known concerning it as is known of heat and light, and more than is known of gravitation.

Apparent Increase of Resistance of Conductors.

When an alternating current passes through a conductor there is an apparent increase of resistance of the conductor due to causes that will be noted further on. The drop which results from this increase of resistance should not, however, be confounded with the inductive drop due to the passage of an alternating current in a circuit. In the former case, with ordinary sized conductors and commercial frequencies, the increase of drop is negligible while in the latter case this is, of course, not true. The causes are different, inductive drop being due to the cutting of lines of force in and out of the area inclosed by a circuit, while the apparent increase of resistance in the conductor is due to the current being crowded toward the circumference, which is equivalent to the cross section of the conductor being lessened.

We can imagine the current flowing through a conductor to consist of an infinite number of filamentary currents, or the conductor to be composed of an infinite number of filamentary conductors, each carrying a current. If alternating, each of these currents will exert an inductive action on all of the others and in turn will be similarly influenced by them. Thus, filamentary conductors which lie nearest to the axis of the conductor will, it can readily be seen, be subjected to greater inductive action than a filamentary conductor lying on the circumference. The consequence is that the inductive or counter e.m.f. thus set up and opposing the flow of current, will be strongest at the axis of the conductor and weakest at the periphery. In other words, there will be greater opposition to the flow of current along the axis, and consequently the flow will be least there, increasing toward the circumference. The effect of this is as if the specific resistance of the conductor were increased by the passage of an alternating current, but we see that the real explanation is that all of the cross section of the conductor is not equally employed in transmitting the current. In the extreme case, where the frequency is enormous, but little current passes through the central portion of the conductor, it being practically dead.

With commercial frequencies, the phenomenon described need not be considered except in the case of very large conductors. For example, with a frequency of 80 the apparent resistance of a 000 conductor is only increased one-hundredth of 1 per cent. With a conductor 2 ins. in diameter, however, the resistance opposed to the passage of an alternating current with a frequency of 80, is twice as great as with a direct current. When it is necessary to use conductors of very large area, as on switchboards where a very large quantity of power is handled, hollow conductors should be used, for the reason that where the cross section is annular, the effect which we have described is very much lessened, since the filamentary currents are at a very much greater mean distance from each other. It is sometimes said that this is equivalent to removing useless copper at the core of a solid conductor and adding it to the periphery, where it will be utilized.

A lightning discharge is oscillatory in character, the thunderbolt thus being comparable to an alternating current of very great frequency; consequently, the resistance offered to a lightning discharge by the best conductor is enormous, since the current only travels along the skin. In this connection, it is interesting to note the different views that have been held concerning lightning conductors from the earliest days. Franklin believed in the use of solid lightning conductors, not knowing, of course, the effect of the frequency on confining the lightning discharge to the skin. About thirty or forty years ago lightning conductors began to be made of sheets of metal, generally twisted in spirals, on the absurd theory that since electricity resides on the surface, the surface of a conductor should be made very large. Later, when some scientific thought began to be given to lightning conduction, a return was made to the solid cross section. About fifteen years ago Prof. Hughes read his memorable paper on the conduction of currents of high frequency, in which experiments were described that definitely proved that the density of such currents is not uniform throughout the cross section, being greatest near the periphery. The theory applying was shortly after worked out, and several years later Lord Kelvin, then Sir William Thomson, published the formulas now in use for calculating the apparent increase of resistance of a conductor with frequency.

A LECTURE ROOM GALVANOMETER.

BY PROF. R. W. QUICK.

In giving experimental lectures in electricity before large classes of students, some type of galvanometer is necessary whereby the deflections of the needle can be plainly indicated to the whole class. This is sometimes accomplished by means of a long pointer attached to the needle, whose actual motion is thus directly observed. On account of the non-sensitiveness of such an instrument, deflections at times are too small to be observed, thus very much limiting its usefulness. Recourse is then had to a sensitive galvanometer of the mirror type and fibre suspension—the deflections being indicated by the movement of a spot of light obtained by the reflection from the mirror of a beam of light from a lantern.

Such a galvanometer fulfills all the requirements of sensitiveness, and gives observable deflections, but has one inherent defect which militates almost entirely against its use in many lecture rooms. Many lecturers have at their disposal only one stereopticon, which is ordinarily used to project on the screen apparatus in an experiment or to exhibit lantern slides. To use this with a mirror galvanometer would necessitate a change of position of the lantern and the consumption of much valuable time if it had to be done, as is so often the case, in the course of a lecture.

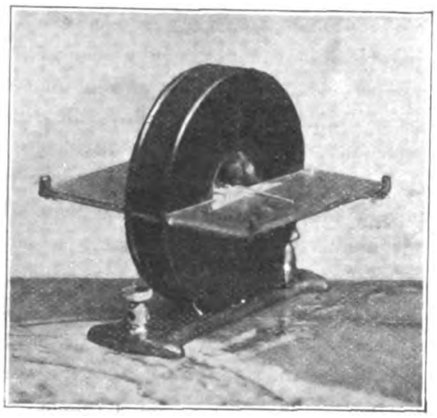

FIG. 1.—LECTURE ROOM GALVANOMETER.

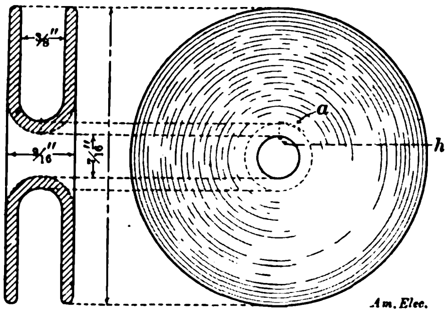
Two years ago the writer designed and constructed an instrument with a view to eliminating the objectionable features of the mirror galvanometer, and at the same time preserving its many good qualities. The characteristics of this galvanometer may be summed up as follows: Its needle deflections are plainly indicated; it is extremely sensitive; it shows quantitative relations of current throughout the whole range of its deflections; and it requires no adjustments in setting up except to turn the focus screw of the objective of the lantern. It only requires a vertical attachment to the lantern, an accessory which can scarcely be dispensed with in the use of a lantern for the projection of physical phenomena.

Having subjected this galvanometer to a thorough test extending over two seasons, and consequently believing that, on account of its simplicity of construction and ready adaptability to any lecture room provided with a lantern and its accessories, it would fill a want, a brief description is here given, accompanied by dimensioned sketches and a photograph of the instrument now in use in the writer's lecture room.

Referring to Fig. 1 the instrument is seen to consist of a hard-wood spool containing the copper wire, arranged in a vertical plane on a narrow wood base, shown separately in Fig. 4. At the centre of the hole through the spool, whose elevations are shown in Figs. 2 and 3, is suspended by means of a single silk fibre, an aluminum pointer, visible in Fig. 1, whose length is 1¾ ins. and whose width at the centre is 1-16 in. On the under side of this pointer, at its centre, and at right angles to its length, is fastened by aid of wax a watch spring magnet a little less than 1-16 in. long. Underneath the pointer, with space for clearance, is placed on each side of the spool a glass shelf containing a scale with divisions proportional to the tangents.



FIGS. 2 AND 3.—END AND SIDE ELEVATIONS.

Placing the instrument on the vertical attachment of the lantern, the light is reflected upward through the glass shelf, after another reflection is rendered horizontal, and the image of pointer and scale is focused on the screen or wall.

With a magnetic needle of the above length and with dimensions of spool as given in Figs. 2 and 3, the galvanometer obeys almost exactly the tangent law, and hence is extremely useful for quantitative experiments. In order to allow a sufficient deflection of the pointer, the hole in the spool should be shaped as shown in Fig. 2.

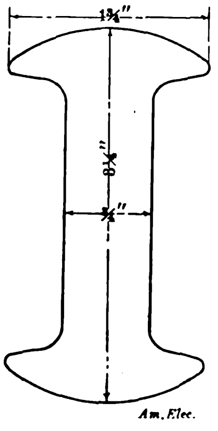


FIG. 4.—BASE.

The glass shelves can be held in place by various methods. A simple way is to pass stiff copper or brass rods or wires through holes near the periphery of the spool flanges, as can be seen in Fig. 1. On these supports the glass shelves are fastened. By far the best method to provide the glass with a scale is to immerse for several minutes a non-exposed photograph plate into the hypo solution, which leaves the film perfectly transparent. After drying, the glass plates, which have been previously cut to proper sizes (2½ ins. x ⅞ in. for the galvanometer shown in the photograph), are firmly secured, film side up, on a table at exactly the distance apart which they will be when fixed on the spool, and by means of drawing instruments and india ink, a circular scale, with divisions proportional to the tangents, can be very accurately drawn on them. The numbering of the divisions should be such as to make the figures in their proper positions on the projected image when the plane of the coil is in the magnetic meridian.

Whatever form the base of the instrument is made to assume, it must allow the free passage of light vertically through the glass scale. The thickness of the one shown in Fig. 4 is 5-32 in. To provide a means of support to the suspended system, a very small copper wire terminating in a small hook, *h*, Fig. 3, is inserted through the spool before it is wound, with its inside end, *a*, turned down and held firmly by the copper wire that is afterward wound on the spool. With considerable dexterity and more of patience, a silk fibre, already attached to the aluminum pointer with its magnet, can be fastened by wax to the hook, *h*, so that the pointer, when properly balanced, will nicely clear the glass shelves.

The size of wire on the spool depends entirely upon whether the galvanometer is to be used with high resistance or low resistance circuits. No single galvanometer can be entirely satisfactory for *all* classes of lecture experiments; for example, in thermal currents a very low resistance galvanometer should be used, while a high resistance instrument is generally desirable in showing induced e.m.fs. A resistance of about 5 ohms, given by No. 24 B. & S. wire on the spool of Figs. 2 and 3, is satisfactory for most experiments.

To minimize the disturbing effects of air currents on the pointer, a paper is cut of proper shape to be inserted just beneath the pointer, and is stuck with mucilage to the under side of the inside edges of the glass shelves, as shown in Fig. 1. The galvanometer should also be provided with a cylindrical case having a glass plate top that can be placed over the instrument when in use in the lantern.

A 5 ohm galvanometer constructed with above dimensions, in the earth's field as controlling force, will give an observable deflection on the screen, when joined in series with a storage cell and 1000 ohms resistance.

Water as a Non-Conductor.

Perfectly pure water is a non-conductor of electricity, but being an almost universal solvent, it is not found pure in nature, and when prepared by distillation soon becomes contaminated. The evil electrical effects of dampness and wet are, therefore, due to the matter dissolved in the water present.

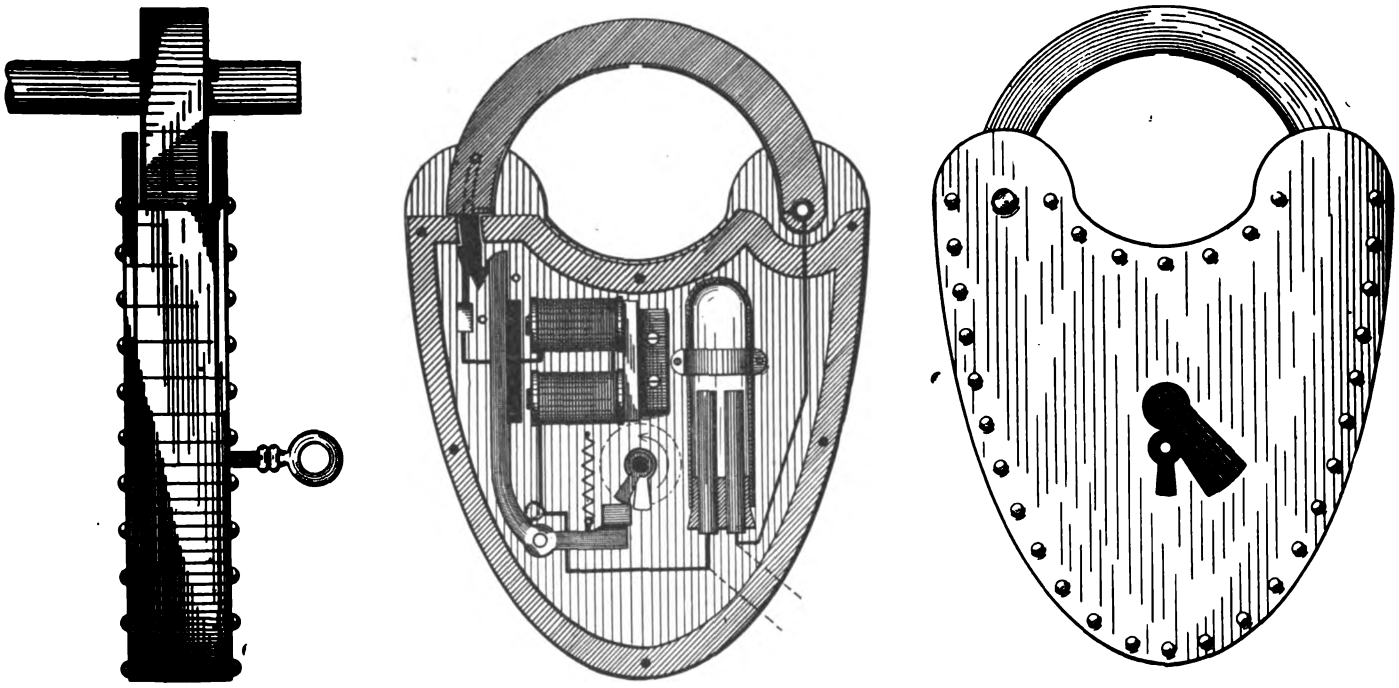
ELECTRICAL APPARATUS FOR AMUSEMENT—IV.

THE OBEDIENT PADLOCK.

BY NEVIL MONROE HOPKINS.

Had the cell doors of the Bastile, or the gates of detention in the fortress San Leon, been equipped with such accommodating mechanism, friendly to those of the Black Art, as the herein described magic lock, the notorious Count Cagliostro would have fared less badly because of his illegitimate use of sleight of hand, together with his fraudulent practice of medicine and association with freemasonry. Although this celebrated trickster caused the bolts in the Bastile to be thrown, regaining his liberty to again practice theft, and impose on the ignorant with his "elixir of immortal youth," the locks of the fortress San Leon were turned upon him with less mercy, imprisoning him until his death in 1795. As the space in the following columns is devoted to a constructive description of a specific piece of mechanism and its accessories, the writer can only refer those interested in this famous quack to the miscellaneous essays of Carlyle, where an absorbing picture of him is painted.

By referring to the first illustration in the series, the "portrait" of the lock may be seen, its true "character" not being learnable from its face. In addition to familiarity with the physiognomy of the lock, one may become intimate through handling, unlocking, and locking by means of its key, without the slightest chance of the lock's real character being understood. Unfortunately for those who practice sleight of hand on the streets of our modern cities, the lock herein represented is the only one in existence, although the following description may lead to the completion of others for the liberation of ghosts and phantoms. The second illustration shows up the internal mechanism of the lock from behind, the back plate being removed.



FIGS 1, 2 AND 3.—FRONT, INTERIOR AND SIDE VIEW OF PADLOCK.

This lock should be made at least 8½ ins. in height, measuring from the bottom, to the top of the hinged staple, and 6 ins. in extreme width. The lock is best made from hard, well seasoned wood, and is put together with furniture glue in combination with brads, or round headed screws. In starting the construction of this padlock, a satisfactory design is drawn full size by means of French curves, and compasses on a smooth piece of board 1 in. thick. If the lock is to be painted, black walnut will answer admirably, the thin covers for the front and back being readily obtained in this wood. Having completed a full size drawing of the lock on the 1 in. board, the design is cut out by means of a band saw, the use of which may be had in almost any patternmaker's shop or saw mill. This may of course be done by hand, employing a fine tapering saw blade used in sawing out circles, but the resultant model is liable to be less accurate.

Having this accomplished, the center must be sawed out, leaving a wall at least ⅜ in. thick all around. Where the staple of the lock hinges, the wall must have an inward curve, as illustrated in Fig. 2, the wall being drawn in with cross sectional lines. Two additional pieces of wood must be sawed accurately to pattern, from wood ⅛ in. in thickness, which form the front and back covers of the lock, by gluing and screwing respectively to the thick pattern or frame. The front plate is securely glued, and screwed to the front of the frame, using some 30 round headed brads or screws for effect. In order to prevent the splitting of this frame by the screws, small gimlet holes must be carefully made for their reception.

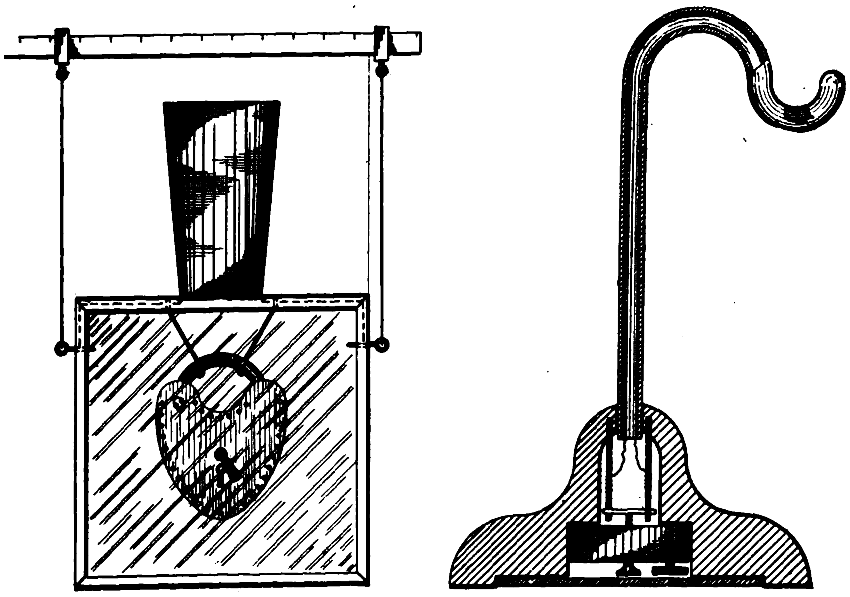
The hinged finger, or staple, is sawed from a piece of the 1 in. board, being a perfect semi-circle ⅝ in. in depth, by the 1 in. in thickness. A thin brass catch is filed to shape, and attached to the free swinging end of the hinged staple as shown. This catch may be made slim and broad, extending across the width of the lock, or it may be a little over ¼ of an inch square, with a 1 in. shank running into a hole in the staple. If a square catch is made, the wall of the framing should have a neat square hole cut out to allow the easy entrance of the catch into the lock. In order to make the connection between the shank of the catch and the swinging staple secure, both should be drilled through, and be provided with little hard wood plugs driven in. The catching mechanism on the inside is very simple, designed to be tripped, or thrown by means of a key, as shown, or by means of the pair of electromagnets. This catch may be made entirely from iron, or be cut from brass, and be equipped with an iron armature opposite the magnet poles.

As the front of the lock is only a thin wooden cover, the magnets and the pivot cannot be made very secure by screwing directly to the wood, the use of a thin brass plate being recommended. This brass plate, not shown in the drawing, can to advantage be made to cover the key hole, being drilled out to just admit the key. In order to prevent the key from wabbling in the lock, the back plate before screwing on should be provided with a pin, fitting into the hollow of a chosen key. A spiral spring keeps the catch away from the magnet poles, and in contact with the locking catch.

It will now be seen that the lock is closed and opened exactly like an ordinary spring lock, having a secret pair of electromagnets in addition capable of releasing the catch with the key absent. This lock being self-contained, carries its own battery for the operation of the magnets. Before describing the type of battery the operation of the lock will be explained.

It will be observed that the brass catch on entering the lock makes contact with a spring jack or electrical contact strip of brass. This spring jack leads to the electromagnets, and thence to the pole of the little battery. The other pole of the battery is connected to the pivot of the swinging staple. This pivot is of brass mounted on a little brass plate for strength, and is screwed to the wooden sides of the lock. Two thin strips of brass or copper are bent around under the staple, and are attached by the smallest brads. As illustrated these will now be readily seen that any metallic body coming in contact with the two brass strips do not meet in the center, a gap of about ⅛ in. being left. One of these strips is secretly attached to the pivot of the staple, and the other to the brass catch. It strips will complete the electrical connections and throw the catch of the lock.

The battery in the present case consists of a large glass test tube or combustion tube, as used in chemical laboratories, fitted with a rubber stopper with two holes. These may be had from any chemical supply house, the combustion tubes being preferable because of thicker glass. The elements of the battery consist simply of a carbon, and zinc stick. As shown, the battery is seemingly installed upside down, but this was intentionally done in order to put the battery out of use when not needed, thus saving the zinc, by turning the lock bottom side up, causing the exciting fluid tery is seemingly installed upside down, but this was intentionally done in order to put the battery out of use when not needed, to occupy the free end of the tube. The exciting fluid may be either a solution of bisulphate of mercury, or of bichromate of potash and dilute sulphuric acid. To excite the battery with bisulphate of mercury, about half a teaspoonful of the powder is put in the test tube or combustion tube, and sufficient water added to allow of the covering of the elements when the battery is in use. To charge the combustion tube with the bichromate of potash and acid, an ounce of sulphric acid should be added to three ounces of water, and a lump of bichromate of potash added the size of a walnut. With this solution the zinc of the battery shoud be amalgamated with metallic mercury. This is quickly done by dipping the zinc in the acid solution for a few seconds, then removing and rubbing with mercury until the zinc shines like a mirror.



FIGS. 4 AND 5.—METHODS OF EXHIBITING TRICK.

The magnets should be wound with comparatively fine wire in order to secure good excitation with a single battery with such small elements. For best results, the resistance of the magnet should equal that of the battery. Of course, if two such cells are added the lock will open with more energy. It will also be apparent that the lock may be worked from an outside battery, whose wires are secretly brought in contact with the copper bands under the staple, if the two wires where they enter the little contained battery are twisted together. These wires are marked with dotted lines, showing how easily the battery may be "shunted out." The back plate of the lock may now be screwed on, and the lock carefully sandpapered in order to make all edges neat looking and even. The back of the lock should have the same number of screw heads showing as the front, for the sake of appearance, but only six of these need be real screws in order that the back may be easily removed. Some little skill and care is necessary in the succesful making of this lock, as it should present only the neatest and most innocent appearance.

Having charged the battery, and screwed on the back, the lock is ready for a test. Fig. 3 shows a method of exhibiting the "wonders of its intelligence." In this case the lock is represented hanging from the end of the magician's wand. The wand has a little metallic saddle of copper or brass attached near one end which may be brought in contact with the bands under the staple of the lock by secretly turning the wand. The conjurer may hang the lock from one finger, allowing the double bands to come in contact with his ring when the lock is commanded to open. Figs. 4 and 5 show two additional methods of showing the trick. Fig. 4 represents the lock hanging from a couple of hooked wires on the inside of a glass box. The box has thin wooden framing and glass sides like a honey box. The screw eyes are for effect, made to pass right through the sides of the framing. The top of the box is provided with little copper plates connected with the supporting hooks, which may be joined by standing any metallic body upon them. In the present case a little tin cup without any bottom is represented standing on the plates. The bottom edges of this cup have been shellaced, making the device inoperative unless the key, or a coin is thrown in.

Fig. 5 shows a design for an automatic device with which the lock may be opened without the assistance of the operator. This little stand may be placed on a piece of glass and covered with a glass shade, and yet the lock will be opened at the command of the magician. This stand has at the hook a couple of small insulated saddles, with connecting wires running to the base. Here a cheap watch movement is provided capable of connecting the circuit at almost any determined time. The performer must know when to expect the watch to make contact, by experimentation after it is once released, or he may say the watch will open when a dispatched spirit has completed a certain journey, arriving at a place of destination, within the glass shade which covers the lock, and stand. The lock can be taken from its stand at any time, and be examined by anyone who may unlock it by means of its key, locking it again himself. Without the key the lock is as stubborn and defiant to the outsider as an everyday mule.

INTERIOR WIRING.

BRANCH CIRCUITS.

BY CHARLES E. KNOX.

Having treated in the previous article of the system and method of wiring, we now come to the problem of laying out the branch circuits.

In the article printed in the February issue we discussed the matter of locating the outlets and lights, and of securing available points for distributing centers and rising points. Before starting to lay out the branch circuits we should obtain from the architect a drawing of the floor construction, showing the space between the top of the beams and girders, and the flooring. In fireproof buildings of iron or steel construction it is almost the invariable practice, where the work is to be concealed, to run the conduits over the beams, under the rough flooring, between the sleepers, when running parallel to the sleepers, and by notching them where running in a perpendicular direction (see Fig. 1). In wooden frame buildings the conduits run perpendicular to the furring (see Fig. 2); they are also sometimes run below the beams. In the latter case the beams have to be notched, and this is only allowable in certain places, usually near the points where the beams are supported. The architect's drawing is therefore necessary in order that the location and course of the conduits may be indicated on the plans.

In discussing the question of distributing the outlets, we selected a dwelling house by way of illustration. For the present, however, we will not confine ourselves to any particular type or class of building, but will consider the problem in a general way, making reference where necessary to points of difference which should be made in the wiring, dependent upon the type of building to be wired. In general, however, unless it is stated to the contrary, our remarks will apply more particularly to buildings which have not been completed before the wiring is installed. These cases form a large majority of the total number. In a later number of the series we will take an example of a completed building and treat more fully of the method of wiring it.

The first point for consideration in laying out the branch circuit work is the number of outlets and the number of lights which may be wired on any one branch circuit work. The rules of the National Board of Fire Underwriters, which are the rules that generally govern electrical work in this country, do not restrict the number of outlets that may be connected to one circuit. The number of lights, however, which may be wired on one branch circuit is limited by the current-carrying capacity of the wire. As No. 14 wire is the standard size for branch circuit work, we will take it as a basis. Of course, No. 12 is very frequently used, but it is advisable to use this or larger sizes only when necessary to reduce the loss in an unavoidably long branch circuit. The allowable current-carrying capacity for No. 14 wire, according to the latest rules of the National Board, is 12 amperes for rubber-covered wire and 16 amperes for weatherproof wires. The number of lights on any circuit is further restricted by the rule in regard to automatic cut-outs (fuses and circuit breakers), which requires that cut-outs "must be so placed that no set of incandescent lamps, whether grouped on one fixture or several fixtures or pendants, requiring a current of more than six amperes, shall be dependent on one cut-out." Of course, we can comply with this rule and yet carry more than six amperes on a branch circuit, by using fixture or local cut-outs. These fixture cut-outs are so objectionable, however, that it is much better to limit the current on the circuit to six amperes and place all the fuses in cut-out cabinets.

This rule may in some cases seem a handicap, but the factor of safety in the carrying capacity of branch circuits should be sufficient to allow the number of amperes to be at least doubled. The reason for this is that it is very common to entirely replace the 16-c.p. lamps on a branch circuit by 32 or even higher candle power lamps. Then, too, it is such a simple matter to extend a circuit or make a "tap" on an existing outlet for additional outlets (and this, too, generally without the knowledge or permission of the electrician in charge of the plant), that it is wise to leave ample margin in the branch for using higher candle power lamps and for circuit extensions. All things being considered, it is probably best to limit the number of lights on a circuit to eight, or at the outside ten, 16-c.p. lamps, the lower number being preferable in the majority of cases. (We assume here that 110-volt lamps, and not not 220-volt lamps are used.)

In determining the number of outlets on a circuit, it is well to remember that each outlet connection is a possible source of trouble. For this reason it is wise to keep the number of the outlets on a circuit at the lowest point consistent with economical wiring. It has been proven by actual practice that the best results are obtained by limiting the number to five or six outlets on a branch circuit. Of course, where all the outlets have a single light each, it is frequently necessary, for reason of economy, to increase this number to eight, and in some cases to ten outlets.

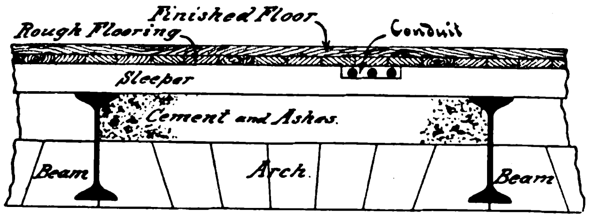


FIG. 1.—FLOOR CONSTRUCTION IN IRON FRAME BUILDINGS.

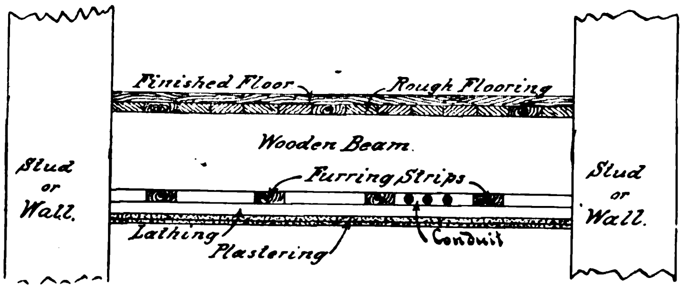

FIG. 2.—FLOOR CONSTRUCTION IN WOODEN FRAME BUILDINGS.

We have already referred to the location of the wires or conduits. This question is generally settled by the peculiarities of the construction of the building. It is necessary to know this, however, before laying out the circuit work, as it frequently determines the course of the circuits.

Now, as to the course of the circuit work little need be said, as it is largely influenced by the relative position of the outlets, cut-outs, switches, etc. Between the cut-out box and the first outlet, and between the outlets, it will have to be decided, however, whether the circuits shall run at right angles to the walls of the building or room, or whether they shall run directly from one point to another irrespective of their angle with regard to the sleeper or beams. Of course, in the former instance, the advantages are that the cost is somewhat less, and the number of elbows and bends is reduced. If the tubes are bent, however, instead of using elbows, the difference in cost is usually very slight, and probably does not compensate for the disadvantages resulting from running the tubes diagonally. As to the number of bends, if the branch circuit work be properly laid out and installed, and the proper size tube used, it rarely happens that there is any difference in "pulling" the branch circuit wires. We may happen, in the event of a very long run, or one having a large number of bends, that it might be advisable to adopt the short and most direct route.

The advantages of running the tubes at right angles to the walls of the building or room are, that the tubes may be grouped much better at the cut-out cabinets; there is much less damage to the sleepers where they have to be notched, a more symmetrical and workmanlike piece of work is obtained, and there is less trouble where tubes cross each other. It very frequently happens that there is very little space between the top of the beams or girders and the finished floor, and when this is true, it is more difficult to keep the tubes down when they run diagonally than when they run at right angles.

It very frequently happens when the tubes are run diagonally that several tubes cross each other at one point, the result being that there are three or more tubes, one on top of the other. If the tubes were run at right angles on the other hand, this would be easier to avoid and much less likely to occur.

The greatest disadvantage of running the tubes diagonally, however, is the demoralizing effect it has on the workmen. It undoubtedly has the tendency to make them run the tubes "any old way," so long as they are continuous; moreover this effect is not limited to the conduit work alone, but is apparent thereafter through the entire installation.

A FACTORY TELEPHONE SYSTEM.

BY D. H. FITCH.

I was asked to furnish a telephone system to connect the several floors and departments of a large sash, blind and door factory.

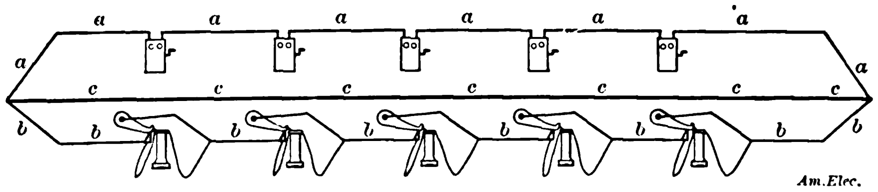

FIG. 1.—GENERAL PLAN OF CIRCUITS.

The conditions to be met were, the noise, vibration and dust from high-speed woodworking machinery, and, prospectively, light and power currents in the building.

There was, so far as I know, no system that would answer. The noise and vibration were extreme, and dust did not permit of any switches in the main circuit.

I aimed to devise an inexpensive system, which would fully meet all of the requirements.

Of the accompanying diagrams, Fig. 1 illustrates the general plan of circuits, and Fig. 2 the details of a station. Fig. 3 shows the transmitting and receiving apparatus. Three wires are employed. The call bells are in series on the call wire, a, Fig. 1; the speech apparatus in series on the wire, b, and c, serves as the return wire for both sides.

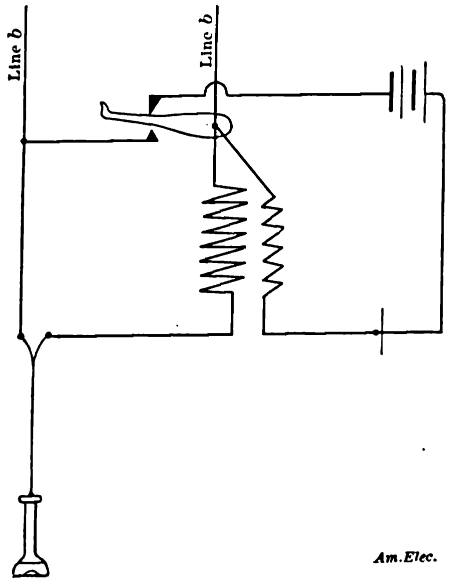

FIG. 2.—DETAILS OF A STATION.

The call boxes are plain magneto bells, with none of the usual telephone switches. At the stations, Fig. 2, the upward movement of the hook lever closes the transmitter battery circuit, and the downward movement connects together the two line terminals, thus shunting the transmitter and receiver.

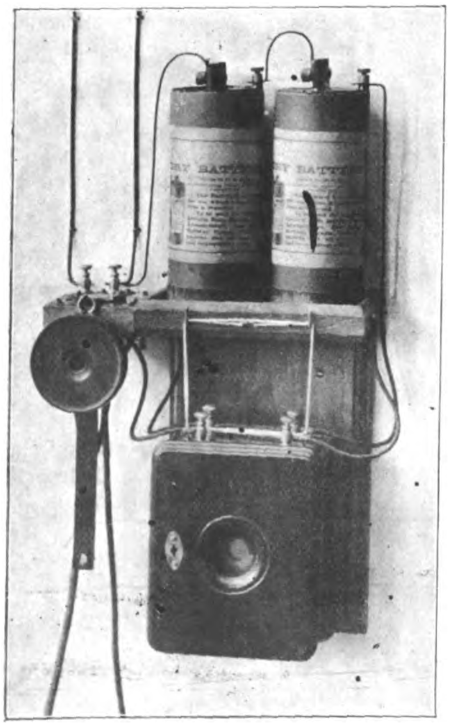

FIG. 3.—TRANSMITTING AND RECEIVING APPARATUS.

The main circuit is never broken, and hence there is no possibility of interruptions due to defective spring contacts—a necessary provision where there is so much dust.

The speech apparatus is placed in soundproof inclosures, and the bells so located outside as to be best heard by the foremen.

The transmitters are suspended on elastic cords, and connections made by means of flexible conductors. The lines between the stations are in the form of a twisted three-wire cable, and hence silent as to light or power currents.

There being no impedence in the speech circuit while the telephones are on the hooks, the number of stations which can be worked in series is limited only by the number of bells which can be rung.

The system has worked very efficiently—in fact more free from disturbance than telephone systems in general. It was put in use in September, 1896, and thus far has required no repair, other than replacing exhausted batteries.

SOME WORKSHOP HINTS.

BY JAMES F. HOBART, M. E.

The armature builder's lot is not always a happy one, mechanically considered, for he has many troubles to contend with which do not always appear upon the surface. For instance, in packing up an armature core, it is a very tedious operation to get the core equalized so it will not be either crooked, or one side longer than the other. Some of the trouble met with in this line is caused by the unequal thickness of the iron from which the disks are punched. Secure the best rolled sheet of iron possible, and cut a transverse strip from it. Careful measurement with a micrometer will show that the iron is thicker in the middle than it is at either edge, and if an armature core be built up from disks cut from one side of a sheet, as shown at *A*, Fig. 1, it will be crooked when the bolts are tightened up, in spite of all that can be done.

A partial solution of this difficulty is to reverse the die to the position shown by *B*; that is, with the key-way in direction of the length of sheet. With the blanks punched in this manner, it is possible to reverse every alternate disk when packing up the armature core, and thus, to a certain extent, pile the disks " tips and butts " like a bunch of shingles. This will prevent the core from being crooked when tightened up, but it will not prevent portions of the circumference from being solid while other portions are slack. Still, it enables a very good core to be built up, and as no material or workmanship is perfect, the result answers very well for the purpose for which intended.

How many builders of generators and motors have studied the proper relation between thickness of commutator segment and thickness of the mica insulation? There is a relation, and a vital one, regarding the life of the commutator and its freedom from sparking. There is considerable difference in the behavior of copper and mica, when both are subject to the same wearing pressure, as in a commutator.

If a special commutator was made up with one-half copper, and the other half mica, and exposed to the action of brushes, what would be the probable condition of that armature after a month of steady wear? Probably the copper and mica would wear differently, one faster then the other. Make another commutator with four copper segments and four mica insulations between, each ½ in. thick, and see how the brushes behave after they have been running on that commutator for one month.

It will be found that the commutator does not wear well when the mica is too thick, and that there is a certain relation between the thicknesses of the two, which makes the difference between a good and a bad wearing commutator. In many commutators put out with machines, the mica is too thick, and does not wear down fast enough to accommodate the wear of the copper. We all know what happens when a ridge, or a series of ridges, are formed on a commutator—that the brushes gouge into the copper just beyond each ridge, making it impossible to keep the commutator in good order, or the machine from sparking. This relation might be profitably studied by a number of concerns that manufacture commutators.

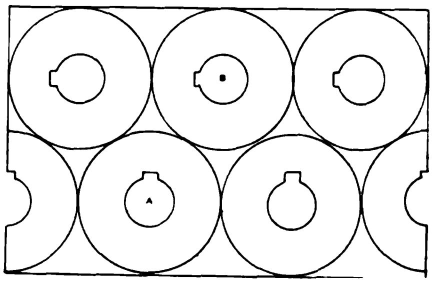

FIG. 1.—PUNCHING ARMATURE DISKS.

One thing which all shops might profitably install is some device whereby shafts and mandrels can be forced into and out of hubs or holes. It is too much like " the good old times " to see two or three men with sledges, one man with a copper hammer or a bar of babbitt metal, and another man holding the work—all these men congregated around a miserable little wheel, gear or drum, engaged in pounding a shaft into it.

Just sit down and figure the actual cost of forcing a shaft home by such means, then figure out what it would cost to do the work with a wheel press or some form of home-made hydrostatic rig, in which power is applied by a 10 or 20 ton "whisky jack," as shown in the outline, Fig. 2.

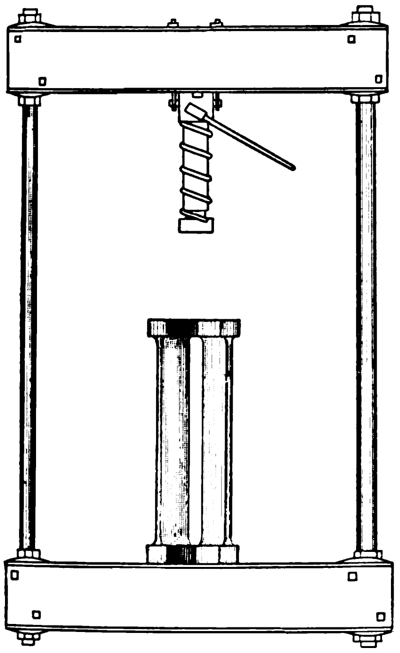
Every shop ought to have a couple of these useful tools, and they can be used for other work besides mandrel pressing, but, better, get one for this purpose alone, and rig it up specially for that purpose. Then it will be where it belongs when wanted. The ordinary V-shaped mandrel driving stand may be used in constructing this, but better get one on purpose for it and let the hand drive stand alone.

Get a couple of pairs of I-beams, long enough to span any work likely to be put into the press, and stout enough to stand the strain of the jack at the length wanted.

Any catalogue of architectural iron will give the dimensions necessary for this. Separate the pairs with a few inches of iron, and bolt the whole together. This leaves a space between the I-beams for a shaft or mandrel to be put through. Connect the two pairs by means of two heavy rods, with shoulder plates at top and bottom to engage the pairs of I-beams, and nuts and washers to screw up outside of the beams.

Make the rods long enough so that the driving block already mentioned, can stand inside when the frame is put together, and still leave room for the length of the jack, and the work that is to be done. Some whisky jacks will work when placed bottom end up. If you have one of this kind, invert it, and belt it to the upper pair of I-beams. If the jack will not work inverted, belt the head to the top of the frame, and attach a coiled spring heavy enough to pull the jack together when the lever is reversed, and the pump valve tripped.

A rig of this kind, with a 20-ton jack, need not cost more than $100, and with it, one man can do more and better work than the six men mentioned above, with all the sledges they can get on to the work. The quality of the work done by apparatus of this kind is much better than that done by hand, as the progression of a mandrel is by steady pressure, instead of by a succession of jerks that must be very hard on the cast iron hub. Indeed, on more than one occasion, the writer has seen castings ruined by one of the strikers missing his aim, and the force of his blow, carrying away an arm, or a segment of the rim of a pulley or wheel.



Am.Elec.

FIG. 2.—HOME-MADE MANDREL PRESS.

The writer recently was shown a very ingenious arrangement of a circular saw for the A. B. See Company, and is for the getting out of elevator work, cleat work molding of special grooves, etc., used in connection with electric elevator work. The saw in question was mounted beside a sliding carriage much the same that an ordinary edging, or "jointing" saw is hung. The peculiarity of this machine is, that the saw should be revolved through an arc of about 60 degs., so as to either cut "square" with the face of board, or to swing around within 30 degs. of parallel therewith.

The saw arbor was mounted in a frame which could be revolved to the desired angle, and then made fast. The belt was kept on the saw pulley by having a long drive pulley to travel on and a guide pulley of the same length to take the belt into the right direction. The saw could have its angle changed in a very few seconds, while running or while at rest.

This arrangement displaces the usual rigging up of tilted rests or fences, and enables the work to be laid flat on a sliding carriage and then, in that position, pushed past the saw. The fence method requires that the work be held in position by the workman and at all times guided by him so as to keep the saw on the line where the cutting is required. In fact, it makes as much difference in the accuracy of the work, as it does when a man who has been trying to grind a straight surface on the edge of an iron bar, is given a planer or milling machine on which he can fasten the work securely, and in that position send it past the cutting tool.

I am not informed that any patent has been applied for in connection with this machine, and think it possible that arrangements could be made with the maker whereby the use of the machine, or even castings therefor, could be procured at a slight expense. The machine would make a unique and most desirable addition to the machine shop tools. For the pattern maker alone, it will be worth much more than its cost.

ELECTRIC RAILWAY PRACTICE.

BY EUGENE C. PARHAM.

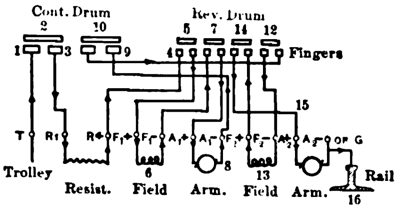
INSTALLATION.

In the previous articles all of the wires, with the exception of several inside the controller, which carry the current of both motors under all conditions, have been gone over, and therefore if there is any trouble it must be between the trolley and ground controller connecting posts.

To proceed with the test we had best have some knowledge of the car wiring diagram of the system in question; that is, a knowledge of the order in which the current from the trolley enters the several devices on the car, and the relation borne by the terminals of these devices to the lettered or numbered binding posts on the controller.

A careful reader may take exception to the expression, "order in which the current enters the several devices," thus, in a measure, defining the current direction as something to be determined; but such is not the meaning to be construed, as we wish merely to signify the relative positions of devices in regard to the grounded and ungrounded sides of the circuit. The question is often asked: "On your equipment, which does the current enter first, the armatures or the fields?" Now this is a very natural way of putting the question, supposing, as is generally the case, that the trolley wire is positive, and that the current flows, therefore, from the wire toward the rail. But the polarity of the wire is really immaterial, except in special cases, as is evidenced by the fact that there are roads running with negative wire and positive rail, in which cases the order in which the current enters the devices has been reversed, but the position of the devices, relative to wire and rail, has not. A more correct way to put the question would be, then, "Which lies nearest the trolley wire, the motor field or the armature?" or "Which do you ground, the field or the armature?" A general answer to the question is, some systems ground the field, and others the armature. The advantages and disadvantages of the two methods will be discussed elsewhere.

On all systems of wiring it is customary to designate the terminals of the various devices by means of the initial letters of their names. These letters are further modified to distinguish the different leads coming from the same device, and, further, the letters are stamped on the controller connecting posts, so the most inexperienced wireman may readily see to what part of the controller the variously tagged hose wires should go. In Fig. 2 we have selected the most common system of lettering, and have further facilitated following the path of the circuit from trolley to rail by adding the arrow heads and numerals. Fig. 2 gives the path of the current on an actual controller, when the drum rests on the first notch series, and the reverse drum is at "go ahead." 1, 2, 3, 4, etc., up to 16 gives the path of the current, as indicated by the arrow heads. In this diagram, all parts not used on the first notch series have been omitted.



Am.Elec.

FIG. 1.—PATH OF CURRENT ON CONTROLLER

We will now resume the test and locate a fault supposed to exist somewhere between connecting posts T and G, in diagram 2. With both hood switches closed, we attach one test line permanently to T, and with the other touch successively posts R 1, R 4, F 1 +, F 1 —, A 1 +, A 1 —, etc., to G. As soon as we touch a post which is nearer the ground than the fault, the test circuit bridges the fault and offers a path to earth through the lamps, which will then glow. Suppose an open circuit to exist between the finger marked 1 and the drum contact ring marked 2; then if no other open circuit exists in the connections the lamps will glow as soon as we touch post R1, and this will prove the trouble to lay between T and R1; but we do not yet know whether the fault is in the wire connecting T to finger 1, or in the failure of contact between 1 and 2, or 2 and 3, or whether it is in the wire connecting 3 and R4. To determine this, touch successively 1, 2, 3 and R4.

Conditions are much complicated where two open circuits happen to exist, for then although the test lamps may bridge one open circuit, there will be another in series with them, so no current can flow, making the indications misleading. To detect such a state of affairs, proceed as follows:

Suppose open circuits to exist between T and R1 and also between A1 + and A1 —; keeping one test line on G, begin at T, and touch R1, R4, etc., until a post is touched where the lamps fail to glow. In this particular case the post will be R1, locating the fault between T and R1; next, attach a test line to T and move the ground test line from post to post in the reverse order. As soon as we touch A1 + the lamps will fail to glow, showing the fault to exist between A1 + and A1 —, that is, in the armature or in one of the wires leading to it. Where more than two open circuits exist, two of them must be located as above and removed before the others can be conveniently sought.

Points about an equipment most apt to give open circuit troubles are, poor connection between trolley stand and roof wiring; defective hood switch; loose controller connection, controller finger making no contact; resistance coil burnt out; motor field or armature lead burnt off; a blown fuse; weak brush springs, short brushes, brushes tight in the holders or absence of brushes altogether; ground terminal burnt off; loose two-way connector, and a dirty or dead rail. A car shed electrician is generally familiar with the weak points of all those equipments under his charge, and can usually locate most of his troubles by a careful inspection.

Consideration at length of what ailments certain symptoms indicate will be deferred until we shall have considered short circuits and open circuits on specified plans of wiring.

If upon throwing the controller on and off a flash is observed, it shows the circuit to be closed, and if the car refuses to respond, the indications are that either motors are opposed, or some more serious wrong connection exists. By trying one motor at a time it can be determined whether they concur in direction or not. Should the motors start the car in opposite directions for a given position of the reverse handle on the controller, ascertain if the same is true on the other controller. If so, one motor's field or armature leads must be reversed. If not so, or if the car has but one controller, the change can be made at the controller.

Trouble due to interchange of wires in wiring the controller generally declares itself very forcibly when the controller handle is advanced beyond the resistance points. The actual symptoms consequent upon some error in wiring will be deferred to a consideration of the several systems of car wiring in detail. Should the car start in the same direction, whatever the position of the reverse handle, it shows the reversing gear to be mechanically defective, i. e., although the reverse handle turns to indicated positions, some missing pin, screw or key prevents the switch or drum from turning with it. The writer knows of but two occurrences of this uncommon trouble.

If upon throwing the handle of the controller to the "off" position, the car gives a sudden lurch forward or backward, according to the position of the reverse handle, it means that for some reason which should not exist, the drum contact rings, which should come into action only on the last notch, have been allowed to swing around and make contact with the fingers. This may be due to any of several causes. 1. Some of the drum rings may overhang too far. 2. Some of the drum castings may have become loose and shifted on the drum shaft. 3. The index wheel may have slipped around. 4. In the shop the "piece worker" may have relied too much on the stop on top the cover and neglected to adjust the index wheel so the pawl dropped clean into the curved notch made especially for the "off" position. 5. Some change might have been made in the depth of this notch or in the size of the pawl wheel to secure smoother or more decided action of the notching spring. All of these defects might exist and yet remain inoperative until the controller handle were thrown off with force enough to exaggerate the evil.

If the series parallel controller is used, and the car seems to start all right with both motors cut in, it might lead one to think that both motors are in good shape when such may really not be the case. When two motors are in series, one of them may be badly grounded and the good motor do all the work of starting. In such a case the bad motor would not indicate its condition until the controller handle reached a multiple notch, in which case the two motor circuits being independent, the bad motor would declare itself violently. To avoid any such complications, always try the motors one at a time.

◆

LESSONS IN PRACTICAL ELECTRICITY

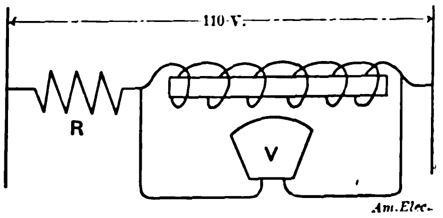
APPLICATIONS OF CONDENSERS IN ALTERNATING CURRENT WORKING.

In the several preceding articles the principles of inductance and capacity were developed, and simple methods given for calculating problems in which these quantities appear. In this article some of the practical applications of condensers will be pointed out.

Before proceeding we would strongly renew our advice to central station superintendents to make a condenser of about 5 microfarads' capacity, according to the instructions given in the preceding articles, the condenser to be used as described for showing alternating current paradoxes—that is, the effect of placing capacity and inductance in parallel and in series. As stated before, such an apparatus could not only be used for the edification of visitors to a station, but—which is of more importance—would enable the owner to obtain a most excellent insight into alternating current phenomena. We hope in an early issue to describe such an apparatus, complete, as one is now being constructed in order to furnish the necessary data.

There are at least three methods in which condensers may be practically applied in current work. One of these, as shown in the preceding articles, is to nullify the reactance of an inductive circuit, thereby causing the circuit to offer no more resistance to the passage of an alternating than a direct current. Another application is in obtaining higher voltages than the voltage of a given alternating current circuit. A third application is in connection with regulating apparatus.

The first mentioned application has been quite thoroughly developed in the preceding articles, so that it will not be here treated at length. As in any practical problem, the given quantity will be an inductance and not a capacity, the data of the first mentioned will have to be determined, and then the necessary size of condenser calculated; that is to say, the self-inductance of the inductive circuit must be determined in henrys.



TO DETERMINE FREE AND IMPRESSED E. M. F.

To determine the self-inductance it will be necessary to know the drop due to the passage, first, of a given direct current; and second, of a given alternating current, the frequency of the latter being known. If access to the station in which the alternating current is generated may be obtained, the frequency can be very accurately determined by finding the r.p.m., multiplying these by half the number of poles of the alternator, and dividing the product by 60. To be very exact, a station tender might be requested to take the revolutions at a given time, corresponding to the time when the measurements are being made.

Referring to Fig. 1, suppose the inductance is in the form of a choking coil. If the resistance of this coil is known, then a source of direct current will not be necessary. Should the resistance not be known, it may be determined by passing a direct current through the coil and noting, by means of a voltmeter, the drop between its extremities. If, for example, the coil is placed across a 110-volt circuit in series with a resistance such that, say, 2 amps. will flow through the coil, and the voltmeter shows that the drop in the coil with this current flowing is 40 volts, then, according to Ohm's law, the resistance will be the voltage divided by the current, or 20 ohms.

Next, the coil is connected across, say, a 100-volt alternating current circuit having a frequency of 133, and it is found that 1¼ amps. pass, which corresponds to a drop of 80 volts for a current of 1 amp. That is to say, with an alternating current of 1 amp. flowing, the drop in the coil is 80 volts or the impressed e.m.f. between the terminals is 80 volts; and when a direct current of 1 amp. flows, the ohmic drop will be 20 volts. Referring now to the triangle of Fig. 2, the impressed e.m.f. is the hypothenuse and the ohmic drop the perpendicular. As the inductive e.m.f. is at right angles to the free or ohmic drop, it will be represented by the base of the triangle, whose value may be found by subtracting the square of 20 from the square of 80, which will give 78 volts as the inductive e.m.f., corresponding to 1 amp. It may here be remarked that in the case of a coil having an iron core, the free e.m.f., corresponding to the perpendicular of the triangle, may usually be neglected, and the inductive e.m.f. assumed equal to the impressed e.m.f., represented by the hypothenuse of the triangle.

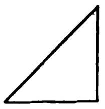


FIG. 2.—INDUCTANCE TRIANGLE.

To determine the value of the self-inductance in henrys, we substitute the formula

$$E = \frac{2\pi n L C}{1000}$$

where L is the self-inductance, n is the frequency and C is 1 amp. Solving this formula, we find that the self-inductance is 93 millihenrys.

Suppose that we had an inductive circuit through which, with a given circuit voltage, we wish to pass the maximum current. That is to say, normally too small an amount of alternating current passed, owing to the choking action of the inductance, and we wish to neutralize this choking action by placing a condenser either in parallel or in series. As has previously been shown, the inductance will be neutralized when the inductive e.m.f. caused by the flow of any current is equal to the capacity e.m.f. that will be set up by the same current, for the reason that these two e.m.fs. act opposite to each other. In other words, if we place the formula for inductive e.m.f. equal to the formula for capacity e.m.f., and find therefrom the value of k, this will give the size of the condenser necessary to neutralize the inductance; or

$$\frac{2\pi n L C}{1000} = \frac{1000000\, C}{2\pi n k}.$$

As we know the value of n and L, and C is unity, we can determine k, which will be the value required. Solving for the inductance just calculated, we find that a condenser of 15.3 microfarads will be necessary to neutralize the inductance of 93 millihenrys.

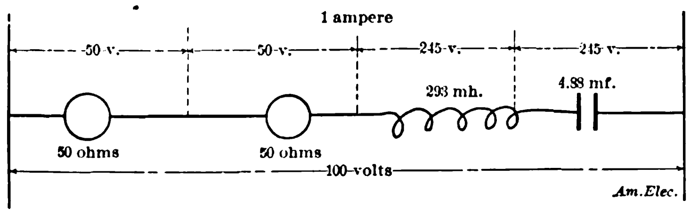

FIG. 3.—INDUCTANCE BALANCED BY CAPACITY.

The same result might have been obtained by placing the 78 volts above found equal to the second term of the capacity formula, or

$$\frac{1000000\, C}{2\pi n k} = 78,$$

whence $k = 15.3$.

A condenser of 15.3 microfarads capacity, however, is very large, as it would probably require over 500 sheets of tinfoil 1 ft. square, if paraffined paper is the dielectric. For an inductance twice as great, the condenser would be half the size above given, and for one ten times as great, one-tenth the size, as the above formulas show that the capacity is inversely proportional to the inductance.

The condenser has been applied in the above manner to polyphased motors, both in series and in parallel,to overcome inductance and thereby decrease the so-called idle current and the size of motor for a given power. Prof. S. P. Thompson has proposed as a solution to the problem of submarine telephony the use of a cable with inductances placed in circuit at short intervals to neutralize the capacity of the cable.

We will next take up the case showing how higher e.m.fs. than that of a given circuit may be obtained by means of a condenser and inductance in series. Referring to the diagram of Fig. 3, suppose we have 4.88 microfarads in series with an inductance of 293 millihenrys. As these values of inductance and capacity have been so chosen that they will neutralize each other, the circuit will act toward alternating current the same as direct current; in other words, the resistance of the choking coil alone will affect the flow of current. Consequently, in the case illustrated,where the voltage of the mains is 100, two 50-volt lamps placed in series will burn at full candle power 1 amp. of current passing.

It may be very easily shown by the formulasfor inductance and capacity that the inductive e.m.f. and the capacity e.m.f. are each 245 volts. That is to say, notwithstanding the fact that the voltage of the circuit is only 100 volts, a voltmeter connected at the extremities of either the condenser or choke coil will show a voltage of 245 volts. By having an adjustable condenser, and a choke coil whose windings may be thrown into different combinations, a range of voltage in the case given may be obtained up to 245 volts. It will be seen that such a combination of an inductance and condenser corresponds to a step-up transformer, and that by its means a source of voltage much higher than the circuit voltage may be obtained for, say, the calibration of instruments. If a choke coil is so wound that its windings may be thrown into various combinations in parallel, or some cut out entirely, voltages below that of the circuit may be obtained, an inductance in this manner thus acting as a step-down transformer.

Prof. Fessenden has suggested that a combination of a condenser and inductance in series may be used for regulation, and the reason will readily be seen by referring to Fig. 3.

For example, if the regulating apparatus is placed between the terminals of either the condenser or choke coil, a drop of 5 per cent or 5 volts in the circuit voltage will produce a drop of 5 per cent or 245 volts, or 12.25 volts between the terminals of the condenser or inductance. By having a still larger inductance in circuit, together with a smaller condenser, a still great difference between the circuit and inductance drop may be produced. In fact, the only limit is in the size of the inductive coil and the amount of strain that the condenser will withstand. The advantage of this method of regulation is that it magnifies the amount of a circuit drop. Consequently if it is desired to have a very close regulation, by means of the above disposition a considerable difference of voltage may be obtained to work the regulating apparatus.

As above implied, the larger the inductance the smaller the condenser necessary to nullify it. This follows from the fact that with a given current flowing, the smaller the condenser the greater will be its charge per unit of area, and consequently the greater the difference of potential between its terminals. At the limit an infinitesimal current would produce an infinite e.m.f. at the terminals of a condenser of infinitesimal size.

On the other hand, with a given current the larger the inductance the greater the e.m.f., for the reason that an increase of inductance implies an increase in the number of turns of the coil, which introduces more lines of force into the coil for a given current, with the result that there are more cuttings of lines of force at each alternation, thus producing a higher voltage between the terminals.

Letters on Practical Subjects

Live Wires.

To the Editor of American Electrician:

Referring to the letter from Mr. James Francis, in the February issue, I can see no reason for his criticism of Mr. A. W. Lee's solution of the "three-wire, two-station" problem, in the January issue. He argues that the third or neutral wire remains unbroken and *alive* at all times, no matter whether the lights are "on" or "off," and wants to know "if the insurance inspector would permit, or accept a job done that way."

Mr. Francis will find in all the diagrams of three-way switch circuits, that have been in preceding issues, that there is not a foot of wire in the circuit that is not *alive* at all times, even when the lamps are extinguished. Of course, some of the conductors get their connection through the lamps, but enough current would flow through three or four lamps to start a fire under certain conditions. Even the common, every-day wiring of private residences is just the same in regard to *live wires*. A 5-amp. single-pole switch controlling six lights leaves "live wires" on both sides of it when it is "open." A 10-amp. double-pole switch leaves "live wires" back to the cut-out, and from there to the main entrance.

Again, if Mr. Francis will look more closely over Mr. Lee's diagram, he will find that there are lots of other "live wires" there at all times, besides the middle wire. The only switch that the inspector calls for to "open" all three wires is the main entrance, or service switch, and as Mr. Lee's arrangement of switches is not intended for service switches, I can see no reason why the inspector should condemn them. But, if he should condemn this circuit, then he should do the same in the case of all others for they are all *alive*. Edgar A. F. Herbert.

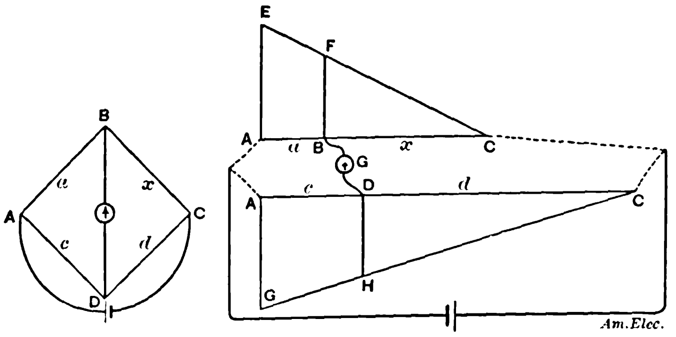
Principle of Wheatstone Bridge.

To the Editor of American Electrician:

The article in your January issue and the letter of Mr. Eastlake in the February number, while illustrating the principle of the Wheatstone bridge, both neglect to give a proof of the proportion existing between the arms when balanced. Following is a simple form of proof:

In the bridge diagram, Fig. 1, there are, of course, two circuits, $A\ B\ C$ and $A\ D\ C$, and the fall of potential on these two circuits may be represented by the two right-angled triangles $A\ E\ C$ and $A\ G\ C$, the two base lines $A\ B\ C$ and $A\ D\ C$ representing by their length the resistances in the two circuits.



PRINCIPLE OF WHEATSTONE BRIDGE.

The potential at the point A is the same in both circuits (since it is a common point for both); that is, $A\ E = A\ G$. Also, when there is a balance there is no current flowing through the galvanometer G; therefore $B\ F = D\ H$. The two triangles $A\ E\ C$ and $B\ F\ C$ are similar triangles, because the angles $E\ A\ C$ and $F\ B\ C$ are right angles and the angle $E\ C\ A$ is common to both.

Therefore the third angle of both triangles is equal, since the sum of the angles of any triangle is equal to two right angles. As the sides of similar triangles containing equal angles are proportional,

$$A\ E : A\ B + B\ C :: F\ B : B\ C.$$

Similarly with the two triangles $A\ G\ C$ and $D\ H\ C$,

$$A\ G : A\ B + D\ C = D\ H : D\ C.$$

Since $A\ E = A\ G$, and $F\ B = D\ H$, we have

$$A\ B + B\ C : A\ B + D\ C = B\ C : D\ C.$$

Substituting the small letters representing the resistances, we have $a + x : c + d = x : d$; reducing the proportion, we have $a : c = x : d$, or $x = da\ /c$.

Denison, Tex. James R. Pratt.

Electrical Sport.

To the Editor of American Electrician:

Some time ago, when in the employ of the electric plant in a Southern town, I was sitting one day in our storeroom—a small room opening into the public market—with my helper, wiring some new fixtures just received. While busily employed in our work a little negro, who had been left in charge of the lunch counter in the market, finding business dull, came over and amused himself by bothering us. After a while he was called away by a customer, and while he was gone we decided to give him a surprise when he returned. We took one wire from a 15,000-ohm magneto and connected it to an old grate bar, which we placed on the ground near the door. We then found an old piece of water pipe about three feet long, with a faucet screwed on one end, and to this we connected the other wire and placed it where the boy could reach it conveniently when he returned. I took the magnet in my lap and had my helper cover the wires with some wrapping paper.

In about half an hour the boy returned, and not suspecting anything, he stood with both bare feet on the grate bar and took the pipe up and tried to blow through it. Finding the faucet closed, he reached down with one hand to turn it on, holding the pipe in his mouth with the other hand. While so situated I gave him the full strength of the magneto. He dropped the pipe with an unearthly yell and fled in terror, not knowing what had struck him. It is needless to say we were not bothered again by the gamin.

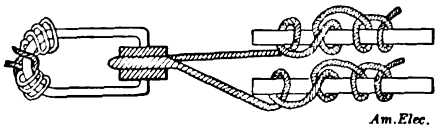
A Come-Along Kink.

To the Editor of American Electrician:

Noticing in your March issue an illustration of an improvised come-along, I send herewith a sketch of one somewhat on the same principle but much superior in operation, since the former would have a tendency to kink the wire. This is made by taking four half-hitches about the wire and close together; the rope is then run around a No. 1 porcelain insulator, through the hole in which a link of No. 4 wire passes, the tackle making fast to the latter. This makes a very handy arrangement to pull two wires at the same time. The knot can be slid along the wire without untying.



COME ALONG.

◆

Dry Cells.

To the Editor of American Electrician:

Referring to the letters of Messrs. Townsend Wolcott and P. M. Heldt, in the last issue, I wish to state regarding the connection of the cells, that they were all properly connected, as was proved during the testing of each cell for e.m.f. with the voltmeter. The instrument I used was a new meter, reading to 10 volts by about 3-16 in. spaces per volt on the scale. I connected the cells in series, and, with an insulated wire in either hand, leading from the voltmeter, I touched the binding post of each cell, and held the wires there just long enough for the voltmeter needle to come to rest, no longer.

I then would take the voltage across all the cells in the same manner. I had a suspicion that something might be not right with the voltmeter, and to make sure, I applied the connections above described to the binding screws of a small six-cell storage battery which happened to be freshly charged at the time. The voltmeter needle went right up to the graduation, as I touched the terminals in the same manner noted in with the dry cells. At 2, 4, 6, 8, and 10 volts, the Cherry instrument indicated the amount due to the given number of storage cells in series open circuit. I cannot, therefore, accept the supposition that the cells were wrongly connected, or that the voltmeter was not fairly correct.

The current derived from each cell was, by ammeter, about 1-6 amp. The resistance per cell, therefore, should have been about 6 ohms. I will here state that at the time of the measurements, and for a week before, the cells had not been used at all, except momentarily, for getting a balance on a Wheatstone bridge, with never less than several hundred ohms resistance in series with the battery. Therefore, polarization could not have amounted to much.

I do not understand Mr. Heldt's statement in the last paragraph of his letter, to the effect that to double the current derived from 6 cells there would be required "24 cells connected in two parallel groups of 12 in series." I would like to see a mathematical demonstration (algebraical preferred) of the matter, for I have been unable to figure the number of cells as he states it. N. F. Jarvis.

Philadelphia, Pa.

◆

Behavior of Dry Cells.

To the Editor of American Electrician:

I have no knowledge of the particular

LIBRARY

make of dry batteries mentioned by Mr. N. T. Jarvis, in your February issue, but they are probably not much better or worse than other dry cells would have been under similar conditions, and the data furnished by him afford ample means of determining their present state.

In the first place they are nearly worn out and have a very high internal resistance—about two ohms. His voltmeter, on the other hand, is of low resistance—probably not over 30 ohms; his working resistance is also very low, and therefore quite unsuitable for such work as he indicates.

The fact that he gets actually less current from the eight cells in series than from a single cell shows only that some cells are worse than others. He does not state whether the half ampere current from one cell was obtained on short circuit, or through a resistance; if the latter, the resistance must be so small as to be practically negligible beside that of the cell. The fact that there is no increase of current on increasing the number of cells shows that they are virtually on short circuit, and that ½ amp. is the full capacity of each cell (considering them uniform), and therefore we know by Ohm's law that the voltage of one cell divided by its resistance must be equal to ½ amp.

A low resistance voltmeter does not give the absolute voltage of a battery by direct reading, but it is really more useful for battery purposes than a high resistance instrument, as, indirectly, it can tell us not only the true voltage but also the resistance of a cell, if we know the resistance of the voltmeter. We are not told the voltmeter resistance, but we can get at it approximately through the other data.

Now, every voltmeter is in effect also an ampere-meter (or milliampere-meter), for the current passing through it is proportional to the voltage between the terminals, and if we know the resistance we can easily find the constant by which to multiply the voltage reading, to give us a reading in amperes or milliamperes.

We do not need this constant at all in this case, and insert it only to make the method clear. Call this constant A. Then A is the current sent through by one volt, $5A$ by five volts, and so on.

Just for example, let us assume in our present case all eight cells of equal voltage and resistance; then calling the true voltage of one cell E, the resistance of one cell R, and the resistance of voltmeter X, we have by Mr. Jarvis' readings,

$$\frac{E}{X+R} = A \text{ or } \frac{8E}{X+8R} = 5\tfrac{1}{2}A.$$

Simplifying, we readily get $X = 14.4\ R$. Now, in any circuit the voltage divides itself up in the same proportion as the resistances; therefore, with one cell in series with the voltmeter, the voltmeter gets 14.4 parts while the cell gets 1 part, and as the voltmeter gets, say, 1 volt, the cell must be using up 1-144 = .07 volt. The full voltage of the cell is therefore the sum of 1 and .07 volt = 1.07 volt. The voltage of the eight cells therefore will be 8.56 volts, but of this, when in series with the voltmeter, the voltmeter will get 14.4 parts while the cells absorb 8 parts. The cells therefore use up 8-22.4 of the whole = 3.06 volts, while the voltmeter shows only the balance of 8.56 — 3.06 = 5.5 volts.

Knowing, now, the voltage of the cells and the limiting current we easily get the resistance, for $1.07 / R = \frac{1}{2}$, therefore $R = .2.14$, which is roughly the ohmic resistance of one cell.

Mr. Jarvis will readily see that with such cells as these he cannot increase his current by adding cells unless he starts with a very high external resistance and a very small current. In all cases, if we wish the current to increase even approximately as the number of cells is increased, we must have the external resistance very high compared with that of the battery—the higher the better. If we must have a comparatively heavy current, then we must also use batteries of low resistance. While the ordinary cheap dry cell gives a voltage on open circuit of from 1.3 to 1.5 volts, and has a resistance of say .2 to .4 of an ohm, it is not suitable for sustained work, unless the current can be kept down to a very small fraction of an ampere by suitable resistance.

Mr. Jarvis would probably get more satisfaction from some other batteries now on the market, for there are some excellent ones of comparatively low resistance, and retain practically the same voltage, under a limited current, during the whole life of the cell.

The figures given relative to Mr. Jarvis's cells are approximate only, even if we assume the correctness of his voltmeter and ammeter. Owing to a rapid polarization, the voltage of an old dry cell is a very uncertain quantity, and it is quite likely after a rest his cells might show on a high resistance voltmeter, over 1.2 volts; but this static voltage is immaterial, for it is only the voltage in service that one really cares about.

Utica, N. Y.

ELECTRICA CATECHIS

197. What causes the armature of a motor to rotate?

It is caused by the magnetic effect of the currents in the armature wires which lengthen the path of the magnetic lines of force between the poles of the field magnet.

198. How can it be shown that there is a magnetic field due to the current?

A simple way to show that the current is surrounded by a magnetic field is to bring a compass needle near a wire that is carrying a current. If the wire is horizontal, and the needle is placed over or under the wire, it will be rotated by the current and will stand about at right angles to the wire (the wire should run north and south, so that the needle would naturally be parallel to the wire). If the wire is vertical, the needle will turn so as to be tangent to the wire. If the needle is moved around the wire, it will take different positions with its axis always tangent to a circle. A current of 10 amps. is strong enough to show these effects easily.

199. How can the magnetic field about a current be shown by iron filings?

Pass a wire vertically through a card or smooth board upon which iron filings or small chips have been sprinkled. Send a current of about 20 amps. through the wire and at the same time slightly jar the card so that the iron bits can move easily. They will gradually arrange themselves in more or less perfect circles, as shown in Fig. 1, which is taken from a photgraph. If one cannot easily get a current of 20 amps., he can get almost as good results by passing the wire through the hole several times, making a coil of large diameter so that the returning wires will not affect the field seriously. With practice and care in selecting iron bits of the right size, one can obtain clearly defined circles about the wire.

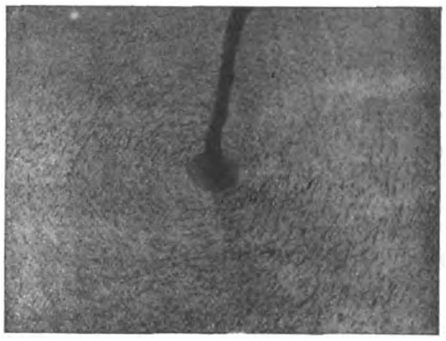

FIG 1.—MAGNETIC LINES OF FORCE.

200. Why is there a clear space close around the wire where there are no iron bits?

Near the wire the field is so strong that the iron bits are drawn to the wire and so leave the space clear for some little distance away.

201. How is the magnetic field about a wire affected by forming the wire into a coil?

Some of the lines will still surround the individual wires, but most of them will unite and pass through the entire coil as seen in Fig. 2, taken from a photograph. The field is seen to be strong through the center of the coil, so that the iron bits arrange themselves in quite definite lines, while outside the coil, the field is more scattered and not strong enough to collect the iron bits into so definite lines. It is seen that the magnet field is strengthened by the current in each wire; in fact, if the wires are close together, the total strength of field is proportional to the product of the current by the number of wires.

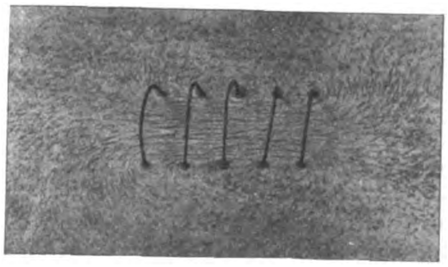

FIG. 2.—MAGNETIC LINES OF FORCE.

QUERIES AND ANSWERS

What resistance can I use with a 4.3 volt, .75 amp. dental lamp on a 110-volt circuit? A. R.

Connect two 110-volt lamps in series with one 110-volt lamp in parallel, and place the dental lamp in series with the combination.

Please recommend a good book on the steam engine and also one on the boiler. A. N.

Jamieson's "Steam and the Steam Engine" and Wilson's "Steam Boilers." There are two grades of the former, one elementary and the other more advanced.

What does the constant 21 mean in formulas for calculating the size of wires? F. E. F.

The resistance of a copper conductor 1 ft. long and having a cross section of one circular mil is 10.5 ohms. As the double conductor of a circuit is usually implied in wiring formulas, this then becomes 21.

How many amperes does the Wheelock 6 x 8 battery deliver? W. I. H.

None, if the battery is open circuited; short-circuited, the current is the quotient of the e.m.f. by the internal resistance; with an external resistance the current is the e.m.f. divided by the sum of the external and internal resistances.

I have an electric door opener which fails to operate satisfactorily; the armature is attracted more weakly the longer the button is pressed. What is probably the matter? F. W.

The battery is probably weak. A battery for this kind of work will naturally act as described when the button is pressed for any length of time, even if in good condition.

What size should a condenser be to work in multiple with an inductive resistance that takes 5 amps. at 100 volts? J. R.

What is the value of the inductive resistance? If the condenser is to nullify an inductance, it would be very large and expensive to make if 5 amps. are to flow—in this case not far from 60 microfarads capacity.

Referring to the article on worm gearing in February number, will the armature lock the wheels the instant the current is off; and if it does and the trolley cames off at high speed, will there not be a serious result? F. K.

The abruptness of the stop in case current is shut off will depend on the flywheel capacity of the armature, which in any practical case will be such as to cause the stop to be gradual.

How can static electricity be dissipated from printing paper? C. E. F.

In large newspaper offices steam is sprayed on the sheet as it leaves the roll; hot air has also been used for this purpose. In dry cold weather trouble from static electricity may be mitigated by keeping the atmosphere of a press room damp by means of a steam jet.

How can cross-talk be prevented on intercommunicating telephone systems where a cable is used? H. R. W.

In such a system, since some of the wires are in common, we know of no method of preventing mutual induction—that is, cross talk. It may be reduced by keeping the wires separated as widely as possible where a cable is not used.

How can I make a spark coil for a gasoline engine, to be used either in connection with a battery or a 50-volt direct-current circuit? G. C. D.

Wind about three pounds of No. 14 wire on a one-inch core of soft iron wire. Use four or five cells of a good sal-ammoniac battery, or a larger number of potash cells. Connect a 50-volt lamp in series when current is taken from a 50-volt lighting circuit; if a 16-c.p. lamp does not give a large enough spark, use a 32 c.p.

In some alternating current arc lighting systems, flat carbons are used in lamps. Of what advantage are they? M. P. C.

Flat carbons were, we believe, originally adopted in order to get an all-night lamp which would not infringe upon the Brush double-carbon patent. An advantage claimed for flat carbons is that the lamp is smoother in working, since the arc can travel along the ends of the carbon as it is consumed, thus requiring less action on the part of the regulating mechanism.

What is the no-load loss of small transformers and their efficiency at full-load? V. D.

In good transformers the loss is from 3 per cent of full load in 20-light capacity, to 1 per cent in 10-k.w. capacity. For example, the loss should not be greater than 30 watts in a 1000-watt transformer, or 80 watts in a 4000-watt transformer or 100 watts in a 10,000-watt transformer, the frequency being 133. For lower frequencies the loss is greater. The efficiency at the above losses and the higher frequency would be about 94, 95 and 97 per cent., respectively.

Can a Blake transmitter be used with a carbon pencil transmitter with satisfactory results? C. W.

Yes, provided each of the instruments is capable of giving good results alone. The secondaries of the induction coils should be approximately of the same resistance in each instrument, as well as the resistance of the receiver coils, but these conditions are not essential. Where several instruments are used on a single line, as on a party line, the ringer magnets and the winding of the generator armatures should be the same in all.

I have a threshing machine run by fourteen horses; could I attach a dynamo to the horse power and run a wire to a motor on the separator; and if so, what would be the loss and what size machine would be necessary? D. H. D.

The loss would probably be 40 per cent., including that of the gears. A machine of over 20 h.p. would therefore apparently be required, but it is very probable that this figure is too large. It would be well to write to the makers and inquire the horse power necessary for running the separator, which will give the size of the motor and consequently of the dynamo.

How can I connect up a battery of Samson cells to keep them from polarizing, and will 30 cells in series polarize as quickly as one cell or if the 30 are connected up in multiple? C. R. P.

This type of cell cannot be kept from polarizing by any system of connection, being of the open-circuit type. The polarization in any cell is directly proportional to the current flowing through it, so that if the current is small, the polarization proceeds slowly. The arrangement of the battery cannot be modified for a given case as implied, being fixed by the watts of energy required from it.

How is the hysteresis loss calculated? R. H. M.

If W are the watts loss per cubic centimeter of iron, N the number of reversals per second, and B the gausses or number of lines of force per square centimeter of section—that is, the flux intensity—then

$$W = K + N + B^{1.6} \times 10^{-7}$$

where $K = .002$ for best wrought iron, and .016 for cast iron. For direct current armatures, B is generally about 15,000, and for alternators about 7,000. Dividing the number of revolutions per second by half the number of poles gives N. For watts per cubic inch, multiply W by 16.4. For transformers B does not exceed 9,000, and N is the frequency.

How does the resistance of a voltmeter affect its reliability? H. L.

The voltmeter being in shunt with the circuit measured, the current will divide inversely as the resistances; consequently, if a voltmeter of low resistance is calibrated on a circuit of one resistance, and is used on a circuit of another, it may give an incorrect result because of the change in the ratio of resistances of the circuit, and also because of the additional drop introduced into the circuit by the current flowing through the voltmeter. In practice it is rare, however, that these conditions are encountered.

In making a Wimshurst machine I have had much trouble from glass discs cracking after being cemented on the hubs; how can this be remedied? R. L.

If the holes are bored in the disc so as not to start any cracks, none will develop subsequently. It is quite difficult to do this, however, as a small chip in the edge of the hole may suffice to start a crack. Plate glass should be used, and a piece of tough paper pasted on either side at the center of the plate; on this is drawn, with a pair of dividers, a circle representing the hole, which is then ground out with a brass tube of the proper size, using emery and oil. It is best to use a drill press or lathe for the operation, and to work from both sides of the glass.

1. Why is it difficult to maintain an arc in a magnetic field? 2. What is an equalizer and what is a compensator? 3. Is there any way in which a live circuit can be charged with static electricity, and if so, what effect would it have on the current flowing? E. E.

1. The magnetic field affects the electric arc in the same manner that it would affect a conductor carrying the same current, deflecting it when there is certain relation between the direction of the arc and the direction of the magnetic field. In one such relation the magnetic field would have no influence on the arc. 2. An equalizer is a conductor of the smallest practicable resistance used to connect together the brushes of the same sign on two or more direct-current machines running in parallel. A compensator is a voltmeter transformer whose windings can be adjusted so as to compensate for circuit drop. 3. If a circuit is entirely insulated, it may be charged statically whether a current is or is not flowing in it, and there will be no influence on the current flowing in the former case.

Apparatus and Appliances

ANGULAR BIT STOCK.

In an article in this department in the March issue, the length of the Meister bit stock described was stated to be 22 ins. This was a typographical error, the length being 12 ins.

HIGH PRESSURE ALTERNATING CURRENT SWITCH.

In the operation of this switch the alternating current arc is rapidly extinguished between metal rolls or balls placed very close together, but the sehvice nit not suitable for use with continuous current.

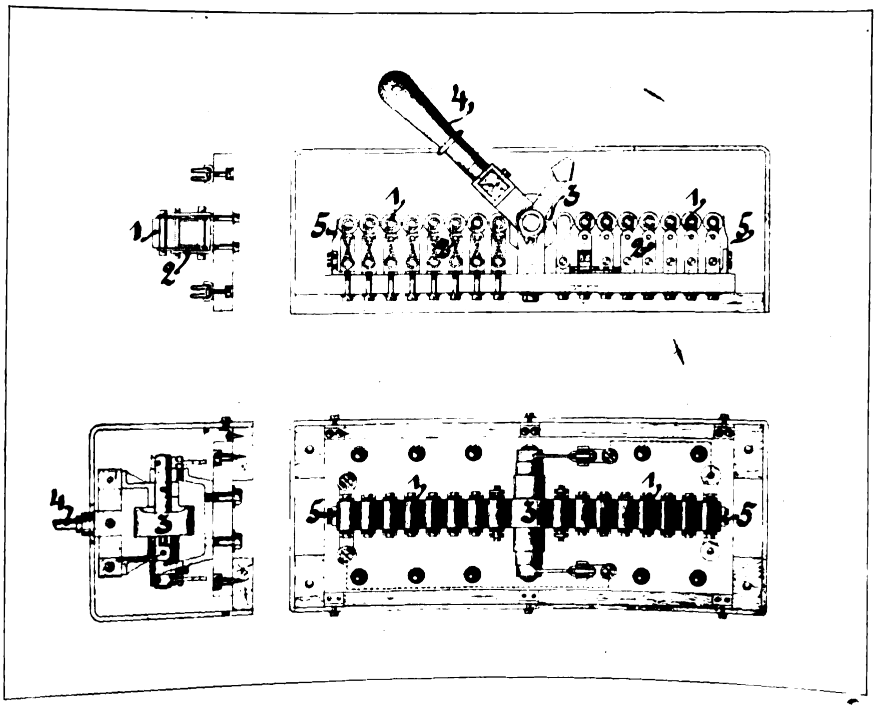
The principle of operation depends, first on the considerable cooling-off effect which the entire mass of the metal rolls exerts on the small arcs produced; and second, on the slight liability to oxydize possessed by the metallic fumes of the alloy which is used, in consequence of which the transitory resistance increases rapidly. Furthermore, in order that a switch in continual use may not cease its functions, the following conditions are imperative: First, that the rolls be rotated at every turn in such a way that the surfaces between which the arc is produced are shifted, in order to increase the cooling effect, and to change the surfaces which touch one another; second, the connecting-up in quick succession of a large number of such gaps, whereby the probability is assured that one of the many interruptions will take place at the moment when the amplitude of the current is approximately null.

These conditions are fulfilled in a simple manner by the switch constructed by Chief Engineer H. Muller of the Electricitäts Actiengesellschäft, late Schuckert & Co., of Nuremberg, which is illustrated herewith.

In this apparatus a continuous path for the current is formed by easily rotating rolls, 1, which are attached to plate springs, 2. The circuit is closed by turning down the lever, 4, whereby the rolls are pressed outward and against each other by means of the eccentric disc, 3. These rolls are released when the lever is raised, thus causing the circuit to be broken. The end rolls are met by powerful flat springs, so that when the other rolls are pressed together these are but slightly displaced. As will be seen without further explanation, all the rolls are caused to rotate when the circuit is opened or closed, and in consequence of this rotary motion, they turn regularly after each operation of the switch, causing new surfaces to be brought into contact. Furthermore, the rotary friction rubs off any oxide produced, and in consequence of these two circumstances the switch can be used for long periods without requiring repairs or renewal, which is a valuable quality in high pressure connections, owing to the danger involved in overhauling the same.

The sparking produced by a switch constructed on this principle is so slight, even in breaking the circuit of high pressure currents up to 6000 volts, that the apparatus can be erected in the immediate neighborhood of instruments of any kind. The arrangement described can also be employed as a multiple-switch. For powerful current it is advisable to place the apparatus in shunt with an ordinary switch (as shown in the cut), which insures for the continuous passage of current a connection as free from resistance as possible.

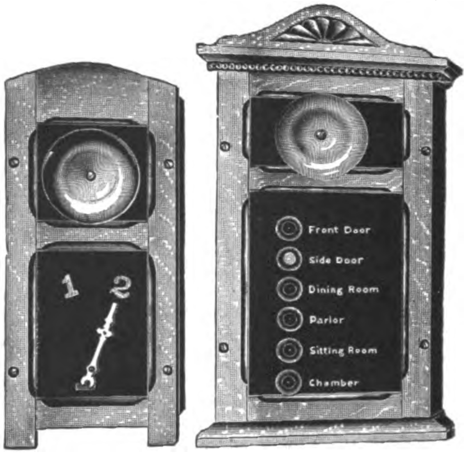
The experiments made during the last two years by the firm mentioned, as well as the regular use of this apparatus in the municipal plant in Nuremberg, and in many other installations, have, it is claimed, fully proved the excellence of its design. Furthermore in parallel connection the superiority of this apparatus has also been clearly established. Even with 150 amps. and 2000 volts the switch performs its functions with scarcely a sign of a spark.



HIGH PRESSURE ALTERNATING CURRENT SWITCH.

AUTOMATIC ANNUNCIATORS.

The accompanying cuts illustrate the "Ideal" automatic house and elevator annunciators. This type of annunciator is automatic in its action, it not being necessary to reset it after each call, as the last call is the only one showing and can be seen at a glance. These features, it is claimed, obviate the constant and violent hammering so often noticed in re-setting an annunciator. Another superior feature claimed for these annunciators is that by avoiding the above-mentioned annoyance the annunciators when once properly installed will not get out of adjustment, but will remain in perfect order. These annunciators are manufactured by the Heath Electric Company, 336 Grand River Avenue, Detroit, Mich.

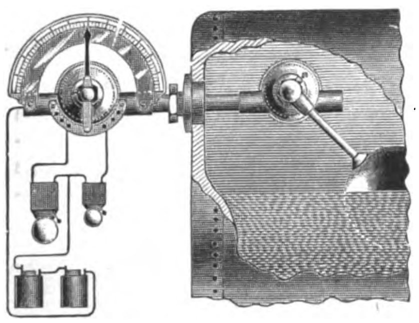


AUTOMATIC HOUSE AND ELEVATOR ANNUNCIATORS.

HIGH AND LOW WATER ALARM.

In the accompanying illustration Figs. 1 and 2 show a water column alarm attachment; that of Fig. 1, including try cocks, water and steam gages and water level indicators. The advantages claimed for this alarm are that no scale or other material can in any way interfere with its operation, the alarm being given by means of an electric bell. A number of signals may be placed in different parts of a factory or other building, each of which will sound when the water reaches a high or low limit in the boiler. The gage glass and dial serves as a check one upon the other. If for any reason the float should become filled with water or should collapse, the low water alarm would be sounded, thus indicating the derangement of the apparatus. There are no links or complicated mechanism to become locked by rust or scale, and no packing is used except for the gage cocks and glass, the stuffing-box through which the spindle passes being without packing.

The whole mechanism consists of a float and rod, which operate a spindle passing through the side of the casing of the umn, at the other end of which is a pointer carrying also a brush for making and breaking the electric circuit operating the alarm bells. Testing switches are placed in the circuit by means of which it can be determined at any moment if the apparatus is in good working order. The makers are the Hercules Float Works, Springfield, Mass.

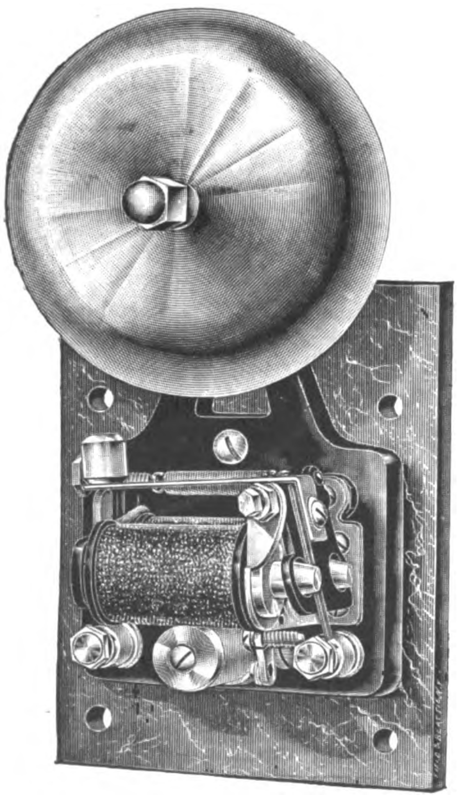


LOW WATER ALARM.

BELL FOR ELECTRIC LIGHT CIRCUITS.

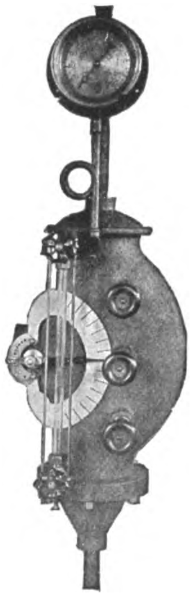
The need of a bell that may safely take current from electric light circuits has long been recognized, and the accompanying cut shows a type arranged for this class of work, though any other kinds of bells, electric or electro-mechanical, can be similarly fitted.

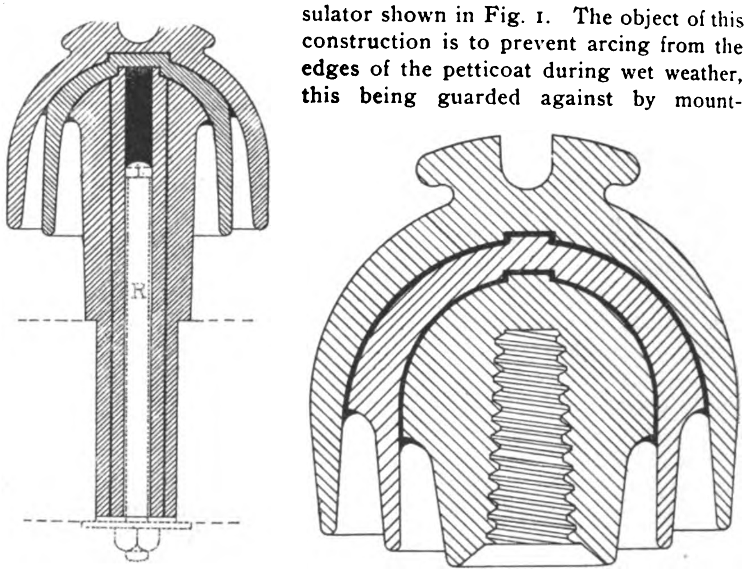
The style of bell shown is mounted on a marbleized slate base, and arranged to operate from circuits up to 500 volts. A special resistance is used, which will, it is claimed, neither melt nor burn, being placed in circuit with the bell. When the armature is attracted, the coils of the magnet are shunted, thus leaving the resistance in circuit, and thereby preventing sparking and burnt contacts. The resistance is so adjusted that at no time can more than one-sixth of an ampere pass through the coils.



BELL FOR ELECTRIC LIGHT CIRCUITS.

Edwards & Company, 144th Street and Fourth Avenue, New York, have originated the above type of bell, which they make in all the usual sizes.





FIGS. 1 AND 2.—HIGH VOLTAGE INSULATORS.

HIGH VOLTAGE INSULATORS.

In the article in the March issue on the Delta transmission plant, mention was made of the high voltage insulators used, of which we are now enabled to present an illustration. These insulators are of the "Boch" glazed and filled type, and are made in three parts of a uniform thickness, thus overcoming the danger in porcelain manufacture of cracks which are sure to occur where there is a thick part and a much thinner part to be dried and fired. Each of the three parts is thoroughly covered inside and out with a glazing, then fitted together, ready for the vitrified kiln, by being placed in the saggers upside down like an inverted bowl. A glazing material is then put into the joints, that is, into the annular channels between the petticoats.

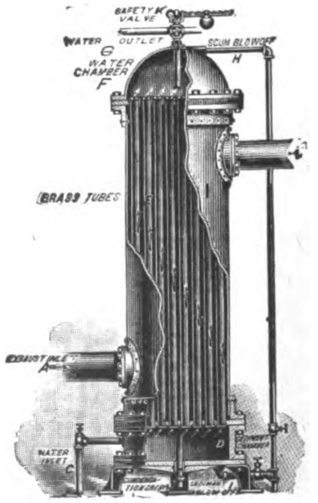
The parts thus put together and supplied with glazing material, are then placed in a kiln, in which, under great heat, the clay shrinks and becomes vitrified and the glazing melts and becomes of a glass-like character. The glaze which was put into the annular channels between the petticoats flows down into and fills all the spaces between the parts of the insulators. The result is that the three parts are firmly united to each other throughout by means of the glass-like glaze, thus, as will readily be seen, insuring both electrical and mechanical strength.

The six skins of glaze and the two solid walls of glaze or glass formed by this method of manufacture, give an insulator that will stand up under almost any voltage, no matter what the general conditions may be. The insulators used at Delta were, before shipping, subjected to a test of 50,000 volts by being placed in salt brine upside down with salt brine put into the third petticoat or pin hole, one pole being in the pan and the other in the testing pin hole.

Since writing the above another patent has been issued to Mr. Boch for the insulator shown in Fig. 1. The object of this construction is to prevent arcing from the edges of the petticoat during wet weather, this being guarded against by mounting the petticoat body on a porcelain post, which passes down through an opening in the wooden cross-arm or support, the metal fastening being secured in the porcelain post by suitably cement. Thus it will be seen that the metal pin is so well protected by the tubular post which sheaths it and passes down through the cross-arm, that leakage of current or arcing across from the petticoats to the pin (liable to occur on high potential circuits of present construction) is thereby entirely obviated, as the exposed end of the pin, its nut and washer on the under side of the cross-arm, are too far away from the conductor to give trouble.

FEED WATER HEATER.

In the feed water heater illustrated herewith there are three principal parts, namely, sediment chamber, heater proper and water chamber. The heat of the exhaust steam is rapidly absorbed by the water that passes through the brass tubes, attaining oftentimes a temperature as high as 210 degs., thereby leading to great economy in the coal consumption. The makers claim that this high efficiency is due to the radiating surface being in excess of

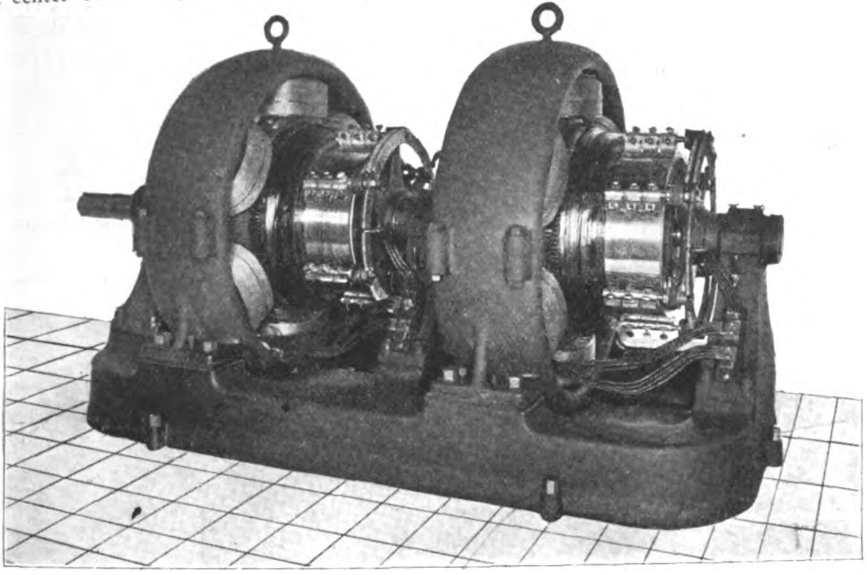


FEED WATER HEATER.

the absorbing surface by an amount equal to the difference of the area of the exterior and interior of the tubes.

The brass tubes are rigidly fixed in the bottom flange, but left free for motion with a steam-tight joint in the top flange to allow for expansion and contraction. The tubes are all straight, which facilitates easy cleaning and secures maximum strength, as bending of tubes always tends to weaken them. Proper provision is made for sediment and scum blow-off and exhaust condensation drip. The change of direction taken by the water immediately upon entering the heater favors precipitating impurities, which is further facilitated by the vertical direction maintained through the tubes. The water leaves the heater from the center of the top chamber free from impurities that are lighter than water, which rise to the top and are blown out.

The Bundy heater above described is manufactured by the A. A. Griffing Iron Company, 66 Center Street, New York.



THREE-WIRE GENERATING SET.

PORTABLE DESK TELEPHONE.

A desk telephone of new design has recently been placed on the market and is illustrated herewith. This instrument is especially arranged for intercommunicating systems of from three to fifteen stations, in business and manufacturing establishments.

PORTABLE DESK TELEPHONE.

An important feature is the entire absence of plugs, switches, or other contrivances for calling individual stations, there being used instead separate signaling keys directly on and in front of circular base, as shown in the illustration. The instrument is of handsome appearance, substantially constructed and the connections are simply and easily made. The manufacturers are the Allen-Hussey Company, 211-213 Randolph Street, Chicago, Ill., who make a specialty of interior and short line telephony.

SPECIAL MULTIPOLAR MACHINE.

The accompanying engraving illustrates a special generator of 150 k.w. capacity, just designed and built by the American Engine Company, for the Crookston Water Works at Crookston, Minn. The machine will be driven by a turbine shaft through a friction clutch coupling, running at 300 r.p.m., and will be used for supplying direct current to a three wire system.

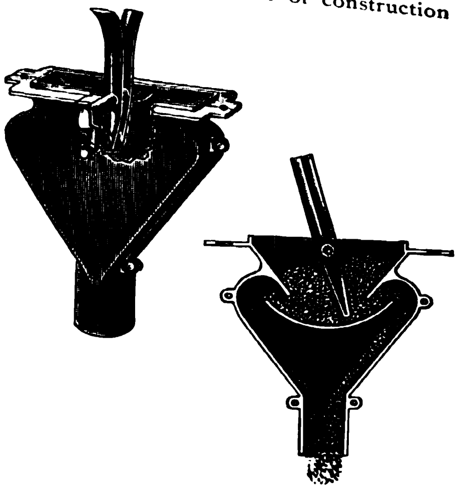
This machine is required to run at very low temperature and without any brush movement, and has been designed to meet the most exacting requirements otherwise. As in all the machines of the American Engine Company—both engines and dynamos—the symmetry and mechanical appearance are salient features.

AN IMPROVED SAND BOX.

The sand box illustrated herewith is made of bronze metal, and has an opening in the box, under which is a curved shelf. The ends of the shelf extend beyond and above the opening in the box, so that the sand cannot escape by gravity. A paddle is reciprocated above the shelf, and the movement of the paddle forces the sand in each direction alternately over the ends of the shelf to the feed spout which leads to the car track. Above the paddle are two fingers which stir the sand. The connecting rod passes forward to the car platform, and is operated by a pin and bell-crank lever, or by a hand lever.

The working parts are simple and the motions direct. The strokes of the foot or hand may follow each other so rapidly as to practically secure a continuous, but small, stream of sand, a decided advantage in hill climbing. It can be easily seen that waste is impossible in this box, as the sand flows only when the lever is in motion, and the quantity of sand is regulated.

The hand hopper inside of the car and directly over the sand box, may be made of any form desired. If the space under the seats is inclosed, a square soap box or any other cheap form of construction may be employed. Small stones, or other small substances will not interfere with the operation of this box, but will pass freely through it. In fact, the company recommends coarse in preference to fine sand, even if it contains gravel stones as large as peas, as it is less likely to pack in the box. This sand box described is sold by the Electric Appliance Company, Chicago.



SAND BOX.

FEEDING PURGERS TO BOILER.

The accompanying cut shows an arrangement for feeding purgers to boilers, either from a barrel or from a cup or tank. When the purger is in the form of a powder it should be placed in a barrel and dissolved and fed as shown in the cut. In the case of kerosene oil or other liquid purgers, an ordinary oil cup can be attached, as shown, at a very small expense. A regulating cup is, however, not necessary, as any receptacle will answer so long as the valve "B," by which oil

C-OIL CUP
D-OIL REGULATOR.
PENBERTHY
WATER SUPPLY IN WHICH ANY SOLID PURGER CAN BE DISSOLVED AND FED TO BOILERS.

BOILER PURGER FEEDER.

can be regulated, is tight. This attachment is applicable to the suction pipe of any injector, it being only necessary to have tight joints to prevent air getting into such pipe.

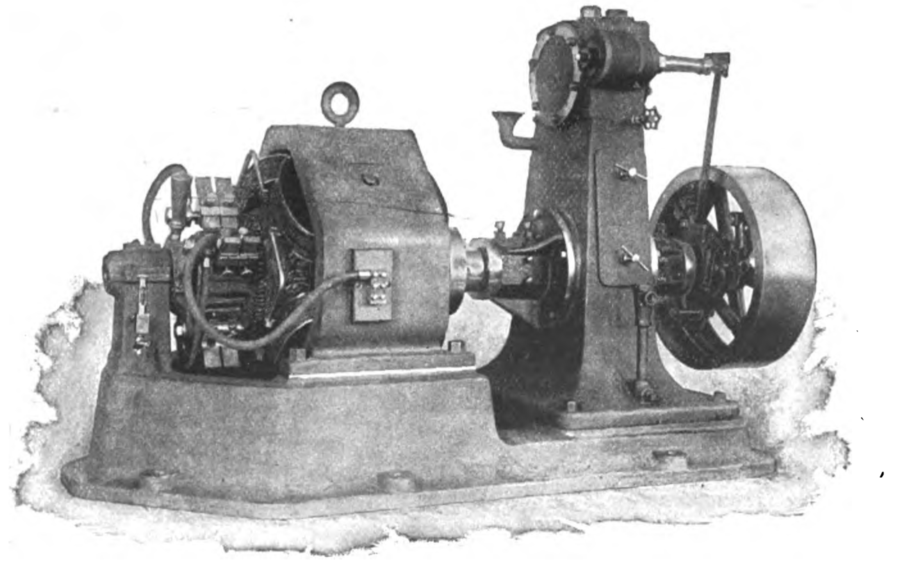
To operate, the valve "B" is closed, the injector is started, then the valve opened to the desired feed. The valve "B" is closed before stopping the injector.

The expense of the oil attachment outside of the cup, which is not necessary, will not exceed 50 cents. A short piece of large steam pipe reduced to ¼ in. will answer as well as the cup "C."

The Penberthy Injector Company, Detroit, Mich., to whom we are indebted for the information herein contained, states that it used kerosene oil for a while and nearly ruined its boiler, and adds: "It is bad—don't use it—but if you will use it, use the above device, which is public property and free for all. Our boilers are eight and ten years old respectively, and they are about as clean as the day they were put in. The boiler inspector of this city and Hartford insurance inspector will no doubt testify to this."

MARINE LIGHTING.

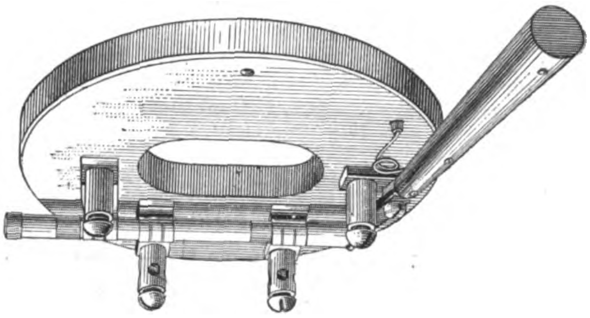
It is interesting to note that the lights used by the divers assisting in the investigation of the Board of Inquiry into the blowing up of the battleship "Maine," were furnished from a generating set consisting of a No. 5 Case engine direct coupled to a 7½ k.w. Bernard dynamo. Owing to the muddy condition of the water, light was absolutely necessary to assist the divers in their examination, and the set herewith illustrated, which is installed on the United States light-house tender "Mangrove," was in almost continuous use for this purpose.



MARINE GENERATING SET.

ARC LAMP HANGER BOARD.

The accompanying illustration shows a hanger board and cutout combined, the method of lamp suspension being such as to be suitable for lamps with terminals close together or wide apart or for lamps supported by a single eye at the center; the board is also well adapted for attaching to lamp hoods. The base is of slate, japanned black, and is made solid or with an oval hole in the center large enough to pass the stack of a single or double carbon lamp. The slide rod is actuated by an insulated handle controlled by a spring which throws the handle either side of the center.



ARC LAMP HANGER BOARD.

The handle is drilled for the insertion of a cord for operating it at a distance. It can also be operated by hand or with pole. The contacts are of phosphor bronze and all parts are either dipped or polished and lacquered, making a board of handsome appearance. The operation of the slide rod is first to shunt the lamp and then cut it in or out entirely and absolutely without sparking. The above board and cutout, known as the "K. & W. Hanger Board and Absolute Cutout," is made by the K. & W. Company, Pittsfield, Mass.

ELECTRIC HEATING IRONS.

The electric soldering iron shown in Fig. 1 is made especially for telephone work—either for use in telephone exchanges or in the manufacture of switchboards. It is 11 ins. long, weighs but 15 ozs., and consumes 90 watts of energy when in operation. The iron shown in Fig. 2 is made especially for tinsmith's work, and is now largely employed in packing houses throughout the country. Fig. 3 shows an electric curling-iron stand, having a base 3½ ins. x 3½ ins., a height of 6 ins., and consuming 90 watts. That is, if run for an entire hour it would cost less than two cents at the highest rate charged for electric current. The above described heaters are made by the American Electrical Heater Company, 197 River Street, Detroit, Mich.

FIG 1.—TELEPHONE SOLDERING IRON.

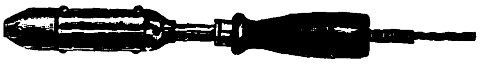


FIG. 2.—TINSMITH SOLDERING IRON.

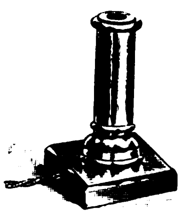

FIG. 3.—ELECTRIC CURLING IRON HEATER.

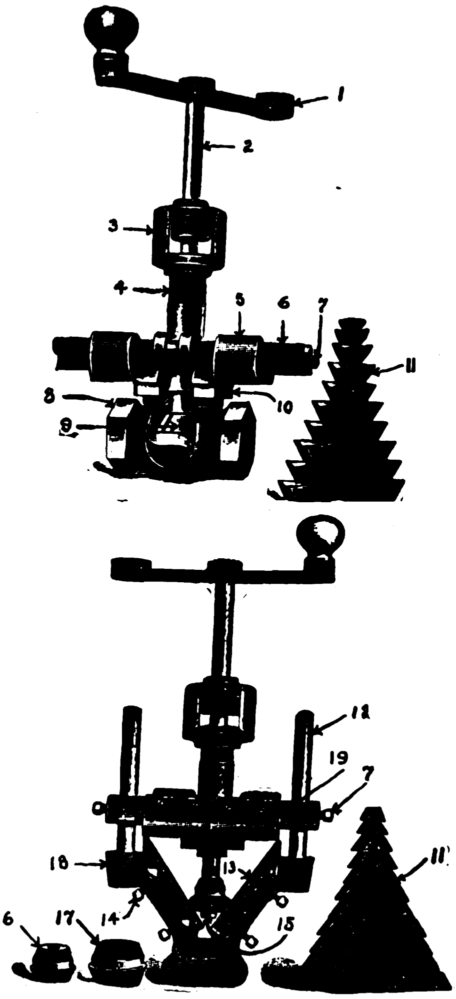
VALVE RESEATING MACHINE.

The value of a practical and reliable valve-reseating machine is now recognized by engineers everywhere, and the type shown herewith can be attached to all makes of valves regardless of the size of thread or diameter of opening in the valve hood. The valve seat is cut with reversible self-clearing tools, which may be ground when dull, which is the only method of invariably obtaining a true seat. The attaching device consists of a block-chuck with gibs placed between the two



VALVE RESEATING MACHINE.

blocks, and the bar to take up the slack. Upon the under side of the blocks is a series of parallel segment-shaped steps, the curved face of each step being threaded to correspond with the threads of valve casings with which the steps are designed to engage.

The screw rod opens or closes the chuck jaws. The cutters for dressing a taper-seated valve are on the inner opposite edges of a V-shaped bar, being attached to it by means of screws that pass through slots in the bar, and thus permit of a rigid angular adjustment of the cutters. It is to be noted that the cutters or blades, by being located on the sides of said bar, have their cutting edges presented on lines tangential and not radial to the axis of the valve being ground. The result of this is that the cutting edges do not catch or unduly bite into the valve, and hence objectionable chattering is avoided and a smooth, easy and free cut is produced.

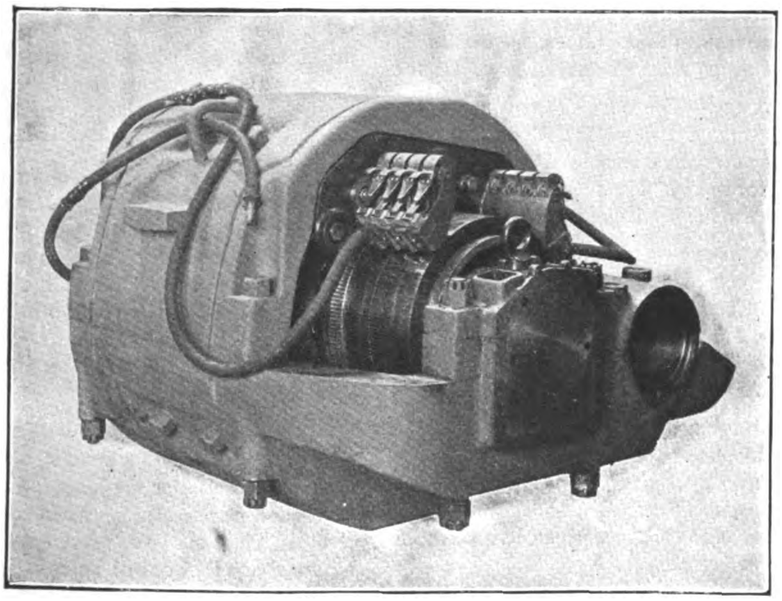
The machine, which is known as the Benton Valve Reseating Machine, is made for all sizes of valves of either flat or taper seat up to 12 ins. in diameter, and is sold by Wendell & MacDuffie, 26 Cortlandt Street, New York, and 53 State Street, Boston.

WALKER ELEVATED RAILWAY MOTOR.

In our last issue a brief description appeared of the 80-h.p. Walker motor, to be used on the Brooklyn Elevated Railway, an illustration of which appears herewith.

The motors were designed by Mr. S. H. Short, of the Walker Company, especially for elevated railway service, and will be built upon the lines of generators. The frame is cast entirely from the best quality of soft steel, the magnetic ring being circular in form and containing four laminated field magnets with pole shoes. Each one of the magnets is wound with bar copper, insulated with asbestos, forming a perfect fireproof coil. The motor frame is divided on a horizontal plane, with the axle bearings and armature bearings carrying the lower half, so that the lower half is supported by the axle and the truck bolster, leaving the upper half of the magnetic frame free to be removed from above, exposing the armature and the whole interior of the motor. The armature bearings are held in pockets cast in the lower frame of the machine, and can be lifted out with the armature from above by means of an overhead crane. The axle is arranged to pass through a tubular cavity cast in the motor frame, so that any oil which may ooze from the axle bearings will run into this cavity and back into the oil wells, with no possibility of leaking into the interior of the motor. The armature bearings are also arranged in solid cast iron boxes containing brasses, and arranged so that the oil which lubricates them returns immediately to the oil wells and does not creep out along the shaft and onto the motor shell. The armature is hollow and provided with air ducts running radially through the laminations to insure perfect ventilation. The winding is made from bar copper, with only one turn for each commutator bar. The modern practice of very few slots is used in the armature, with four inductors in each slot, the insulation being entirely of mica, rendering it also fireproof.

The frame of the motor is left practically open for complete ventilation, so that the heated air on the interior of the motor can escape freely, thereby increasing the capacity for the motor for sudden and heavy over-loads. The motor is so designed that it will not spark under any condition of load, and can take currents two or three times the normal current of the motor without damage to any part of the machine.



WALKER ELEVATED RAILWAY MOTOR.

The brush holders are provided with four brushes each, held firmly in movable brass and bronze boxes, each box being connected directly with the terminals of the brush holders by means of flexible cables, so that the current is not permitted to pass through any moving joints, which would cause heating. The commutator bars are insulated from the shell by means of continuous molded insulation made from pure mica. The commutator bars are made from drop forged copper of the purest quality. The current density in the brushes is about 35 amps. per sq. in., or about the same as is used on the latest types of generators. These machines are so designed that they will run in practice as cool as ordinary generators in the station. The carrying capacity of the copper used in the machine is very great, the resistance being reduced to a minimum, so that they are very efficient for very heavy overloads —a necessary requirement for motors which have to start heavy trains at short intervals of time.

The motors are also provided with armature covers, which can be used to close the motors up tightly during the winter weather, when they will be required to run through snow.

These machines are built especially for elevated railway work, although they can be applied to heavy surface railways, such as branch lines of steam railways, many of which are now experimenting in this line. A large number of these motors have also been ordered by the Metropolitan and West Side elevated railways in Chicago, where they are to be used in operating four-car trains. The Brooklyn motors are, however, of 80 h.p. each, while the Metropolitan motors are of 150 h.p. each. The wheels used are 33 ins. in diameter, with steel tires.

PERSONAL.

MR. I. FUJIOKA, of Tokio, Japan, has arrived in the United States, where he will spend some time before sailing for Europe. Mr. Fujioka is the leading Japanese electrical engineer and electrical manufacturer in Japan, his apparatus being noted for excellent design and mechanical execution.

M. GEORGE PELLISSIER, editor of *L'Eclairage Electrique* and a prominent French electrical engineer, recently arrived in New York, on his way to Auckland, New Zealand, in the interest of a Parisian syndicate to examine some electric railway and lighting properties.

PROF. MASSASHI NAMBA, professor of electrical engineering at the University of Kioto, Japan, is on a visit to the United States in order to inspect the latest electrical developments. Prof. Namba began his electrical studies under Prof. Mendenhall, at the Tokio University, and completed them under Prof. Mascart, at Paris, having for a time been an assistant in the laboratory of each. The University of Kioto has but recently been founded, a part of the Chinese indemnity fund having been set aside for that purpose.

MR. E. J. WESSELS is meeting with much success with his new venture, the *Universe*, an illustrated newspaper for the young. In these days of yellow journalism and the reading habit among the young folks, the time was ripe for a well-written and well-edited publication, which parents can safely place in the hands of their children, to satisfy their desire to know what is going on in the world. The *Universe* (which is published at 96 Fifth Avenue, New York), is most satisfactorily supplying this need.

Mr. Frankland Jannus has removed from Washington and taken offices in the Havemeyer Building, New York. Mr. Jannus has had sixteen years' experience with patent cases of all kinds at Washington, and will continue in New York his practice in all matters relating to patent interests.

Mr. Geo. T. Hanchett, electrical engineer, has removed to 123 Liberty Street, New York, where he has every facility for preparing engineering drawings and tracings on short notice. Mr. Hanchett has associated with him competent draftsmen and mechanics, which render his facilities for performing engineering work very complete, every means being at hand for the design and actual construction of electrical machinery and models. A specialty will also be made of perfecting inventions and apparatus, so that they can be manufactured in excellent quality at a minimum cost; and of the design of special machinery to accomplish certain work.

NEW BOOKS.

Elements of Electro-Chemistry Treated Experimentally. By D. Robert Lupke. Translated by M. M. Pattison Muir. Philadelphia: J. B. Lippincott Company. 223 pages, 54 illustrations. Price, $2.50.

This work treats, in as simple a form as the subject will permit, of the modern science of electro-chemistry as developed by Nernst, Ostwald and other German electro-chemists, and of which until recently English readers have had little knowledge. Although the main purpose of the book is to set forth the purely scientific aspects of electro-chemistry, the practical sides of the subject have not been left altogether unnoticed, technical electro-chemical processes, such as electro-metallurgy, receiving attention.

Universal Electrical Directory for 1898. By J. A. Berly. London: H. Alabaster, Gatehouse & Company. Large octavo, 1180 pages. Price, 6 shillings.

The seventeenth annual volume of the "Red Book" has been increased by 70 pages, making in all about 1100 pages of directory matter. The entire world is covered, the American section, for instance, containing no less than 4080 distinct names and addresses, the total number of names of firms and individuals in the volume being 23,794. Among new matter are additions to the financial information, and telegraphic addresses and local telephone addresses in the British section.

Model Engines and Small Boats. By Nevil Monroe Hopkins. New York: D. Van Nostrand Company. 74 pages, 50 illustrations. Price, $1.25.

The amateur with a taste for mechanics will find this a most interesting work, giving, as it does, clear instructions, accompanied with excellent engravings of detail parts, for making an oscillating and slide-valve engine and a small boiler. By the system of the writer, no patterns or castings are required for constructing small engine cylinders, and the boilers may be made without the use of special tools. A final chapter is on elementary boat design, and a system of hull construction, using wooden ribs in combination with cardboard plating, which is stated to give entire satisfaction under trying circumstances.

Mechanical Draft. A Practical Treatise. Boston: B. F. Sturtevant Company. 385 pages, 109 illustrations.

That this handsome volume is issued primarily as a commercial publication is only evident from the illustrations of apparatus, which are all by one manufacturer. Otherwise the book is what it purports to be—a practical technical treatise on mechanical draft, and as such is better adapted for the use of the engineer than any other work on the same subject published. The titles of the various chapters are as follows: Water.—Steam.—Combustion.—Fuel.—Efficiency of Fuels.—Efficiency of Steam Boilers.—Rate of Combustion.—Draft.—Chimney Draft.—Mechanical Draft.—Advantages of Mechanical Draft.—Fans for Mechanical Draft.—Applications of Fans for Mechanical Draft.

TRADE PUBLICATIONS.

Generators and Motors.—Jas. Clark & Co., Louisville, Ky., in a well gotten up pamphlet illustrate and describe the "Willey" generators and motors, all of the details of which are separately shown in cuts.

Switches.—The O. S. Platt Manufacturing Company, Bridgeport, Conn., have issued a new catalogue, in which all of the many forms of "New England" switches are shown in good engravings.

Resistances.—Carbon resistances are the subject of a pamphlet issued by the Raster Carbon Rheostat Company, 414 Ashland Block, Chicago, in which the reader will find something of interest on the practical use of carbon as a resistance.

Armorite.—An interesting pamphlet comes from the Armorite Interior Conduit Company, Pittsburgh, Pa., in which the processes used in the manufacture of armorite conduit are described, with accompanying illustrations.

Gas Engines.—The New Era Iron Works, Dayton, Ohio, have issued a folder containing some excellent illustrations of the New Era gas and gasoline engine and a number of flattering testimonials to the excellence of this standard machine.

Fan Motors.—E. B. Latham & Co., 136 Liberty Street, New York, in a pamphlet devoted to fan motors, illustrate and describe a full line of these indispensable conveniences for the summer for both direct and alternating current.

Tuerk Fans.—In an extremely fine specimen of the printers' art the Hunter Fan & Motor Company, Fulton, N. Y., illustrate the 1898 models of the Tuerk ceiling electric fan. A prospective maker of a catalogue will do well to get a copy of this little brochure as a guide for his printer.

Friction and Lubrication.—The engineer will find in a recent publication of the Joseph Dixon Crucible Company, Jersey City, N. J., entitled "Friction and Lubrication," a concise and well-written treatise on the practical aspects of these subjects, including selection and uses.

Telephones.—The Central Telephone Company, 1123 Pine Street, St. Louis, in the 1898 edition of its catalogue illustrates and describes the various types of telephones, magnets, etc., of its manufacture, as well as a complete line of telephone supplies.

Electric Heating.—Electric soldering irons, laundry irons, tailors' irons, curling-iron heaters, electric heating discs, etc., form the subject of a catalogue issued by the American Electrical Heater Company, Detroit, Mich. The practical form of all the apparatus shown is evident from the cuts.

A Modern Engine.—In this day of handsome trade publications to say that one is the handsomest specimen of current issue means much. This remark, however, applies to a recent circular issued by the Ball Engine Company, Erie, Pa., entitled "A Modern Engine," which will well repay the cost of a postage stamp to obtain.

Shade Lamps.—The Electric Appliance Company, Chicago, in a handsomely executed little pamphlet, illustrates a variety of shade lamps for the office and family circle, including desk and typewriter lamps. Among these are the Espersen adjustable lamp shade, the Klemm portable desk lamp and the Dale bracket lamp.

Electrical Insulation.—In a 48-page pamphlet the H. W. Johns Manufacturing Company illustrate over 150 different kinds of molded mica and vulcabeston electrical material, including trolley line insulators, weather-proof sockets, controller parts, field spools, bushings, etc. The final pages are devoted to "H. W. J." car heaters and electrotherms.

Walker Circulars.—Walker circulars 1066-1069 are on the electric plant of the Astoria Hotel, electric locomotives, boosters and electric railway generators, respectively. That on boosters very clearly explains the principles of an apparatus which is entering largely into use, and every part of Walker generators is illustrated in detail in circular No. 1069.

Lundell Fan Motors.—The Sprague Electric Company, 20 Broad Street, New York, has issued a handsome catalogue of 1898 models of Lundell motors, the cover being particularly artistic in design. One of the features of the catalogue consists of excellent Bartlett wood cuts, showing every detail of the Lundell motor, even the most minute.

Special Incandescent Lamps.—The General Electric Company, in a handsome

44-page pamphlet, illustrates and describes lines of candelabra, special series, and battery lamps. Some of the first mentioned are in especially handsome shapes. The two latter classes comprise lamps for decoration signs and for every purpose to which small lamps have been put in the trades and arts.

WAGNER BULLETINS.—Bulletins 9A and 10 of the Wagner Electric Manufacturing Company, St. Louis, are on type G and type F transformers, respectively. All of the details of the transformers are illustrated and much technical information included, such as tables of efficiencies, notes on the aging of iron and testing of transformers, curves, of regulation, core losses, efficiency, etc.

A JAPANESE TRADE CATALOGUE.—We have received from Charles Wirt, 1028 Filbert Street, Philadelphia, a copy of pamphlet printed for a Japanese company with an unpronounceable name, which is intended for distribution in the "Land of the Rising Sun." This is one of the straws showing which way the wind blows as concerns the advancement of the Japanese in the industrial arts.

STEAM SPECIALTIES.—It is seldom we see a catalogue so full of practical information as one recently issued by the A. A. Griffing Iron Company, 66 Centre Street, New York. While its ostensible object is to bring out the merits of Bundy apparatus, the information it contains on steam working gives the pamphlet the character of a technical treatise on the subject, written moreover from the standpoint of the working engineer.

HYDRAULIC FITTINGS AND FLANGES.—Thorpe, Platt & Company, 97 Cedar Street, New York, are sending out a pamphlet issued by the Tight-Joint Company, on high pressure air and hydraulic fittings and flanges, which give about fifty pages of useful technical information on the design of hydraulic plants and hydraulic pressure transmission. Many tables are included, and formulas are given for calculations of hydraulic detail.

INCANDESCENT LAMPS.—The General Electric Company, in view of the large number of applications made for information, which is embodied in the second part of its recently issued Edison Incandescent Lamp Catalogue, has published this information in a separate 16-page pamphlet of small octavo form. This information is of value to all users of incandescent lamps, and the General Electric Company will be pleased to supply copies of the pamphlet on application.

ELECTRIC GAS LIGHTING.—In a 136-page catalogue, the Electric Gas Lighting Company, 195 Devonshire Street, Boston, illustrates and describes every variety of electric gas lighting devices, and a full line of electrical house goods. Several handsome inset sheets in colors show a new type of candle burner attachment, the Samson battery and the Nosmas battery. The descriptions of apparatus are particularly well gotten up, the catalogue in this respect answering the purpose of a technical treatise on electrical house goods.

GEARS.—Steel gears and pinions form the subject of a small and artistic pamphlet, well illustrated and printed, issued from the press of the General Electric Company, under the title, "A Modern Gear Plant." It contains a description of the extensive plant that the company has established at the river works at Lynn, for the exclusive manufacture of steel gears and pinions, which is equipped throughout with the most modern machinery. This pamphlet will be sent on application to any of the company's sales offices, one of which is found in every large city in the United States.

CONTRACTORS' HANDBOOK.—The Montauk Multiphase Cable Company, 100 Broadway, has issued a handbook of much value to electrical engineers and contractors, consisting of a compilation of insurance statistics, giving the specific causes of fires over a period of thirty years, and the percentage for each cause. As the multiphase cable is a continuous fire-alarm, thus affording almost perfect protection against fire-hazard, the data of the book will greatly assist dealers in showing its value to prospective purchasers through reference to the figures showing the hazard to which their property is exposed without such protection.

COMMUTATOR BARS.—The Forest City Company, in a large page catalogue, illustrates to scale some scores of commutator bars, including not only those in general use, but bars for machines no longer manufactured. The "Protected" rail bond is also shown in excellent illustrations.

ELECTRIC LIGHT AND POWER SPECIALTIES.—Zimdars & Hunt, 127 Fifth Avenue, New York, in a large page catalogue with a striking cover, give a number of illustrations of the automatic switch and motor starters of their manufacture, the illustrations being made from photographs of the various articles themselves, taken just previous to the printing of the catalogue. In addition to the excellent half-tone engravings, there are others giving diagrams of connections.

FAN MOTORS.—The Western Electric Company, Chicago and New York, has issued a handsome 36-page illustrated fan-motor catalogue, printed in two colors and substantially bound in a neat and artistic cover. Every type of fan-desk, column, bracket and ceiling, is illustrated and described, both for direct and alternating currents. Detailed illustrations are given of a direct current desk and ceiling fan, and an alternating-current fan, showing all of the working parts. A column fan is shown which is particularly adapted for restaurants, soda-water fountains, drug stores, ice cream parlors and saloons, consisting of a fan somewhat similar to a ceiling fan, but mounted on the top of a column, at the base of which is a red birch table, 4 ft. in diameter. Battery fans take up three pages, and a complete list is given of fan accessories, such as flexible cord, attachment plugs, receptacles, etc.

BUSINESS NEWS.

INCLOSED ARC LAMPS FOR THE NAVY.—The Buckeye Electric Company, Cleveland, Ohio, has received from the Navy Department a large rush order for Jandus inclosed arc lamps.

THE D. A. KUSEL MANUFACTURING & ELECTRIC COMPANY, 1110 Pine Street, St. Louis, reports the telephone business in a very flourishing condition, and states that it is at present in receipt of orders which will keep the entire factory force rushed for some weeks to come.

THE WALKER COMPANY has recently secured a very handsome and commodious suite of offices on the sixteenth floor of the Commercial Cable Building, 18-20 Broad Street, New York. The suite includes a private hall, general offices, private offices for the officials of the company and all the latest conveniences for the modern transaction of business.

PROPOSALS WANTED.—The City of Columbus, Ohio, returned unopened the proposals that were to have been considered March 24, for furnishing the machinery, lamps and pole line for a municipal plant, and have invited new ones, to be opened April 13. Further information may be obtained by addressing James A. Fanning, clerk.

STORAGE BATTERIES.—The Electric Storage Battery Company, of Philadelphia, in its annual report, states that for the year ending December 31, 1897, the sales amounted to $1,026,925, against $572,281 for 1896, or an increase of $454,644. The net profits for 1897 were $340,008, and for 1896, $148,799, showing an increase of $191,209.

THE WARREN-MEDBERY COMPANY, of Sandy Hill, N. Y., has been incorporated for the manufacture of electrical supplies, with a capital of $25,000. The directors are Horace J. Medbery and S. C. Medbery, of Ballston Spa, N. Y.; H. B. Warren, of Yonkers, and W. H. Cunningham, H. E. Tidmarsh, Lincoln Paris and G. W. Wait, of Sandy Hill.

TELEPHONES.—The Stromberg-Carlson Telephone Manufacturing Company, Chicago, reports that it has just taken a contract for the complete installation of the Farmer's Mutual Telephone System, of Henry County, Ill. This equipment will consist of about 200 toll line instruments and will be, without doubt, one of the largest farmers' lines ever equipped.

SAFETY CONDUIT.—L. A. Chase & Company, Boston, are the selling agents of the new type of conduit made by the Safety Conduit Company, of Rankin Station, Pa. By a new process of manufacture, the interior surface of ordinary gas-pipe is rendered entirely smooth, so that under no circumstances can the insulation of wires be injured when drawn in.

DIRECT CONNECTED UNITS.—The New

Britain Machine Company, New Britain, Conn., successor to the J. T. Case Engine Company, is running overtime in order to keep up with their orders for engines to be used with direct connected generating sets. This company makes a specialty of sizes from 2½ to 25 h.p., nothing larger than the latter being constructed.

Westinghouse, Church, Kerr & Co. are to supply a complete equipment for a new power house of the Detroit, Ypsilanti & Ann Arbor Railway, consisting of five Westinghouse generators of 225-k.w. each, direct-connected to Westinghouse compound condensing engines; Babcock & Wilcox boilers, Roney mechanical stokers, economizers, apparatus for mechanical draft, etc.

Motors for the Navy.—The Bullock Electric Manufacturing Company, of Cincinnati, Ohio, is supplying a number of motors to the New York navy-yard, for operating drills and other large machinery in the construction shops. Owing to the present activity in naval matters, rush orders were given by the Government to complete the machines at the earliest possible moment.

The K. & W. Company, Pittsfield, Mass., has increased its capital stock, the additional capital to be used for the enlarging of its plant for the manufacture of Hardy incandescent lamps. The demand for the Hardy incandescent lamp has been both rapidly and steadily increasing, as has also the demand for the K. & W. new absolute cut-out hanger board and the K. & W. composite dynamo brush.

Electric Conduits.—The Safety Conduit Company, of Rankin Station, Pa., advise us that their "Loricated" electric conduits will be installed in the new U. S. Appraisers' warehouse, corner Greenwich and Christopher Streets, New York, and also in the Prudential Building, Atlanta, Ga. The former building will require in the neighborhood of 30,000 ft., the latter building over 50,000 ft. of iron armored conduit.

The Triumph Electric Company, Cincinnati, Ohio, made the following sales between March 1 and 15: Motors, one each of 67, 30, 7½ and 1 h.p.; five of 5 h.p. and two of 2 h.p.; generators, one each of 30, 15, and ¾ k.w.; two of 100 k.w. and two of 3 k.w.; elevator motors and controllers, one of 5 h.p., and three of 10 h.p. Also, a motor-generator of 4 h.p., a cloth cutter and a marble switchboard. This company booked 95 orders the first ten weeks of the year.

A St. Louis Office Building.—The Commerce Realty Company is erecting a large mercantile building at the corner of Ninth and Tenth Streets, St. Louis, which will have a very complete electrical equipment. The plant will consist of three 150 h.p. boilers, with down-draft furnace, two 300 h.p. Hoppes feed-water heaters, three compound Weston Imperial engines of 120 h.p. each, direct connected to three 75 k.w. General Electric generators. There will also be two passenger and six freight Sprague electric elevators. Bryan & Humphreys are the consulting engineers.

The Keystone Electrical Instrument Company, of Philadelphia, has appointed Mr. W. R. Garton, 414 Ashland Block, Chicago, Ill., its Western representative, with headquarters as above. This change means that the Keystone Company is out for all the Western business in sight, and with a representative of Mr. Garton's large acquaintance and well-known business energy, largely increased sales of its instruments in his district will result. Since the first of the year the company has had its force working day and night to keep pace with its orders, and is now preparing to largely increase its present facilities.

The Harrisburg Foundry & Machine Works has secured the services of W. R. Fleming, of the firm of W. R. Fleming & Company, of New York, Boston and Philadelphia, as vice-president and general manager, and will shortly make a considerable increase in its facilities for manufacturing automatic engines for electric service. It is intended to add several new lines of engines, so as to broadly cover the whole field of steam engine practice. It is also understood that the company will rebuild its entire plant upon a plan and scope which will place it in a superior condition for the manufacturing of its machinery, which has become so well known throughout the country.

The Central Telephone & Electric Company, 1123 Pine Street, St. Louis, reports that it is kept hustling to fill its orders. This firm is just installing a complete exchange at Baton Rouge, La., which will consist of 150 instruments to start with, and ultimately many more, as subscribers are still coming in. The satisfaction given by the instruments of this concern has been the means of rapidly extending its business, and the reputation it has gained for first-class superior goods is a permanent assurance to the purchaser that he will secure from this company the most up-to-date and perfect instruments obtainable.

The Rochester Electric Motor Company, Rochester, N. Y., has changed its management, the present officers being F. C. Kimmel, president, and Edw. F. Davidson, secretary and treasurer; P. T. McDonald remaining as superintendent. The works have been moved into larger quarters at the corner of Mill and Platt Streets, where with better facilities the growing demand for Rochester dynamos and motors may be more promptly filled.

Ball Engines.—On account of the great demands for its engines for electric light and power purposes, the works of the Ball Engine Company, Erie, Pa., builders of the Ball engine, have been operated night and day since September last.

Voltage Regulators.—The Alma (Mich.) Electric Light & Power Company has just placed an order with the Belknap Motor Company, of Portland, Maine, for a Chapman voltage regulator for a 60-k.w. alternator. The Warren (Pa.) Electric Light Company has just placed an order for a regulator for a 120-k.w. alternator, and the Milton (N.H.) Electric Light Company, one for a 100-k.w. alternator. The Belknap Motor Company has engaged space for an exhibit at the Electrical Exhibition to be opened in May at Madison Square Garden, New York City, where will be shown a line of Chapman voltage regulators and other electrical machinery. It also contemplates having an exhibit at the Paris Exposition in 1900.

The Metropolitan Electric Construction Company is now doing all of the installation work of the Sprague Electric Company, an arrangement to that effect having been recently closed. The announcement was made in a striking two-color circular by the Sprague Company, in which circular it was pointed out that the Construction Company would not only contract for installation and maintenance of Sprague machinery, but of any other machinery as well. The offices of the Construction Company, as well as those of the Sprague Company, are in the Commercial Cable Building. The officers are W. D. McQuesten, president and general manager, and Mr. Wallace E. Carver, treasurer.

Self-Setting Annunciator.—The advantages of a self-setting annunciator which is not subjected to constant and violent hammering in resetting, and hence does not get out of adjustment, are described in the circular catalogue issued by the Heath Electric Company, 335 Grand River Avenue, Detroit, Mich. This company also manufactures the "Ideal" automatic annunciator for house use. This annunciator is also automatic in resetting, and as the last call is the only one showing, this feature makes it one of the most convenient and desirable annunciators in use. The Heath Electric Company reports a very brisk demand from the supply trade for house, elevator and two-way annunciators and also for burglar alarms.

Mica Insulation.—The Mica Insulator Company, whose offices are at New York and Chicago, with a branch at London, England, recently received from one of the large builders of electrical machinery orders for over 5000 "Micanite" segments of a large pattern (many of which were more than 17 ins. in length); and from another leading manufacturer of electrical apparatus an order for 2000 segments; also, from one of the leading motor builders an order for 26,000 segments. Such orders would seem to bear out the claim of the company, that its segments are softer and wear down more evenly than mica segments. A sample set of segments for any one of the smaller machines will be furnished free of expense to electrical manufacturers or repair concerns who may wish to personally demonstrate their value.

The Duplex Manufacturing & Electric Company, 84 Adams Street, Chicago, has just placed a large number of its Duplex wire lamp guards for incandescent lamps in the stations and stairways of the Union Loop, Chicago. This guard is meeting with much favor, and is being purchased in large quantities by such companies as the Boston and Maine Railroad, Southern Pacific Railroad, The Pullman Company, Chicago, Rock Island, Pacific Railroad, Union Stock Yards and by factories and mills generally. Mr. L. M. Cole, president of this company, states that they are being favored with very large orders, and that the Duplex guard has proven itself a winner wherever used.

The Sprague Electric Company.—The organization of the Sprague Electric Company, which our readers well know was formed by the consolidation of the Interior Conduit & Insulation Company and the Sprague Electric Elevator Company, is being rapidly perfected. The offices of the company now occupy practically the whole of three floors in the Commercial Cable Building. The company recently secured a suit of rooms in the Marquette Building, Chicago, which will be in charge of Mr. Millard B. Kitt and Mr. E. B. Kittle, long identified with the company. Well-known electrical men and houses are being rapidly secured to represent the Sprague Company in various sections of the country, and the organization bids fair to be a remarkably strong one in every way.

The M. B. Wheeler Electric Company, 99 Ottawa Street, Grand Rapids, Mich., have just been incorporated for $25,000, under the above name. This company was formerly located at 25 Fountain Street, Grand Rapids, under the firm name of M. B. Wheeler & Company. The officials of the new company are A. O. Wheeler, president; S. D. Kopf, vice-president; M. B. Wheeler, secretary and general manager, and F. I. Cruse, treasurer. This concern has just finished the installation of 220 interior telephones in the recently remodeled Sherman House, Chicago. It is also doing the entire wiring for the mammoth factory of the Bissel Carpet Sweeper Company, of Grand Rapids, and also a complete installation for H. Leonard & Sons' wholesale house, in the same city, besides many minor installations throughout the State. Mr. A. B. Smith, who has had over fifteen years experience in the telephone business, a portion of which time he spent with the Bell Telephone Company, will give his personal attention to the telephone department of the above concern.

Rope and Bond Insulating Paper.—The Mica Insulator Company, of New York, Chicago and London, announces that it has recently made an addition to its already extensive line of oiled cloth and paper insulations, and is now prepared to furnish "M-I-C Compound" rope and and bond paper. This line of insulation is made from rope and bond paper treated with two baked coatings of M-I-C compound. The rope paper is furnished in sheets 1 yd. wide, 2 yds. long and packed between sheets of plain paper. The average break-down test is 739 volts per mil, the thickness being 4½ mils. The bond paper is furnished in sheets 19 ins. x 24 ins. and 22 ins. x 34 ins., the average break-down test being 859 volts per mil, the thickness being 5 mils. The company will be pleased to send samples to electrical manufacturers, street railways or lighting stations upon application.

A Special Bundy Separator.—The A. A. Griffing Iron Company, Jersey City, N. J., has just completed and forwarded to James Rees & Sons, Pittsburgh, Pa., a special Bundy separator for removing oil from ammonia gas. While the Bundy separators are regularly made for work of this kind, in this particular case the requirements were a trifle unusual, as the working pressure is 500 lbs. to the square inch. The separator is ordinarily strengthened and reinforced with special packing glands for operating on ammonia lines, but for such an enormous pressure extra care and attention has to be exercised in order to prevent the escape of any gas. The experience which the A. A. Griffing Iron Company has had in manufacturing separators for use under difficult and adverse conditions enables them to furnish just what is wanted.

Walker Apparatus.—Among the foreign orders recently received by the Walker Company, are twenty double No. 3-S street car equipments, three single No. 3-S equipments and eighteen double No. 3-N equipments, for Paris, besides four 150-k.w. belted generators with two generator panels. Messrs. Bagnall & Hilles, of Yokohama, have ordered two 25-k.w. direct-connected generators for Singapore. Recent domestic orders include two 150-k.w. 3-phase synchronous motors for the Lachine Rapids Power Company; a 700-k.w. alternator, single phase, for the Buffalo & Niagara Falls Electric Light & Power Company; two 400-k.w. belt driven generators for the Syracuse Construction Company, and one 120-k.w. belted generator for the Northern Electric Company,

The Belknap Motor Co.
OF PORTLAND, MAINE,

are very busy in the manufacture of Chapman Voltage Regulators; about ¼ of their entire force is devoted to this work alone. Orders have recently been received from Bath (N. Y.) Illuminating Co., New Haven Electric Light Co.; Potomac Electric Light Co.. (third one ordered within few months). Northern Electric Light Co., Philadelphia; Middletown (Conn.) Electric Light Co., three regulators. Pawtucket R. I. Electric Co.; Mutual Electric Light Co., St. Antonio, Tex.; Mt. Morris Electric Co., New York City, (two) recent shipments of Chapman Regulators have been made, (2) Johnstown, Pa.; Electric Co., Stockton, Cal., Gas & Electric Co., B. C.; Smelting & Refining Co., Trail, B. C.; People's Electric Co., Orange, N. J.; Thomas Oakes & Co., Bloomfield, N. J.; Clute Bros., Cohoes, N. Y.; H. T. Cushman Mfg. Co., North Bennington, Vt., Lebanon (N. H.) Electric Co.; Haverhill (Mass.) Electric Co., &c., &c. The sale of Motors and Dynamos manufactured by this company is lively at the present time; their New York and Boston representatives, Brewster Eng. Co, 27, Thames Bldg., and the L. I. Fletcher Co., Boston, are hustlers and no mistake. About 200 H. P. in motors having been received from Brewster Eng. Co. since Jan. 1st, and a similar amount from L. I. Fletcher Co., more than 40 machines being sold since Sept. 25th by the latter company.

Modern Switchboards.
BY
Albert B. Herrick.

An elaborate essay, treating of the construction of Switchboards for all purposes, together with a historical sketch of the appliances used thereon, from the inception of the art to the present time. Fully illustrated with several hundred cuts, diagrams, tables, etc., especially prepared for this publication, the whole forming a very handsome book of 220 pages, printed on super-calendered paper, 9x11 inches, and bound in vellum cloth.

Price, $3.00 by express prepaid.

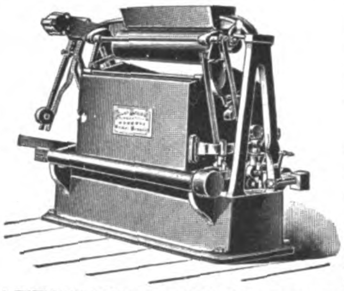
of Baltimore. The Norton & Attleboro Railway, of Attleboro, Mass., has purchased four double No. 4-A-S and two double No. 5-S equipments, besides a 250-k.w. direct-connected railway generator. Besides the generator above referred to, the Northern Electric Company, of Baltimore, has ordered 100 Walker arc lamps, making in all 300 in three months. The company has also recently taken a contract from the Government to build three disappearing gun carriages for 8-in. rifles of the Crozier type, '96 model.

CORRESPONDENCE INSTRUCTION. — Our esteemed contemporary, the *Electrical Engineer*, has established the "*Electrical Engineer* Institute of Correspondence Instruction," the methods of which are based upon a new system of instruction similar to that employed in the Toussaint Langenscheidt system of language teaching, now in extensive vogue abroad. The requirements for admission to the course is nothing more than ability to read and write. The elementary courses begin with simple arithmetic, and an unlimited time is granted the student to complete his course of instruction, teaching being continued without extra charge until the student has acquired a diploma or a certificate of efficiency or until he voluntarily resigns. Text books are to be furnished without extra charge. The course may be sold or transferred at any time, and extensions of time in case of shortness of funds will be granted. In short, the aims of the institute are to enable anyone desirous of obtaining a thorough knowledge of the electrical and allied arts to acquire it through the instrumentality of carefully prepared printed lessons supplemented by a system of confidential correspondence carried on between the student and the institute, in which the student is at liberty to ask as many questions as he likes, until he is satisfied that he thoroughly grasps every point in the lesson he is studying. The direction of the institute instruction has been placed with Mr. Herman A. Strauss, E. E., an engineer with thorough electric and mechanical training, acquired in this country and abroad, and who also brings to his work a practical experience in teaching.



HIGH CLASS MACHINE TOOLS
for Machine Shops and General Metal Finishing Use.
Machines, Fixtures, Small Tools and Gauges for the manufacture on the interchangeable plan of Guns, Sewing Machines, Typewriters, Cash Registers, Bicycle Parts, etc.
Brass Finishing Machinery.
Reliable Counting Registers, Standard Measuring and Testing Machines.
Drop Forging Machinery: United States Standard Threading Machines and appliances.
Milling Cutters, Combination Lathe Chucks.
AUTOMATIC WEIGHING MACHINES for accurately weighing coal and all material of a uniform size handled for storage and distribution.
Lathes, Planers, Shapers, Drilling and Milling Machines for Tool Room use.
Bar Iron Limit Gauges, useful to protect the buyer of bolt iron against the delivery of material of sizes unsuitable for use without changing dies for heading or threading and of excessive weight.
Brigg's Standard Pipe Thread Gauges, useful for testing pipe and fittings to insure their delivery in condition for connection without rethreading when ordered to said gauges.

Study Electrical Engineering at Home

by our perfected correspondence method, under the guidance of ENGINEERS OF REPUTATION. Other courses are also taught. Terms to suit the student's circumstances. ELECTRICAL ENGINEERING taught by an ORIGINAL plan. This Institute was the FIRST TO TEACH THIS SUBJECT BY MAIL. It is endorsed by educators and technical men. Catalogue sent free on application. INSTITUTE FOR HOME STUDY OF ENGINEERING. 72-73 Blackstone Building, Cleveland, Ohio.

A TECHNICAL EDUCATION 50 CENTS A WEEK

THE new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2 00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary textbooks.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 48 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

The International Correspondence Schools,
Box 1025. SCRANTON, PA.

"A COLLEGE EDUCATION BY MAIL."

ELECTRICAL ENGINEERING TAUGHT BY MAIL FOR LESS THAN 7 CENTS A DAY.

STUDY AT YOUR OWN HOME by enrolling in THE HOME SCHOOL OF ELECTRICAL ENGINEERING.

The tuition fee can be paid either in advance or in installments, by paying **$2** when enrolling and the balance at the rate of **$2 a month,** which is **less than 50 Cents** a week. This includes all Text Books and Drawing Plates, and a complete set of Electrical Experimental Apparatus.

The tuition fee for the course, once having been paid, in cash or in installments, entitles you to instruction until you have satisfactorily completed each subject in the course, even if it takes five years or more to finish it.

The following courses are taught in The Home School of Electrical Engineering:

Complete Electrical Engineering. Electrical Station Engineering. Complete Station Engineering. Electric Lighting.
Electric Railways. Telegraphy and Telephony. Electroplating.

Besides these we teach courses in the Home Schools of Mechanical, Steam, Civil and Sanitary Engineering, and in the Home Schools of Art, Architecture and Trades. WRITE FOR CIRCULAR P and state in what subject you are interested. This circular contains sample Instruction and Question Papers, list and prices of courses, and a sample drawing plate.

WANTED TO PURCHASE.

WANTED.—Mixed lot of about one thousand, 50 and 100 volt direct and alternating current fan motors. Address, THEO. K. JACKSON, Ann Arbor, Mich.

HELP WANTED.

WANTED—A thoroughly competent man to take charge of the armature and field winding department of one of the leading electrical companies. With application, state experience, what wages would be expected, and also if now engaged in this work. Address, "C. E. K.," care of AMERICAN ELECTRICIAN CO., New York.

WANTED—Salesman for electrical work. A permanent position offered by a large manufacturing company for a first class salesman on electrical apparatus. The position offers a large opportunity for an ambitious man of the first class. A technical training and a considerable amount of electrical engineering are necessary. Preference will be given to a man who can secure business immediately. In replying give full information covering the following headings: Age, Education, Business experience in detail, Amount of business successfully handled, Salary expected, state whether married or single, give five references. Address, "X. Y.," care of AMERICAN ELECTRICIAN CO., New York.

SITUATIONS WANTED.

WANTED.—A position in an electric light station at general wiring with an opportunity to work myself up. I have four years of experience and good reason for wanting to change place. Can furnish first-class reference if desired. Address C. P., care AMERICAN ELECTRICIAN, New York.

WANTED—Electrician has $1,500 to invest in electric light or other electrical business. Address, F. B., care AMERICAN ELECTRICIAN, New York.

Wanted! Wanted!! Wanted!!!

We desire to purchase copies of the May, June, August and November, 1896, and January, August and September, 1897, issues of the AMERICAN ELECTRICIAN, and will therefore extend the subscription of any subscriber two months for each clean copy sent us. We also desire copies of April, 1897, and January, 1898, and will extend subscriptions one month for each clean copy sent us. The postage should be prepaid, the rate being one cent for each four ounces.

American Electrician Co., Havemeyer Building, New York, N. Y.

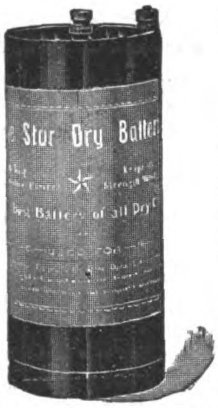
THE STAR DRY BATTERY



High Voltage--1.5 to 1.6.

THE BEST BATTERY OF ALL DRY CELLS.

The construction of the Star Dry Battery is different from any others and many times more durable.

Highest regenerative power. Loses none of its strength while remaining inactive. Used for Telegraphs, Telephones, Annunciators, Railway Signals, Electric Gas Lighting, and all open circuit and intermittent work. The Star Dry Batteries are manufactured in four standard sizes:

No. 1, 7x3 inches in diameter; No. 2, 6x2½ inches in diameter; No. 3, 4x1¾ inches in diameter; No. 4, 3x1 inches in diameter.

Price for set of Samples, free Express, $1.50.

We also manufacture

THE MULTIPLE X-RAY STAR BATTERY.

Especially manufactured for Spark Coils.
The only Dry Battery that can be used for such work successfully.

Send for descriptive Circulars and Net Prices.

SPECIAL OFFERING!

An Opportunity for Bargains in Electrical Apparatus.

We offer the following apparatus, now in the service of the Home Electric Light and Power Company, Elkhart, Ind., and will be replaced by April 1st with electric apparatus of larger units.

Two 50-light 2,000 Cp. Standard Arc Dynamos, self-oiling bearings, regulator, sliding base pulley, etc.

One 60-light 2,000 Cp. No. 8 Wood Arc Dynamo, oil cup bearings, regulator, sliding base, pulley, etc.

Four 45-light 1,200 Cp. No. 7 Brush Arc Dynamos, oil cup bearings, dials, sliding base, pulley, etc.

One 1,000-light National alternator, 1,000 volts, 16,000 alternations, complete with switch board instruments and exciter, and an extra armature for Alternator.

One 800-light Westinghouse Compound Wound Alternator, 1,000 volts, 16,000 alternations, self-oiling bearings, complete with switch board instruments and exciter.

One hundred Edison-Sperry 2,000 Cp. single carbon H. T. Arc Lamps, with ⅝-in. carbon holders.

Twenty-five Wood 2,000 Cp. single carbon H. T. Arc Lamps with ½-in. carbon holders.

Fifty T. & H 1,200 Cp. single carbon Arc Lamps with ½-in. carbon holders.

Twenty-five Hafermeister 1,200 Cp. single carbon Arc Lamps with ½-in. carbon holders.

We also have a number of Wood Split Pulleys and Clutches, Leather Belts, etc.

This apparatus will be thoroughly overhauled, re-painted and varnished and bright parts all polished.

Prices are exceedingly attractive and will interest you. Write us. Address,

THE ELECTRICAL BROKERAGE CO.,

STANDARD
ELECTRICAL
DICTIONARY
SLOANE
NORMAN W. HENLEY & CO.

"The dictionary gives evidence of a large amount of painstaking work on the part of the author, and possesses features which must be commended. Among these, the author, wherever occasion required it, has furnished the synonyms of terms, and the book is given an additional value by an alphabetical index, which enables it to be consulted for terms both collectively and individually. The work will prove of value to the reader, whether professional or non-professional. The definitions are put tersely and concisely, so that the inquiring reader can carry away a defined, net impression as to what is meant. Any student who will spend his leisure hours over the volume will be amply repaid for his time and trouble. The book is very clearly printed in bold type on good paper, and is well bound."—*Electrical Engineer.*

Gentlemen:—Yours of 10th in regard to Elden Circuit Breakers at hand. We have three of these circuit breakers in our station on two "A" 120 and one "A" 35. They have given us utmost satisfaction and never fail to work on several occasions when it was necessary. They are an equally good protection against over-loads and lightning, which has been demonstrated this summer. We are very much pleased with the apparatus and take pleasure in recommending it.

Yours truly, (Signed)

Students of Elementary Electricity,

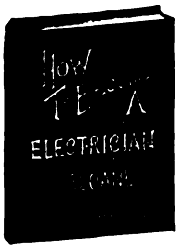
And those interested in the subject from a financial or other indirect connection, as well as electricians desiring information in other branches than their own, will find in these works precise and authoritative statements concerning the several branches of applied electrical science of which the separate volumes treat. The reputation of the authors and their recognized abilities as writers, are a sufficient guarantee for the accuracy and reliability of the statements contained. The entire issue, though published in a series of ten volumes, is nevertheless so prepared that each book is complete in itself and can be understood independently of the others. The volumes are profusely illustrated, printed on a superior quality of paper, and handsomely bound in covers of a special design. Cloth. Price per volume, $1.

Copies of this or any other electrical book published will be sent by mail, POSTAGE PREPAID, to any address in the world on receipt of price.

AMERICAN ELECTRICIAN COMPANY, Havemeyer Building, New York.

How to Become a Successful Electrician

Illustrated. $1.00.



"Every young man who wishes to become a successful electrician should read this book. He will not be an electrician when he has mastered the book, but if he follows the advice there given he will become an electrician at some future time, if he is capable of becoming anything. It may be called a minimum book, for it tells the least that will be necessary, but it tells it in such a way that no worthy young man will be satisfied with the minimum, but will strive for that greater knowledge that will compel true and continually growing success. It is filled with good common sense, and is the clearest and most practical book on the subject we have seen."—*Public Opinion.*

Arithmetic of Electricity.

Fourth Edition. Illustrated. Price, $1.00.

ARITHMETIC
OF
ELECTRICITY
SLOANE

A Practical Treatise on Electrical Calculations of all kinds, reduced to a series of rules, all of the simplest forms, and involving only ordinary arithmetic; each rule illustrated by one or more practical problems, with detailed solution of each one. Followed by an extensive series of Tables.

"We have already reviewed 'The Arithmetic of Electricity' in these columns. The best testimony of the nature of its reception by the public is the early issuing of a third edition. The object of the work is to give a practical review of the mathematics of electricity within the scope of those who are not conversant with algebra and the higher mathematics. It comprises a large number of rules, illustrated by one or more examples each, while, in order to remove from it anything of the empirical aspect, a chapter is devoted to demonstrations of the rules which require it."—*Scientific American.*

CAN I BECOME AN ELECTRICAL ENGINEER?

This question has been put repeatedly by thoughtful and ambitious thousands.
We have been urged again and again

To Do Something for Those Who—Outside of College—Seek an Electrical Engineering Education.

These accumulating requests demanded recognition—they rose to the nature of a command. We now respond to them publicly after having—during the past two years—been engaged in elaborate preparations to fully meet this need of the times. The work is now consummated, and we take pleasure in announcing herewith

∴ THE INAUGURATION OF ∴

The Electrical Engineer Institute of Correspondence Instruction,

the organization of which is based on a new and carefully worked out

Our Principles:

1. To help those who lack education.
2. To make it possible—by a system of easy payments—for the poorest to obtain a first-class technical education.
3. To grant to anyone instruction, irrespective of age or previous education.
4. To allow the student unlimited time in which to complete his course.
5. To make every student a class by himself, so that the quick learner may not be held back, nor the dull student left behind.
6. To enroll any student at any time—instruction beginning at once.
7. To furnish the student—without extra charge—all our text-books required throughout his course.

SYSTEM OF HOME INSTRUCTION BY CORRESPONDENCE.

This INSTITUTE is fostered and upheld by

The ELECTRICAL ENGINEER,

a journal of recognized authority in matters electrical both here and abroad.

The Guarantee of The Electrical Engineer can be relied upon.

(Refer to anyone connected with the electrical industry.)

The Electrical Engineer Institute of Correspondence Instruction offers to the ambitious youth, as well as to the practicing engineer, education in his profession or improvement therein as his requirements may demand. Our aim is to assist those who lack education, and to make it possible for them to acquire such training.

What we will do for our Students:

1. We will grant you most generous terms to pay for your tuition.
2. We will allow you to sell your course or transfer it at any time.
3. If at any time you are short of funds we will grant you extensions of time in which to pay.
4. We will allow you to drop your course and take it up again at any future time without additional charge.
5. We will furnish you at all times with technical information on any subject.
6. We desire to be regarded not alone as the instructors, but also as the advisers of our students.
7. We will aid you in every way we can to become a successful engineer.

AT AN INSIGNIFICANT COST—PAYABLE IN INSTALLMENTS OF $2.00 per Month.

The Following is a Partial List of Electrical Subjects Taught in the Various Courses of

THE ELECTRICAL ENGINEER INSTITUTE OF CORRESPONDENCE INSTRUCTION.

1. PRINCIPLES OF ELECTRICITY AND MAGNETISM.
2. LABORATORY INSTRUMENTS AND MEASUREMENTS.

We have in preparation complete courses in all the other engineering and industrial sciences. A later announcement will state the opening of these courses. We shall be pleased to receive communications from interested parties.

REQUIREMENTS FOR ADMISSION: Nothing more than the ability to read and to write. Our Elementary Courses begin with Simple Arithmetic. Unlimited time granted the student to complete his course. Instruction continues—when a course has been paid in full—without extra charge until the student has acquired a diploma or certificate of proficiency or until he voluntarily resigns.

Visit us, or write us freely, stating the particular subjects in which you desire instruction and we shall be pleased to answer fully. All communications to us are regarded as strictly confidential.

ST. ANTHONY FALLS WATER POWER PLANT.

The construction of the recently inaugurated water power electrical generating plant at St. Anthony's Falls was undertaken by the St. Anthony Falls Water Power Company, the plant when completed being leased to the Twin City Rapid Transit Company for the purpose of furnishing power to all the street railway systems of both Minneapolis and St. Paul, which are operated by the Twin City Company. The engineers of both the above named companies worked in unison and the result is most creditable, whether viewed from the standpoint of hydraulic, mechanical or electrical engineering. It is interesting to note that the plant has supplanted more steam driven belted electric machinery with its direct connected generators and rotary converters, than any plant in the world.

A visit to one of these railway substations is most instructive as it will show the great advance made in the last few years in electrical apparatus. It seems almost impossible at the first glance to realize that the neat and compactly built rotary converters with their respective banks of transformers, could replace the ponderous triple-expansion engines, counter-shafting and endless amount of belting, and battery upon battery of boilers, economizing besides the space before used for the storage of coal.

Three of the old power stations have practically been closed, and are now used as substations for the accommodation of the rotary converters. These, of course, take up much less floor space compared with the former plant; in fact, room enough was obtained to install the converters without removing any of the old plant.

Water Rights.—The site of the present plant is located in Minneapolis just below the great St. Anthony Falls of the Mississippi, where there is a long stretch of rapids. The power company has the water right for the entire width of the river at this place, but great care has to be taken not to interfere with the water rights of companies located above the plant, for if too much water were held back by the dams of the St. Anthony Company, the head above would be considerably diminished. This is amply taken care of in a manner which will be explained later. Fig. 10 is a map of the site of the plant.

Main Power Station.— The power house is located at the end of the main dam on the north side of the river, as shown in Figs. 7 and 10, and in reality forms a portion of the dam. The foundations are built of cut

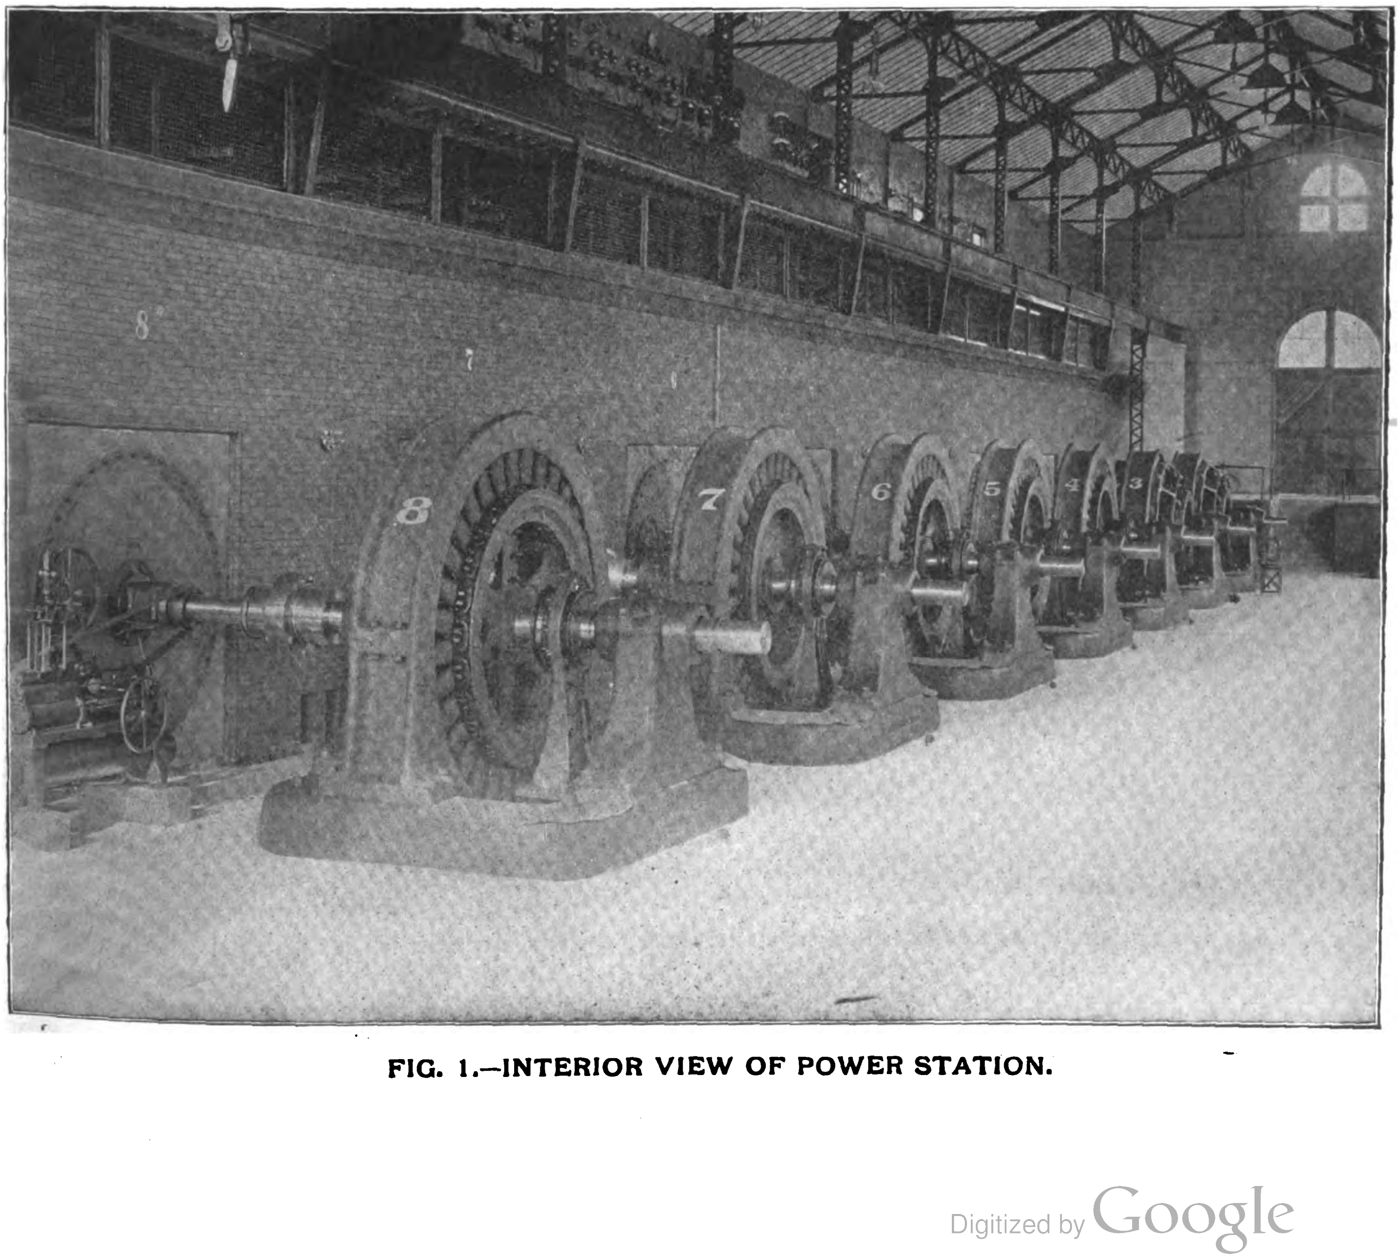

FIG. 1.—INTERIOR VIEW OF POWER STATION.

granite and the walls are of hollow tiling with sandstone trimmings. A steel frame, as shown in the interior view of the power house (Fig. 1), supplements the wall and supports the roof, which is covered with slate. This cut gives a general interior view of the station, showing the generators which are already installed. The station is 250 ft. long and 80 ft. wide, outside measurement, and there is accommodation for ten 700 k.w. units directly coupled to horizontal water wheels. The height of the building from floor to ridge of roof is 45 ft. Ample room is provided, as will be seen in the illustrations, for the installation of engines if it is found necessary to use them at times of low water or when the plant is increased. The station is also provided with an electric crane capable of handling any of the machinery in the station. The cross sectional view, Fig. 3, represents the station as originally designed; as built the roof structure is different, and the switchboard gallery is in a recess in the side wall of the electrical generator room, as shown in Fig. 1. The arrangement of machinery in Figs. 2 and 3 is, however, properly shown. Fig. 2 is a plan view of the station showing the arrangement of the turbines and generators, as actually installed, except that each unit is not provided with an exciter, there being two separately driven exciters, as elsewhere described.

FIG. 3.—CROSS-SECTIONAL VIEW OF POWER STATION AND WHEEL HOUSE

Hydraulic Work.—The dam is shown in

LIB ARY

Figs. 7 and 10. The retaining wall can be seen in Fig. 7, and extends along the north shore 740 ft. from the power station to a point a short distance beyond, where the wing and head dam form an angle. This wall had to be built for the protection of the bank, and is constructed entirely of cut granite. It forms one side of the fore bay, which is also well shown in Fig. 6.

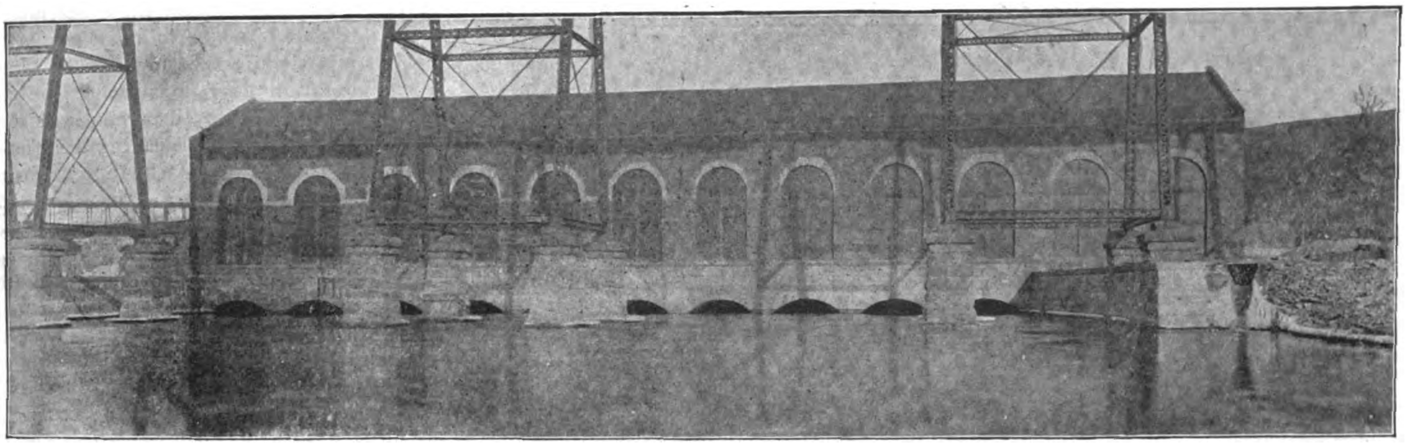

FIG. 4.—POWER STATION AND TAIL RACE

As may be seen from Fig. 10, the main cross-wall starts from the west bank of the river and runs directly across for a distance of 500 ft. This is the length of the wall proper, and does not include gates or waste ways. It then branches off at an angle and runs down stream nearly parallel to the east bank for 370 ft., to the upper end of the large waste way, shown in Fig. 4, close to the power station. Between the waste way and the power house the wall is continued, but at an increased height. All of the construction is of the best cut granite laid in cement.

As before stated, the power house forms a portion of the dam. There is a rack at the fore bay side of the power house extending its full length, and the water, after passing through this, enters the wheel chamber and flows from the draft tubes into an arched tail race underneath the power house.

In addition to the main wheel chamber there is another small chamber at the north end of the building, used for the purpose of driving two exciters.

The head has a maximum of 22 ft. and a minimum of 16 ft., with an average of 20 ft. The wheel chamber wall can be seen from an inspection of Fig. 1, which also shows the switchboard, placed on top of it; it is faced for its entire length with glazed brick. Fig. 8 also shows a portion of the wall and one of the direct-current generators.

The set of waste gates near the power station, shown in Fig. 6, are known as "bear traps." They are made in two sections. The apron, M (Fig. 9), forming the gate proper, is hinged at its lowest point, and the support against which it rests, or, more properly speaking, which supports it, is another apron, N, somewhat smaller in size, placed some distance in front of it, and having rollers, R, along the entire top edge. These rollers rest against the outer surface of the main apron.

When the gate is fully open, the supporting apron closes down with the main apron on top of it. The gates are raised by simply opening a valve in a large pipe, A, B, under the apron, which allows the water to pass from the fore bay, underneath the gate and underneath the front of the apron having the rollers along the edge. The pressure of the water is sufficient to raise this gate and maintain it at any desired height. By means of an outlet, C, D, from the chamber between the gates, they can be instantly closed by shutting off the water at the intake and opening the valve, which allows the water below the gates to escape, when they will collapse upon themselves.

One of the strongest advantages of this gate is that the water in flowing over carries off all debris which comes into the forebay, and which would otherwise catch in the racks.

The gates in the south side of the river, indicated in Fig. 10, are of the ordinary

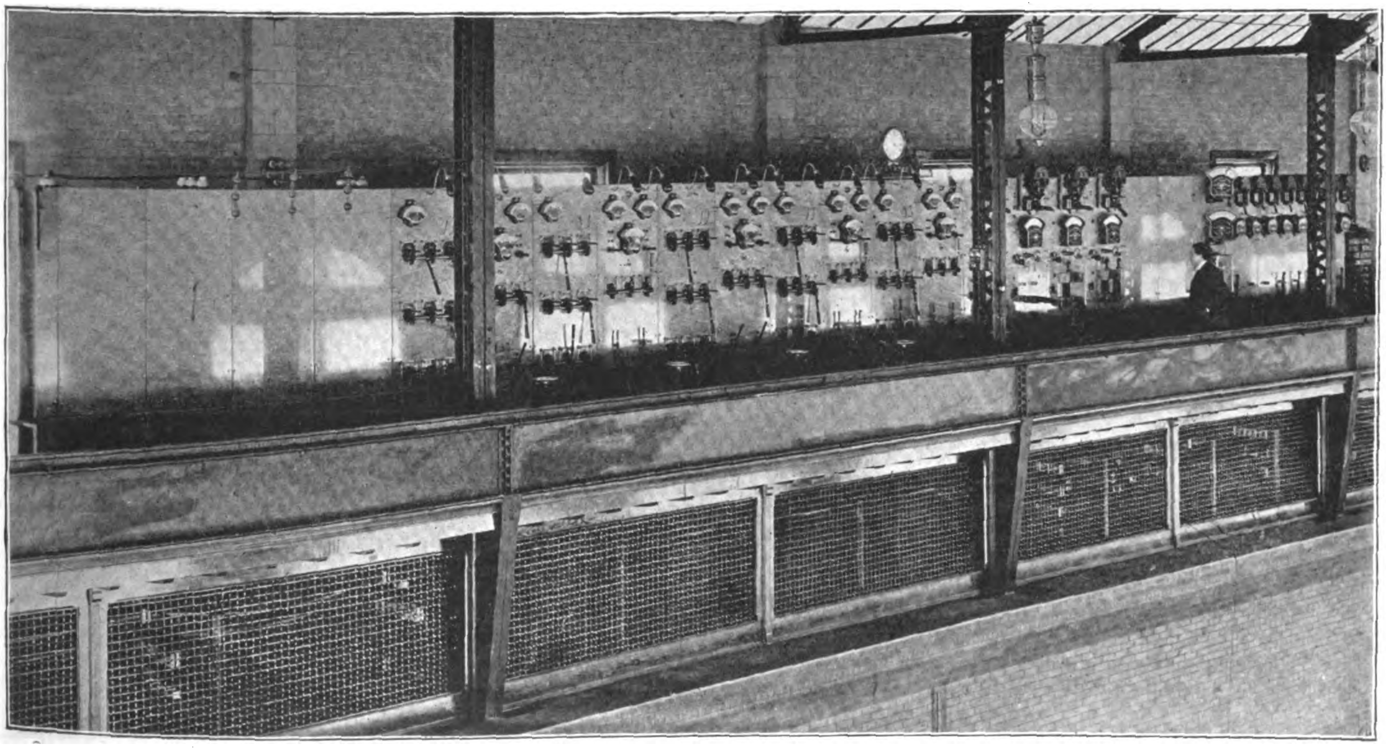

FIG. 5.—SWITCHBOARD AND CABLE RECESS

slide type and three in number. They are operated by large screws furnished with ball bearing nuts and operated by a small water wheel placed in one of the piers.

In addition to the granite walls forming the dam, there is a wing wall running from the power house side of the bear trap gates to a position below the abutment of the railway bridge, shown in Fig. 7. The top of the wall is shown to the extreme left of Fig. 4. This wall is to protect the power house and keep the tail race clear.

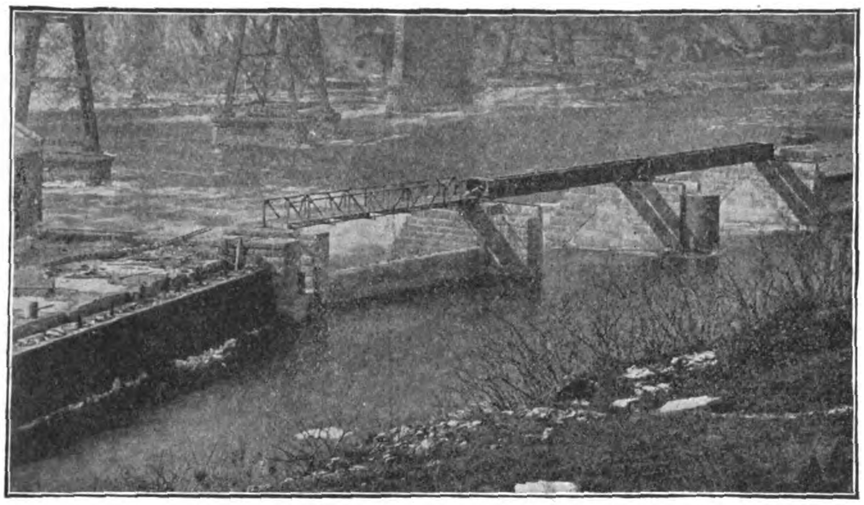

FIG. 6.—BEAR TRAPS

Water Wheels.—The main water wheels for this plant were furnished by the Stilwell-Bierce & Smith-Vaile Company, and are of their well known Victor type. As shown in Fig. 2, to each 700-k.w. unit there are two pairs of 42-in. horizontal wheels, giving a total of four 42-in. wheels directly connected to each generator shaft. These wheels are designed and guaranteed to develop 1000 h.p. per set, or 250 h.p. each.

This method of installing wheels is an innovation in low head work and forms an exceedingly compact and efficient unit.

In addition to the wheels just described there are two sets in the wheel chamber at the east end of the house, which were manufactured and installed by the D. S. Morgan Water Wheel Company. These wheels are for the purpose of operating generators for furnishing exciting current to all the three-phase machines in the station.

Governors.—The governors were furnished by the Lombard Water Wheel Governor Company, one of which is shown in Fig. 8, driven by a belt connected to a small pulley on the generator shaft. The excellent results given by these governors in other installations leaves no question as to their satisfactory operation in this plant. Each governor operates the gates for each full set of four wheels.

Electrical Apparatus.—All of the electrical apparatus installed in this plant was manufactured by the General Electric Company. In the main station there are at present installed five 700-k.w. three-phase generators having 32 poles and operating at a speed of 130 revolutions, giving frequency about 35. One of these is shown in Fig. 13.

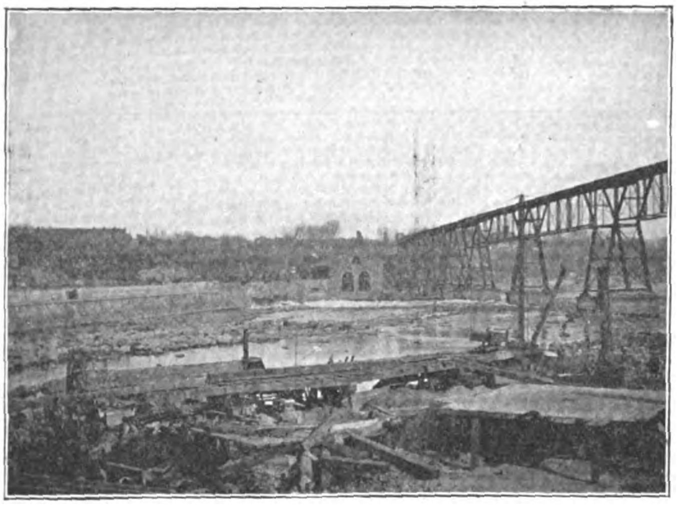

FIG. 7.—POWER HOUSE FROM SOUTH SIDE OF RIVER

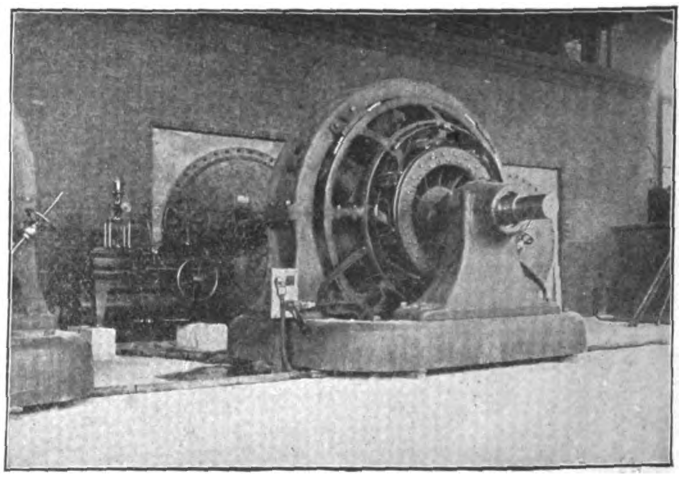

FIG. 8.—700 K. W. DIRECT CURRENT GENERATOR

These machines are of the well known General Electric type, with the field poles built up of laminae thoroughly insulated from each other by a coating of japan. The poles and windings are arranged in such a way that the windings can be easily removed from the magnet yoke without disturbing either the armature or the field frame.

The field winding is wound on shells and insulated therefrom by oiled cotton tape and veneer. The armature is of the iron-clad type, ventilated by means of ⅜-in. air ducts; the armature laminae are dovetailed into the armature spider, thereby dispensing with the use of bolts through the core. The bearings on these machines are self-aligning and self-oiling, "genuine" babbitt metal being used for lining.

The base frame is so constructed that the field frame can be moved parallel with the shaft for the purpose of cleaning the armature or for repairs. The approximate weight of the armature is 25,000 lbs., and the complete weight of each machine about 84,000 lbs.

In addition to these machines, there are two direct-current 700-k.w. generators, having eight poles and running at a speed of 130 r.p.m. These machines are wound for a pressure of 575 volts at no load, and over-compounded to a voltage of 600 volts at full load. They feed the 500-volt railway circuit direct through cables of 500,000 c.m. cross section.

The armature is of the well known iron-clad type and is ventilated by means of ducts in the core .4 in. in width. The armature winding on these machines consists of copper bars laid in the slots, the winding being of the type known as the "barrel."

The commutator is designed so that the current density at the point of contact with the brushes does not exceed 35 amp. per sq. in. at the full rating of the machine, and the difference of potential between commutator bars is very low.

There are two 100-k.w. six-pole exciters, running at a speed of 280 r.p.m., and wound for a voltage of 575 volts at no load, and over-compounded to 600 volts at full load. These machines have armatures of the iron clad type, ventilated in practically the same manner as the machines previously described.

Main Station Switchboard.—The station switchboard was designed with a view to having two separate sets of busbars, so

LIBRARY

that the attendant in charge may run any particular machine on either of the two busbars. A view of all connections of the main station and switchboard is shown in Fig. 12. This sketch shows the connections of the main station to all generators and also to the three rotary converter substations. There have been some minor modifications made in the wiring since this diagram was made, but none that are worthy of note, with the exception of the line to the St. Paul sub-station, which has but one circuit from the power station. A general view of the board is given in Fig. 5, which also shows the screens covering the cable recess. The switchboard consists of 23 panels, as follows:

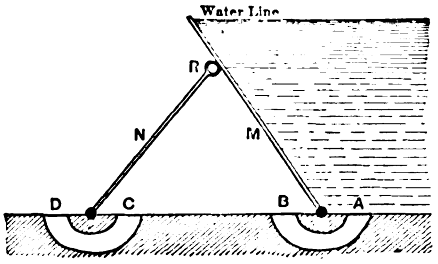

FIG. 9.—DETAILS OF BEAR TRAP

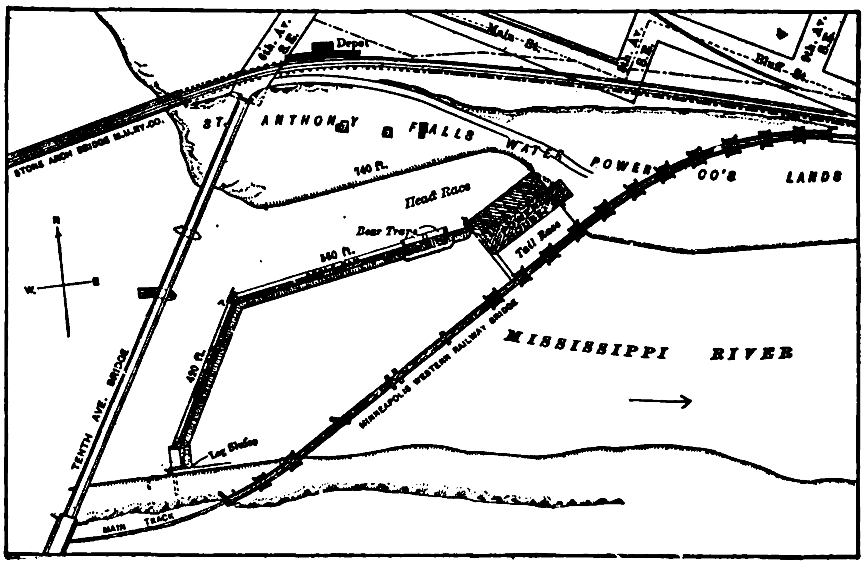

FIG. 10.—MAP SHOWING LOCATION OF PLANT

One station panel, equipped with one 700-volt, illuminated dial Weston voltmeter; one 2500-amp., 600-volt Thomson recording wattmeter, the panel being surmounted with a 12-in. dial 8-day clock and head-piece.

Five alternating current generator panels, each equipped with one 200-amp., deadbeat, inclined coil ammeter; one 5250-volt inclined coil voltmeter and station transformer; one generator rheostat; one high-voltage main switch (porcelain chamber): two single-pole field switches; one 2-point phase lamp switch; two pilot lamps; one phase lamp and one potential plug; one 700-k.w. single-phase indicating wattmeter, and three fuse blocks.

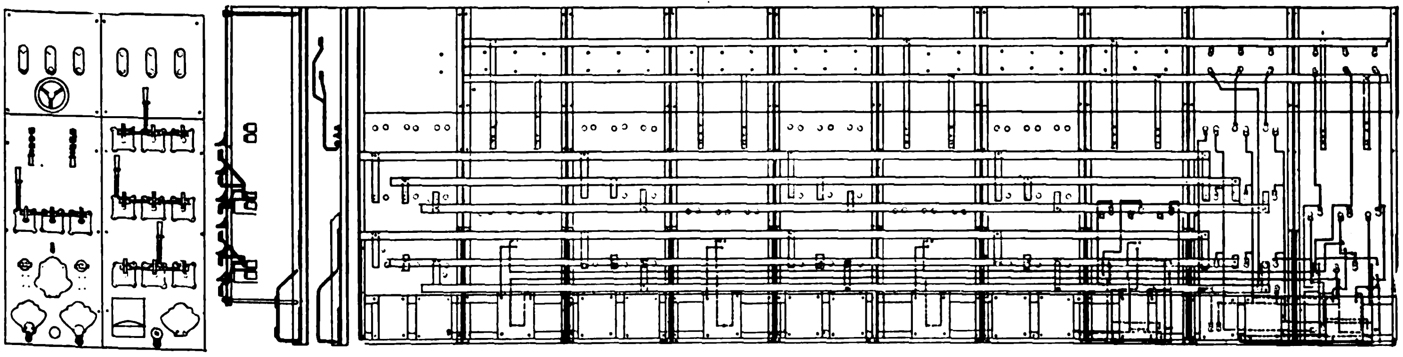

FIG. 11.—A. C. GENERATOR AND FEEDER PANELS AND REAR VIEW OF CONNECTIONS

Two continuous-current railway generator panels, each equipped with one 1200-2000-amp. circuit breaker; one 2500-amp. illuminated dial Weston ammeter; one generator rheostat; one lightning arrester; two single-pole, double-throw main switches; one lightning switch; one 2-way field switch; one potential plug; one pilot lamp; one resistance lamp, and two bus wires on the back. (Equalizer switches are furnished, but are located at the generator.)

Five alternating-current feeder panels, each equipped with one 200-amp., 3500-volt, alternating, three-phase Thomson recording wattmeter and two station transformers; three porcelain chamber, high-voltage coupling switches; one pilot lamp; six busbars at the back; one indicating wattmeter, 700-k.w. capacity (single-phase type); three fuse blocks.

Eight special railway feeder panels, each equipped with two 300-500-amp. circuit breakers; two 200-amp., round-pattern, Weston ammeters; one pilot lamp; two single-pole main switches; two busbars at the back.

Two exciter panels, each equipped with one illuminated dial Weston voltmeter; one round-pattern Weston ammeter; one rheostat; two single-pole, double-throw main switches; two single-pole field switches; two busbars at the back; one automatic circuit breaker.

The static switchboard shown in Fig 16 is for the purpose of taking care of static discharges. There are three panels, two being designed for the two 3500-volt circuits, and one for the 12,000-volt circuit. The only difference between the 12,000-volt and the 3500-volt panels is that the former has a greater number of discharge gaps and more graphite resistance. The panels are connected to the line through switches; the circuit of the static panels can be opened at any time without disturbing the flow of current in the line. This is for the purpose of cleaning and adjusting the discharge gaps with safety.

The fuse blocks on the alternating current panels are of the expulsion type, and each block has two fuses in parallel.

In addition to the panels just described, there are six blank ones, to be used when the remaining generators are installed; these consist of two A.C. generator panels two A.C. feeder panels, one D.C. generator panel and one station panel.

Transformers.—The static transformers in this plant are of the standard air-blast type and are 21 in number, of 233-k.w. capacity each. Six of these are placed in the main station for the purpose of raising the generator voltage from 3450 to 6900 volts, and the remaining fifteen are placed in the three substations, two containing six, and the third three.

This type of transformer is too well known to need an extended description, although it might be interesting to refer to some of the most important features of its construction.

The first and greatest aim in the manufacture of any transformer is to thoroughly insulate the high potential from the low potential windings. This is accomplished in this transformer through the method of cooling, which admits of a heavy insulation being placed on the coils without unduly restricting the escape of heat. In addition to this, solid diaphragms of heavy insulation are placed between the high and low potential coils. Air ducts separate this diaphragm on either side from the adjacent coils.

How effectively this insulation fulfills its duty may be judged from the fact that the transformers for this plant were tested with a 20,000-volt potential between primary and secondary windings, and it could have safely been tested for considerably higher voltages. Transformers of this type have been built for higher voltages with similar insulation, and have successfully withstood a test of 80,000 volts.

Another one of the problems connected with the building of large electrical apparatus is to properly dispose of the heat generated within the windings. This problem has been very successfully met in electrical apparatus which has revolving parts, by so designing these parts that they act as blowers, thereby setting up currents of air in their interior. It is not surprising then that this method, which has proved so thoroughly satisfactory in revolving apparatus, should prove equally satisfactory in static transformers.

In order to present the proper amount of surface to the circulating air, the coils of the transformer are separated from each other by narrow air ducts, and the sheet iron of which the transformer core is composed is separated into small groups by similar ducts.

The air is forced through a main duct which runs underneath all of the transformers. This forced draft is obtained from an electrically driven blower set, and the air, after passing through the coils in the core, escapes into the surrounding atmosphere, having absorbed the heat in its passage through the transformers. So carefully and thoroughly has this system been carried out that each transformer has some 350 sq. ft. of cooling surface. As a result, no portion of the windings have a temperature rise of more than 35 deg. C. above the surrounding air after having carried their full rated load for an indefinite time.

It is a fact worthy of note that this very effective cooling is accomplished with an expenditure of power of but one-tenth of one per cent of the capacity of the transformer.

The efficiency of these transformers is a fraction under 98 per cent. While this is not as high an efficiency as can be obtained in the design of transformers, it represents practically the most economical design where power is as cheap to produce as it is in this plant. Good regulation rather than extremely high efficiency is, of course, to be desired in a water power plant, and consequently the transformers were designed for the very close regulation of 1 per cent from no load to full load.

As is seen from the cuts, the transformers are very compact and of neat appearance. They are thoroughly protected by an enclosing case, no portion of the windings being exposed. The high potential coils have their terminals brought out through the casing in porcelain bushings, and rubber-covered cables connect these terminals to the lines.

The transformers are connected as follows: To receive 3450 volts on the primary and step-up, the two primary coils are placed in parallel and the transformers connected in delta on their primary side. To obtain 6900 volts on the secondary, the two secondary coils are placed in series and the transformers connected in delta on their secondary side. To obtain 12,000 volts, the primary connection is not dis-

LIBRARY

turbed, but the secondary is connected in Y with the two secondary coils in series. From this connection we obtain $6900 \sqrt{3}$, or 11,937 volts.

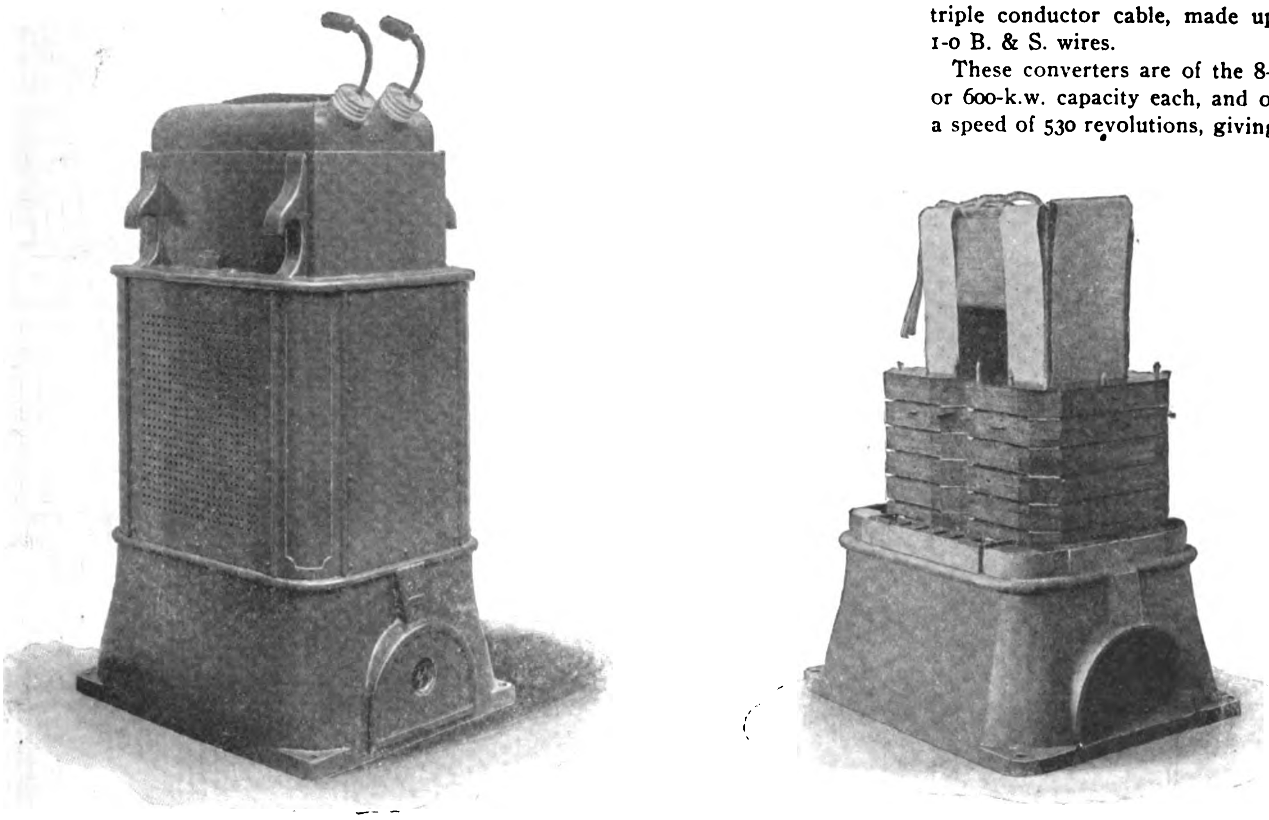
The dimensions of the transformer are, height, 58 ins.; floor space, 38 ins. x 32¾ ins.; weight, approximately, 4500 lbs.

Induction Coils.—A three-phase open magnetic circuit inductance coil is placed between the transformer and each rotary in order to give greater range of adjustment in the direct current voltage of the rotary.

On most power transmissions there is sufficient inductance in the system, due principally to the inductance of the line, to allow a considerable range of adjustment in the voltage of the rotary by changing the field excitation without any considerable idle current being produced.

In this transmission, due to the comparatively short distances between generator and rotary, and to the extensive use of cable rather than overhead line, the inductance of the system is so low that the introduction of this artificial inductance is necessary in order to get the desired flexibility in the voltage.

These coils also serve the purpose of preventing any idle current circulating between two rotaries operated from the same transformers when their field adjustment is not carefully made.



FIGS. 14 AND 15.—233 K. W. AIR BLAST TRANSFORMER

The coils themselves are so simple as to hardly need description, consisting simply of bundles of iron wire, with a finely stranded cable wound around them, the three being assembled in a protecting case, through which circulates a small current of air obtained from the same blower that cools the transformers.

Each of the three sub-stations is provided with three 50-inch Buffalo blowers, each directly connected to a 4-pole, 2½-h.p., 600-volt, motor, operating at a speed of 500 r.p.m.

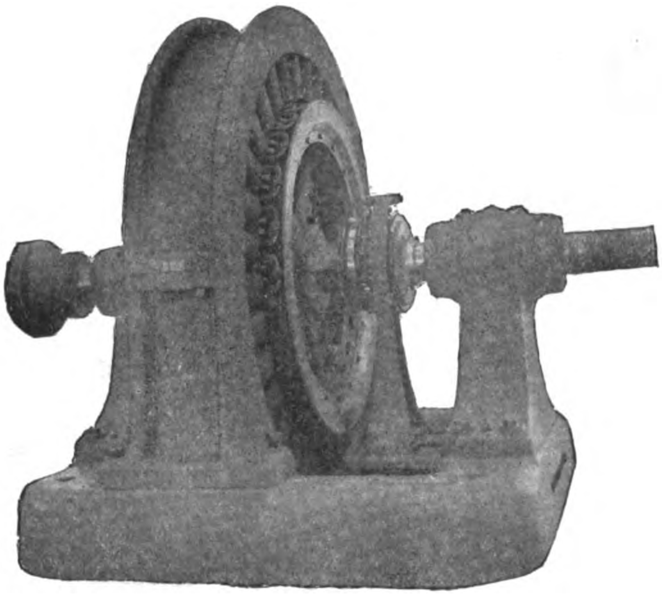


FIG. 13.—700 K. W. THREE-PHASE GENERATOR

Rotary Converters.—There are installed in the three sub-stations five rotary converters. Two of these are in what is known as Substation No. 1, located in the heart of the city of Minneapolis, and 9000 ft. from the power station, current being transmitted at a pressure of 3500 volts over two triple-conductor paper-insulated, lead-covered cables, each equivalent to No. 3-0, B. & S., and furnished by the National Underground Conduit & Cable Company. Another is in Substation No. 2, located in Minneapolis, and 23,700 feet distant from the power station, and operated at the same potential as No. 1 Station, through one triple conductor cable, each conductor being 4-0 gauge. Two are in Substation No. 3, located in St. Paul, distant about ten miles from the power station. The current is transmitted at a potential of 12,000 volts through one triple conductor cable, made up of three 1-0 B. & S. wires.

These converters are of the 8-pole type, or 600-k.w. capacity each, and operated at a speed of 530 revolutions, giving 580 volts on the direct current side at all loads up to normal.

The armature is of the iron-clad type, and is thoroughly ventilated by means of 5-16 in. ducts. The armature spider is calculated for a safety factor of 6, and so constructed that all shrinkage strains are obviated; the laminae are dovetailed into the armature spider, dispensing with the use of bolts in the core.

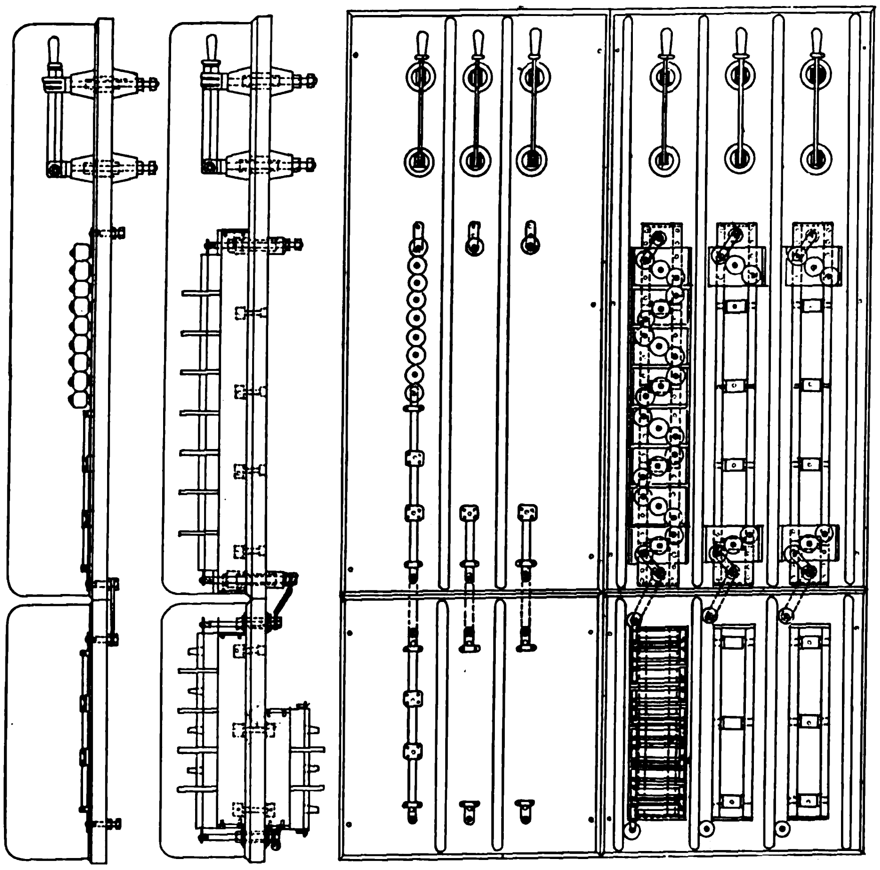

FIG. 16—STATIC DISCHARGE PANEL.

The commutator is assembled on a separate spider, mounted upon the armature spider. The voltage delivered to the A. C. side of the rotaries is approximately 350 volts.

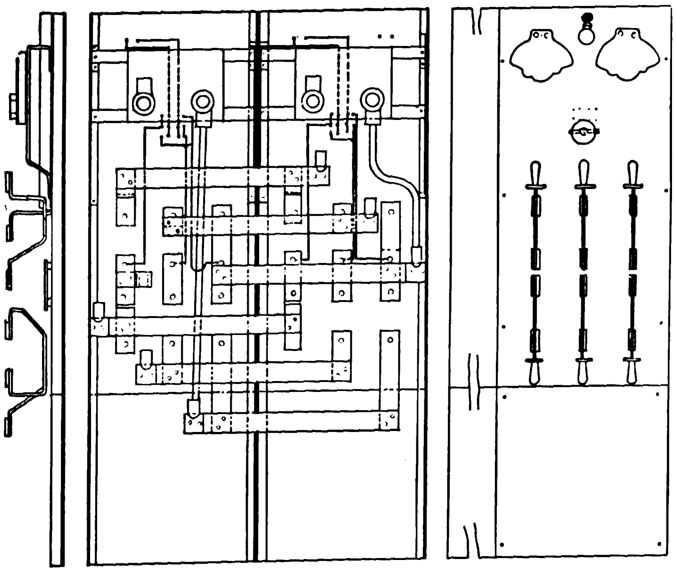

FIG. 17—ROTARY CONVERTER PANEL, A. C. SIDE.

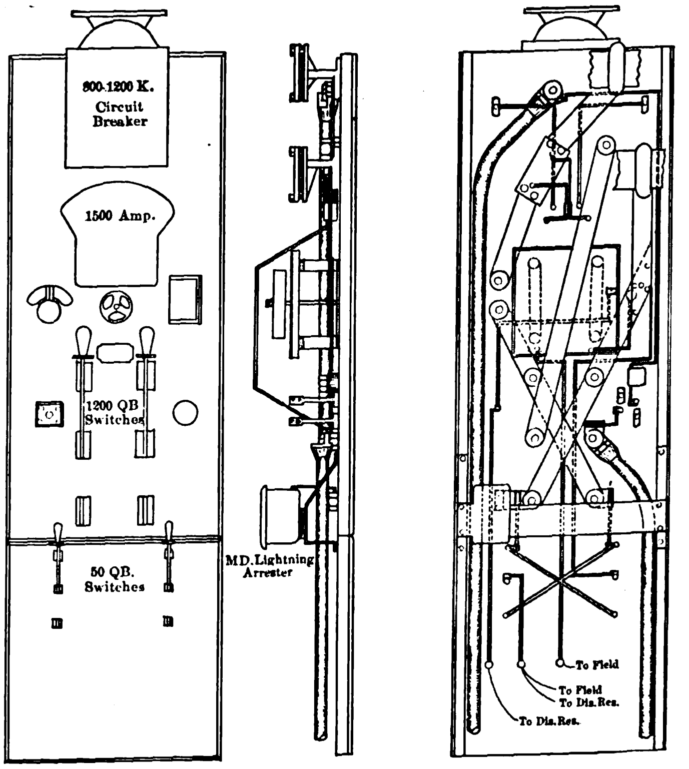

FIG. 18—ROTARY CONVERTER PANEL, D. C. SIDE.

Substation Switchboard.—The switchboards for the three substations will consist of ten blue Vermont marble panels, divided into three units, two having two alternating and two direct-current panels, and the other, one alternating and one direct-current panel. Fig. 17 shows the connections of the rotary converter panels, alternating current slide; and Fig. 18 direct-current side.

Each of the alternating panels will be fitted with the following apparatus: One 650-volt, inclined coil, dead-beat, voltmeter; one 1500-ampere, inclined coil, dead-beat ammeter; one pilot lamp; one potential plug; six single-pole quick-break switches. On the back will be one current transformer for ammeter, and the necessary busbars.

Each continuous current panel will be equipped with the following apparatus: One 800-1200 circuit breaker; one 1500 ampere, illuminated dial Weston ammeter; one generator rheostat; one lightning arrester; two single-pole, double-throw, main switches; one lightning switch; one potential plug; one pilot lamp; one two-way field switch; one resistance lamp; one illuminated dial Weston voltmeter, reading 750 volts each side of zero, mounted on a hinged bracket beside panel; two single-pole, double-throw field switches on sub-base.

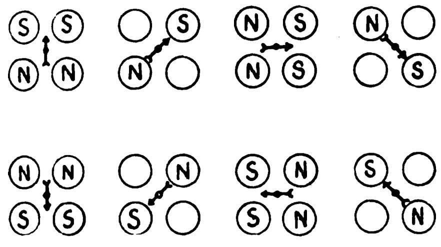
Each D.C. panel is provided with an automatic cutting-out device for the purpose of protecting the rotaries in case of reversal of current. It is so aranged that if the current on the direct-current side of the rotaries is reversed, the circuit breaker will be automatically thrown out.

The hydraulic work of the plant was constructed by local contractors, supervised by Mr. William de la Barre, engineer of the company. The electrical work was in charge of Mr. Edward P. Burch.

THE INDUCTION MOTOR.

BY ALFRED E. WIENER, E.E., M.E.

Though the induction motor has passed into its practical stage but a short time ago, the discovery of its principle dates back about seventy-five years. It was during 1822 and 1823, when engaged in magnetic observations, that Arago observed that the needle of one of his compasses, which was mounted upon a copper base, came to rest much sooner than other ones which had ordinary wooden cases. He reasoned that some force, unknown to him, was the cause of this behavior, and, arguing from the principle of action and reaction, he succeeded, in 1824[1], in deflecting and even dragging into rotation a magnetic needle suspended over a revolving disc of copper.



FIGS. 1 TO 8.—BAILY'S ROTARY FIELD, PRODUCED BY VARIOUS MAGNETIZATIONS OF FOUR ELECTROMAGNETS.

In 1825 Babbage and Herschel, two English experimenters, reversed Arago's arrangement, and showed that the revolvable copper disc can be set in motion by spinning beneath it a strong magnet.

Six years later (1831) Faraday proved that the rotation of the magnet in Arago's experiment, and of the copper disc in the Babbage-Herschel arrangement, was caused by the reaction of electric currents produced in the copper disc by electro-magnetic induction; for, when revolving the copper disc between the poles of a stationary magnet, he was able to collect electric currents by means of sliding contacts placed against the center and periphery of the disc, respectively. Although the latter arrangement, familiar by the name of "Faraday's Disc," soon led to the construction of the magneto-electric, and, subsequently, of the dynamo-electric machine, it was not until 1879 that the next important step toward the invention of the induction motor was taken.

In the year above named, Walter Baily[2] demonstrated by experiment that Arago's copper disc may be set into rotation, not only by spinning a permanent magnet bodily, but by revolving instead the *magnetic field* produced by a number of electro-magnets. He used four comparatively long vertical cores, which, by means of a special commutating switch, he successively magnetized, as shown in Figs. 1 to 8, so as to obtain a *rotary magnetic field*.

In Baily's motor continuous currents were used to excite the electro-magnets, but in 1883 it was shown by Marcel Deprez that a true rotary field can be produced by the combination of two alternating currents having a difference of phase of a quarter period.

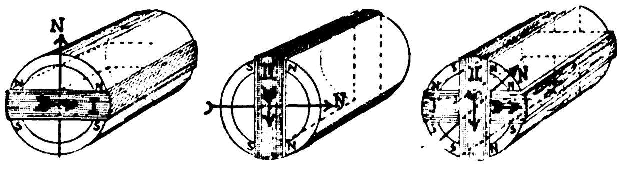
In 1885 Prof. Galileo Ferraris independently constructed a motor in which rotation of a copper cylinder was caused by currents induced in it by a progressively shifted magnetic field, the latter being produced by two-phase alternating currents.

The principle of the induction motor thus having been fully established, it remained to work out its parts so as to obtain a commercial machine of high efficiency. This task was accomplished by Nikola Tesla, who, during the years 1886 to 1891, took out a series of important patents (now owned by the Westinghouse Company, Pittsburgh, Pa.); by M. von Dolivo-Dobrowolsky, 1887 to 1891 (Allgemeine Electric Company, Berlin, Germany); by Haselwander, 1887 (W. Lahmeyer & Company, Frankfort, Germany); by Charles S. Bradley, 1887; by Charles P. Steinmetz (General Electric Company, Schenectady, N. Y.); by Wenström (1890), and numerous others.

The modern induction motor thus developed is in the following, discussed under four headings:

I. Principle of Rotary Magnetic Field.

II. Structure of Induction Motor.



FIGS. 9, 10 AND 11.—MAGNETISM SET UP BY HORIZONTAL AND VERTICAL COIL.

III. Induction Motor Field Winding.

IV. Induction Motor Armature Winding.

In Part I. the production of a rotary field by polyphase alternating currents is shown; in Part II. the principal parts of the practical motor are treated; and under III. and IV., the various modes of winding and connecting of induction motors will be given.

I. PRINCIPLE OF ROTARY MAGNETIC FIELD.

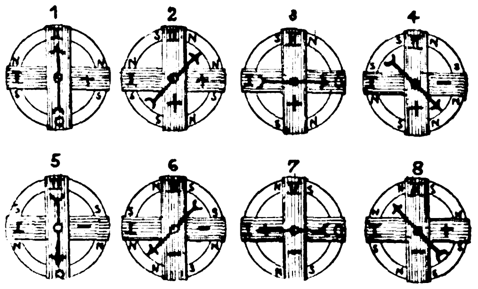
If two or more coils are arranged around an iron core, the magnetism set up in that core by currents passing through the coils is the resultant of the magnetizations due to each coil separately. Thus when the two equal coils, I. and II., Figs. 9 and 10, which, when traversed by equal continuous currents in the directions indicated by arrows, cause a vertical and a horizontal magnetization, respectively, are combined upon one core, as shown in Fig. 11, the direction of the resultant magnetization makes angles of 45 degs., with both the former directions. This can easily be seen from the polarity of the iron core, as marked in Figs. 9, 10 and 11.

If alternating currents, differing in phase from each other—that is to say, currents of equal frequency and value, but not reaching their zero value at the same time—are sent through these coils, the direction of their resultant magnetism is not constant, but varies continually, and thus a *rotary magnetic field* is obtained. In order to prove this, let us consider the conditions necessary to establish a rotating magnetic field by means of continuous currents. Since the polarity due to any coil is reversed by the reversal of the current in that coil, it is evident that a rotating magnetic field can be obtained by means of coils I. and II., if the following changes are made successively:

	Current Through Coil I.	Current Through Coil II.	Direction of Resultant Magnetism.	
1.	+	0	0	Fig. 12
2.	+	+	45	" 13
3.	0	+	90	" 14
4.	—	+	135	" 15
5.	—	0	180	" 16
6.	—	—	225	" 17
7.	0	—	270	" 18
8.	+	—	315	" 19
1.	+	0	360	" 12

Now let us plot two alternating currents differing in phase, Fig. 20.

It will be seen that exactly the above eight conditions exist in each complete cycle. At point 1, the current I (flowing through coil I) has a + value, while current II (in coil II) just passes through the zero-line. From point 1, the current II gradually rises while I decreases until at point 3 it is zero, while II still has a + value; between points 1 and 3, therefore, the condition 2 exists, namely, both I and II are positive. At point 5 current II has become 0, while I is, —, and between 3 and 5 there are various stages of condition 4. Between 5 and 7 both currents have — values, corresponding to condition 6. At 7, current I is 0, and II is —, and from 7 to 1 the — value of II gradually changes to 0, while *I* rises in + values; hence, between 7 and 1 there exists condition 8, while at 1, the original condition is again attained and the cycle begins anew. Thus we see that two alternating currents, differing in phase from each other, when sent through the two coils, cause a revolving magnetic field, the advantage of the alternating over the continuous current being, besides, that the changes from one direction to the next are not sudden, but gradual, thus insuring a more uniform motion of the rotating magnetic field.



FIGS. 12 TO 19.—COMBINATION OF TWO CONTINUOUS CURRENT COILS, PRODUCING ROTARY MAGNETIC FIELD.

A true rotary motion of the resulting magnetism is also obtained in the case when three coils traversed by three alternating currents, differing in phase by 120 degs., are combined upon one core. Plotting three such currents, I, II, III, Fig. 21, we find that there are twelve easily distinguishable points in each cycle, for which the respective conditions are as given in the following table:

---

11	—	0	+	I " III	300	" 34
12	—	—	+	I " II	330	" 35
1	0	—	+	II " III	360	" 24

The magnitude of the two equal currents at points 1, 3, 5, 7, 9 and 11 is, by Fig. 22,

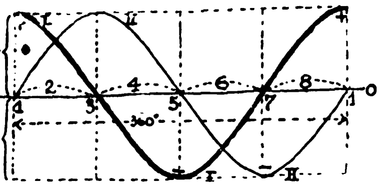

FIG. 20.—TWO ALTERNATING CURRENTS DIFFERING IN PHASE BY 90 DEGS.

$$X = I \times \sin 60^\circ = .866\ I,$$

or .866 of the maximum value, *I*, of the current intensity, while at points 2, 4, 6, 8, 10 and 12 the equal currents in the two coils, according to Fig. 23, have the strength:

$$Y = I \times \sin 30^\circ = .5\ I,$$

or ½ of the maximum current at that time flowing in the third coil.

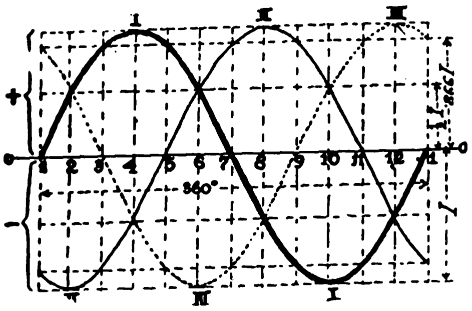

FIG. 21.—THREE ALTERNATING CURRENTS DIFFERING IN PHASE BY 120 DEGS.

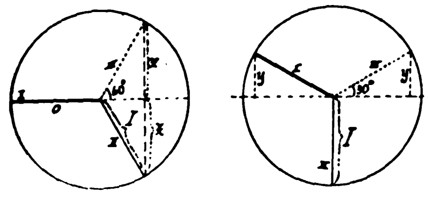
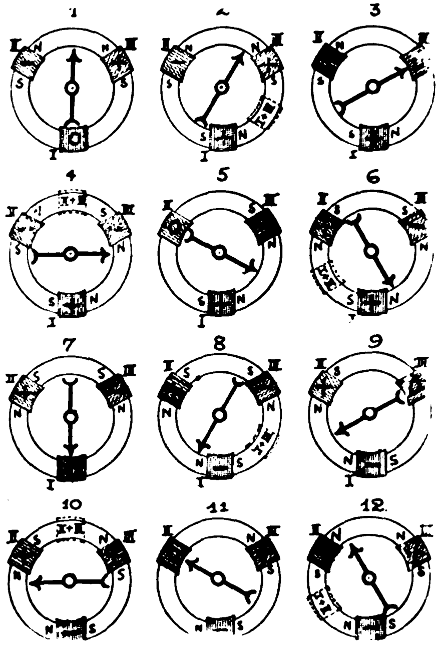
The magnetizations due to the separate coils and the direction of the resultant magnetization for these twelve points are shown in Figs. 24 to 35.

In Fig. 24 the current in coil I is 0, that in coil II is —, and in coil III is +. Assuming that a + current in any coil causes a magnetic flux through the core in the counter-clockwise direction, both the north-poles due to coils II and III are directed upward, and the resultant magnetism has a vertical direction, or 0°. In Fig. 25, the currents in coils I and III, as can be seen at point 2, Fig. 21, are both +, are equal to each other, and are each of one-half the strength of the — current flowing in coil II. The dotted coil, placed half way between I and III, and having equal magnetizing strength to coil II, can therefore be considered as representing the combined magnetism of coils I and III, and the direction of the resultant magnetism of the three coils is found to be perpendicular to the diameter indicating the position of coil II, that is, 30 degs. in advance of the vertical line. All the other directions of the resultant magnetism are determined similarly to the cases of Figs. 24 and 25, respectively. Thus, in Figs. 26, 28, 30, 32 and 34, corresponding to points 3, 5, 7, 9 and 11, two coils only being active, the resultant magnetism has a direction coinciding with the position of the third or neutral coil; and in Figs. 27, 29, 31, 33 and 35, corresponding to points 2, 4, 6, 8, 10 and 12, one coil being traversed by a current of one polarity, and the remaining two by currents of half the strength but of the opposite polarity, the resultant magnetism has a direction perpendicular to the diameter marking the position of the coil of largest current-strength.



FIGS. 22 AND 23.—RELATIVE STRENGTH OF CURRENTS IN THREE COILS OF A THREE-PHASE SYSTEM.



FIGS. 24 TO 35.—DIRECTION OF RESULTANT MAGNETISM DUE TO THREE ALTERNATING CURRENTS DIFFERING IN PHASE BY 120 DEGS.

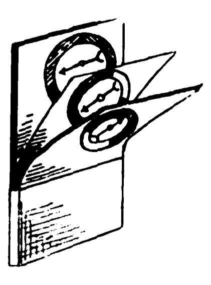


FIG. 36.—KINETOSCOPE, SHOWING MOTION OF ROTARY FIELD.

An excellent way to show the motion of a revolving field, both for the lecture-room and for home study, is to prepare small sheets of paper, each containing one of Figs. 12 to 19 for a two-phase field, and of Figs. 24 to 35 for a three-phase field (simplified, if desired, by omitting the coils themselves, and only indicating their polarity by different colors) and to unite, in the proper rotation, and exactly concentric with each other, a number of these sheets covering two or three cycles into the form of a "kinetoscope," as shown in Fig. 36. When passing the sheets in one way the revolving field will be seen to rotate in one direction, while, when moving the sheets backward, the rotation of the magnetic field is in the opposite direction, showing that the reversal of the order of the coils has the effect of reversing the rotation of the magnetic field.

◆

ERECTING A HIGH VOLTAGE TRANSMISSION LINE.

BY S. H. DAILEY.

In this article the writer intends to give detailed instructions for the erection of a transmission line, and to that end will take all of the operations into consideration, supplementing them with illustrations taken from actual work upon a line, and also with such drawings as are necessary to fully describe the work.

The conditions of an assum[illegible] line will be dealt with, and a general idea of the requirements of the work will be roughed out in a set of specifications. These specifications are merely in a skeleton form to fit the conditions of this example.

Specifications.—Poles are to be [illegible] 5 ft. in the ground, 90 to 110 ft. apart in line and 80 to 90 ft. on curve. They are to be of an average height of 36 ft., with a minimum diameter of 7 ins. at the top and 14 ins. at the ground line.

To carry four conductors, 18 ins. apart, on a 5-ft. cross arm, and on peak of pole 15 ins. from top arm, to run the entire length of the line, a barb wire, which is to be grounded every half mile.

A second gain 18 ins. from top of first gain is to be cut at time of erection.

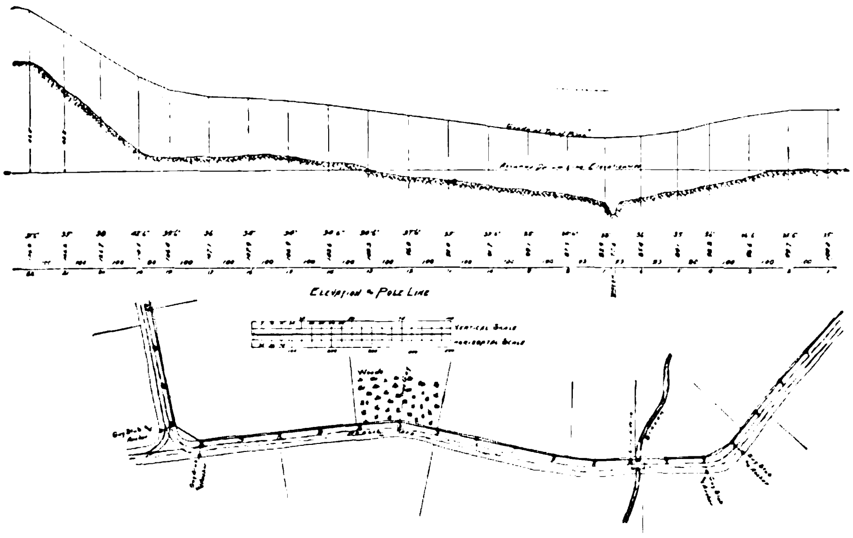
Cross arms are to be fastened to poles by two 7 in. x ½ in. lag bolts, which must be screwed into the pole—not driven. To further secure the cross arm, it must be braced with iron braces 1¼ in. x ¼ in., secured to the cross arm with ⅜ in. bolts and to the pole by 3 in. x ½ in. lag bolts. All bolts and braces to be thoroughly galvanized.

Six ft. below the top gain is to run a telephone line—metallic circuit—supported by brackets, one on each side of the pole. All poles, where the line makes a deviation from a straight course at an angle greater than 10 deg., are to be securely guyed or anchored.

Locating the Line.—The most desirable and cheapest to erect and maintain is an air line between the power house and the point of distribution. However, circumstances will not allow this, and the conditions may compel following the public road. Having decided upon the route the line is to take, the first operation is to "peg it out" by placing a peg to indicate where the poles are to be set.

Before driving any pegs, the route should be gone over and a definite decision made as to which side of the road is to be used, a rough sketch being made at the time for future reference, taking into consideration that the line should follow that side which will require the least tree trimming, and also avoiding crossing any more public roads than absolutely necessary.

The tools and implements to begin with will be a 100-ft. measuring line (a steel tape divided into feet and tenths of a foot will be found the most convenient, as the decimal parts of a foot can be handled easier in calculating than inches and fractional parts); one hand axe; two white muslin flags, 2 ft. x 3 ft., fastened to the ends of 12 ft. pine sticks 1 in. square, the other ends being pointed so as to be easily stuck into the ground; one stick 1 in. square 5 ft. long; a piece of chalk or lead to number the pegs as they are placed. The peg can be made of pine or hemlock, 18 ins. long, 1½ ins. square and pointed at one end.



FIGS. 1 AND 2.—ELEVATION AND PLAN OF POLE LINE.

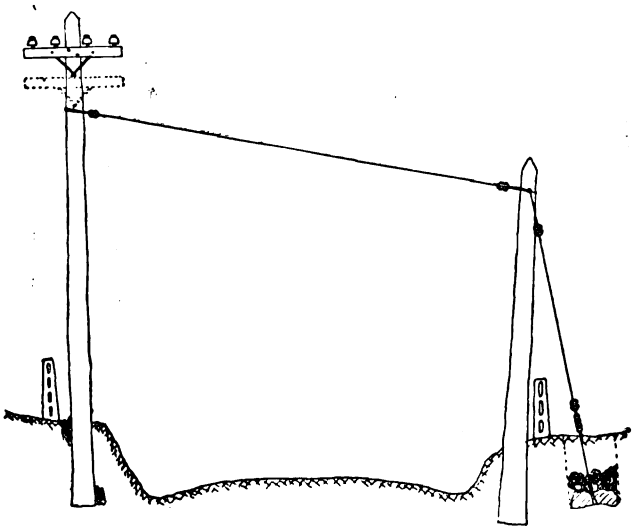


FIG. 3.—GUY STUB AND ANCHOR.

It must be held continually in mind that the straighter the line the cheaper will be its maintenance.

Fig. 2 is a plan of the pole line, assumed for illustration only, and showing a public road with a transmission line running along one side; it also gives an idea how to make a permanent plan of the line for reference which, since it will be found useful for consultation in more ways than one, should be made as carefully as possible with respect to the distances and courses of the road.

It will not be necessary to use an instrument to line up the pegs, as the eye is sufficiently accurate in conjunction with the flags.

Beginning at pole No. 1, measure off as many 100 ft. lengths as thought convenient—say in this case to a turn in the road, which is position of No. 4—and drop a peg at each mark. Now have the helper place his flag in the position where No. 4 is to be located with regard to the fence and road gutter, and return to No. 1. Hold the 5-ft. stick on No. 1 peg driven home, and sight between the stick and flag. In this case we find that a straight line connecting these will come too far into the road at an intermediate point, say No. 2, so the helper moves to No. 2 with the flag and there places a peg the same distance from the fence as No. 1. This is No. 2, and the distance and number of peg noted in first and second columns of a note book ruled like Table I, to be used later in plotting the elevations for grades.

Next, have the helper place one flag where No. 4 is to go, and place the stick on No. 2; the helper, taking the other flag, goes to No. 3, and his flag is lined with the stick held on No. 2 and the flag at No. 4. Pegs Nos. 3 and 4 are driven and numbered, and the distance put down in note book. Going then to flag No. 4, it will be found easier to turn on two poles than one, the angle being thus divided up not being short enough to require a reverse turn, which will be described later.

For this turn it will be better to shorten the distance between poles to 80 ft., thus taking some strain and weight from the poles and not going too far into the fields.

Having decided on the location of No. 5, a straight line takes us to where No. 8 stands, which, being measured, is 279 ft. This will give three poles at 93 ft. distance between poles 5 and 6, and 6 and 7, 7 and 8; this distance will answer, but it is better not to go below 90 ft. or over 110 ft. in a straight line. In this instance it suits the conditions very well as there is a stream of water near No. 7 which will be good for a ground wire.

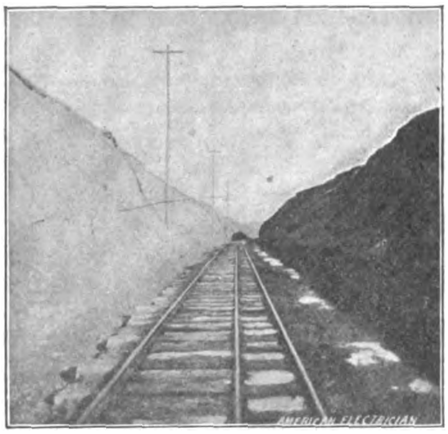

FIG. 4.—LOCATING POLES IN A RAILROAD CUT.

Fig. 3 is an elevation of a guy stub and anchor, showing the manner of locating poles relative to fences and road gutters; the latter must be kept away from, for otherwise not only will the authorities object, but during a rainy spell water will be continually washing around the pole, tending to loosen it and throw it out of line.

Referring to Fig. 2, which gives a plan of the line, poles 4, 5, 18 and 19 will need to be guyed and anchored; pegs showing the position of the guy stub and anchor should be driven at these points. In placing a guy stub, locate it so as to divide the angle which the line makes at that point.

Fig. 4 shows the manner of locating poles in a railroad cut, and Fig. 5 shows part of a transmission line, where the conditions are severe as to curves.

Grading.—Having finished laying out the line, the next operation is grading it, in order to determine the length of poles needed at each peg, so as to have an easy grade in the wire, thereby distributing the strain evenly on all poles.

Fig. 1 is an elevation of the pole line, and shows a profile as pegged out, the elevations being taken at each peg. To work this out there will be needed a level, a 16-ft. pole ¾ x 1½ in., divided into feet, and each foot divides into 10 spaces, which will be 1-10 of a foot or decimal, .1.

AMERICAN ELECTRICIAN

FIG. 5.—CURVES OF POLE LINE.

A convenient form of keeping notes is given in Table I. This table shows that the distance between poles 1 and 2 is 100 ft., which was marked down when "pegging" out. Setting the level in a convenient position, place it between poles 1 and 2 so that the line of sight will fall above the ground at these points. Have the helper hold the measuring stick at peg 1, take a sight at it and put down in the book under the column of "Back Sights" on line with No. 2, the height—say in this case, 5.2 ft. The helper now goes to peg 2 and holds the stick on it while another sight is taken at it, the level of the instrument not having been changed; this result is placed down under column of "Front Sights"—say 5.5 ft. The operation is the same for each succeeding space.

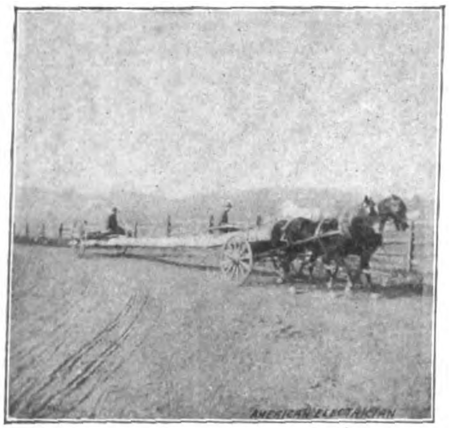

FIG. 6.—HAULING POLES.

It will be noticed here that the difference between the two readings is .3 ft.; the front sight being the larger, it follows that No. 2 is .3 ft. lower than No. 1, which .3 is placed in the column of "Fall." Being careful to place the back and front sights in the proper column, and noticing that the difference between them is always on the side of the greater, a mistake can hardly occur.

In Table I, between poles 6 and 7, will be noticed a reading which is the bed of the stream; this was taken while getting the elevation of 6 and 7 merely as an aid in plotting the profile, and does not come in with the additions in checking up the table. Between poles 19 and 20, 20 and 21, the rise was too great to admit of one reading, so it was divided in two, as the table will show.

TABLE I.—NOTE FORM.

Pole.	Distance.	Rise.	Back sight.	Front sight	Fall.	Elevation.	Remarks.
1						100.0	
2	100	—	5.2	5.5	.3	99.7	
3	100	—	4.4	7.5	3.1	96.6	
4	100	—	2.7	7.1	4.4	92.2	Stub Guy and Anchor
5	80	—	3.5	6.6	3.1	89.1	Stub Guy and Anchor
6	93		4.0	11.2	3.7	85.4	
			3.4	1.2	7.8	77.6	Stream
7	93	—	3.4	5.9	2.5	82.9	Ground Wire
8	93	4.6	8.0	3.4	—	87.5	
9	100	1.6	6.0	4.4	—	89.1	
10	100	2.6	6.4	3.8	—	91.7	
11	100	2.7	6.5	3.8	—	94.4	
12	100	1.6	6.0	4.4	—	96.0	
13	100	4.3	6.5	2.2	—	100.3	Tree Guy
14	100	3.3	7.8	4.5	—	103.6	
15	100	3.3	6.5	3.2	—	106.9	
16	100	1.0	6.1	5.1	—	107.9	
17	100	—	4.1	4.9	.8	107.1	
18	100	—	4.9	5.6	.7	106.4	Stub Guy and Anchor
19	80	4.1	5.6	1.5	—	110.5	Stub Guy and Anchor
		7.5	8.5	1.0	—	118.0	
20	100	8.7	9.7	1.0	—	126.7	
		8.7	10.0	1.3	—	135.4	
21	100	6.8	8.3	1.5	—	142.2	
22	100	13.8	14.5	.7	—	156.0	
		74.0	148.6	92.6	18.6		
		18.6	92.6				
		56.0	56.0				

Having finished running the levels, check the table to see that the readings were placed in their proper columns. Add up the columns "Rise," "Back Sight," "Front Sight" and "Fall"; then if the work is right, the difference between "Rise" and "Fall" should be equal to the difference between "Back" and "Front" sights. If such is the case, then deduce the elevation of each point as follows:

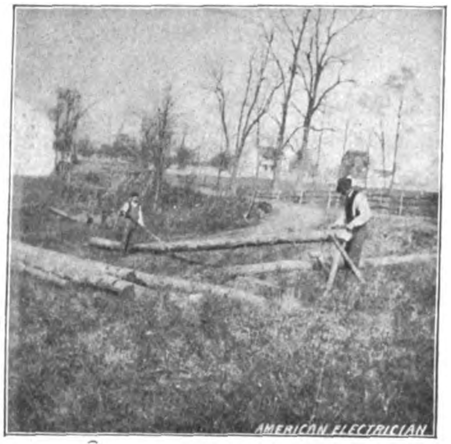

FIG. 7.—GAINING POLES.

Assume a datum of sufficient elevation that the lowest point will not go below *o*; in this case 100 is used, being the elevation of peg 1. No. 2 is in the Fall column by .3 and must be subtracted from 100, giving 99.7 ft.; place this in column marked "Elevation." No. 3 is again lower by 3.1 ft., which gives 99.7 — 3.1 = 96.6 ft., and so on; finally, the elevation of No. 22 above No. 1 is 156.0 — 100.0 = 56 ft., which it will be noticed, is the difference between the "Back" and "Front" sights, the stream elevation not being counted. The levels or elevations being reduced, the surface line may be represented in the form of a section as in Fig. 1.

The vertical and horizontal scales of a section are seldom the same, which produces a caricatured representation; the vertical scale being so much greater than the horizontal, shows the grade with greater clearness than if both scales were the same. The original scales used in this section are, vertical 1 in. = 20 ft.; horizontal, 1 in. = 100 ft.

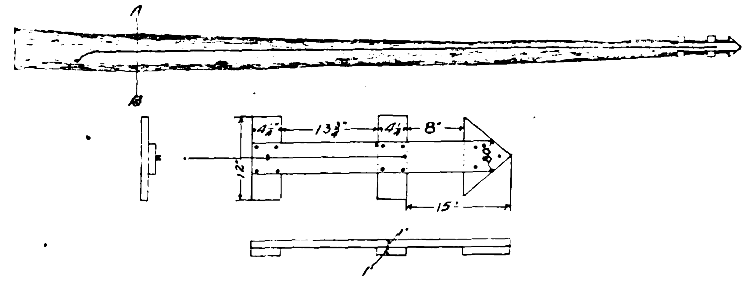

FIG. 9.—GAINING TEMPLATE.

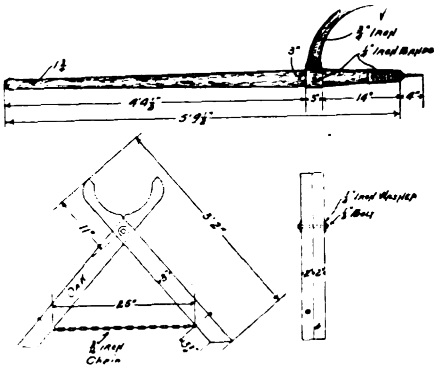
To make the section in this example, first draw the horizontal or assumed datum line, representing 100 as the datum to which the elevations were reduced. On it mark off the distances between pegs corresponding to column headed "Distances;" number the pegs below the datum line, putting down the distances between these numbers. Above the distances, vertically, put the height of the surface of the ground from column of elevations for each peg.

At peg 2 let fall a perpendicular from the datum line, and on it mark off the fall, .3 ft., which is the level of the ground at this point; in like manner proceed with each succeeding peg, being careful to note whether it is a rise or fall. Now the lines connecting these points represent the elevation on the ground of the pole line, and the section is now ready to plot the grade of the wire or top of poles.

In drawing the grade line, set up at different points perpendicular lines, representing poles, of the average height decided upon—this case 36 ft., allowing 5 ft. in the ground, and connect the tops with a line, being careful not to have any sharp vertical curves in it. To this grade line erect perpendiculars at each peg, which will be the length of pole required. Measure them with the scale, allowing 5 ft. to be in the ground and place the height of each over the elevation figures at the bottom. Add together the length of all the poles, divide the sum by the number of poles and see whether this result will bring you within the average height; if not, the grade line must be dropped toward the datum line to accomplish the desired result.



FIGS. 7 AND 8.—CANT HOOK AND POLE BUCK.

A very convenient paper to work out a profile on can be had from any engineering supply house. It is ruled to a scale of 4 divisions to the inch horizontally, and 20 to the inch vertically, and called profile paper.

The problem has now assumed such shape that the poles can be cut and distributed at the proper pegs. In distributing poles, see that all the tops are laid up hill with butt near the peg, as this will save much time in raising. Fig. 6

shows the manner of loading poles, and Fig. 7 the operation of gaining and trimming. The necessary tools and implements for gaining are as follows:

A small pole buck, Fig. 8; cant hook, Fig. 7; broad wood chisel; foot adze; hatchet; saw; paint pot, brush and paint; gaining templet, Fig. 9.

It will require two men at this work, and they should be started as soon as the poles are laid out so the raising gang can go on without having to wait for gaining. On the position of the gain in a pole depends a great deal. First, it must be cut in such a place and way that when the cross arm is put on it will set parallel with the ground; second, it must be put on that part of the pole which will allow the greatest bend to run with the line and not at right angles to it, thus making a far prettier looking line; third, the gains must be cut so as to allow of a snug fit of the cross arm, thereby helping to keep the weather out and insuring longer life of cross arm and pole.

To decide on the proper place to cut the gain, roll the pole till the greatest crook or bend is down next to the ground; now the gain must be cut on the side directly opposite, or that part turned up; this, as will be seen, puts the greatest bend in line, in which position the line strain will be better and the crookedness will only show from a side view.

Fig. 9 shows the gaining templet and the manner of placing it on the pole, so that the cross arm will set horizontally. By means of such a template, and following the method given below for using it, a pole line may be erected that will give every satisfaction.

The templet, as will be noticed, is arranged to mark off the peak and two gains. The peak will be 15 ins. from the top of the first cross arm, and the cross arms 18 ins. apart, thus allowing the line wires to be 18 inches apart in all directions, as the pins are also set 18 in. apart. On the templet there should be a string attached to the top of the first gain mark, passing between two nails at or near the bottom of templet and exactly in the center. Place the templet upon the pole, after having the pole in position as above described, so that the string will be in the middle of pole at that piont. Now, have the other end of the string held in the center of the pole 5 ft. from the butt, or where the level of the ground meets the pole when it is set on line *AB*; then move the templet until the string falls in between the two nails on the bottom gain, when the templet will be set to mark gains and peak.

Saw the gains 1 in. deep, chisel out smooth and cut the peak according to marks; paint well all parts cut. Knots and bumps should be trimmed off smooth with the adze.

A concluding article will deal with the digging, raising and setting of the poles, guying and anchoring the same and stringing the wires, and will give detail instructions for the work; also the necessary tools, and the amount of work capable of being done with a certain number of men, whereby an approximate idea of the cost of labor on a line can be had.

ARMATURE WINDINGS AND CONNECTIONS.

BY PROF. ARTHUR L. RICE.

PLAIN AND FORCED TWO-CIRCUIT WINDINGS.

The Gramme ring winding of the two circuit form, unlike the multiple connection, is not available for any number of poles, but must be connected especially for a given number of poles. For instance, if the armature of Fig. 1 (Fig. 6 of the April issue) is to be used in a six-pole machine, the condition to be fulfilled will be: $2 \times 11 + 2 = 6 \times$ pitch; $22 + 2 = 24 = 6 \times$ pitch; pitch $= 4$. There is no alternative, because $22 - 2 = 20 = 6 \times$ pitch, and 20 is not divisible by 6. The connections would then be as follows:

Bar	to conductor	to bar	to conductor	to bar	to con'r.
10	I.	3	V.	7	IX.
11	II.	4	VI.	8	X.
1	III.	5	VII.	9	XI.
2	IV.	6	VIII.	10	I.

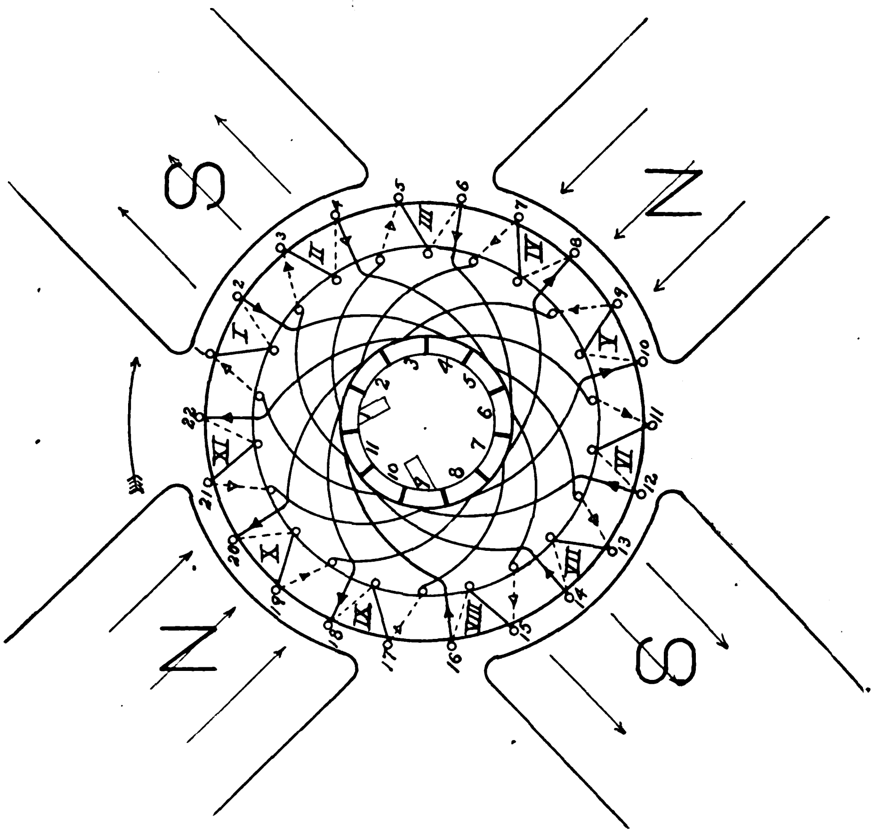


FIG. 1.—FOUR-POLE TWO-CIRCUIT GRAMME RING WINDING.

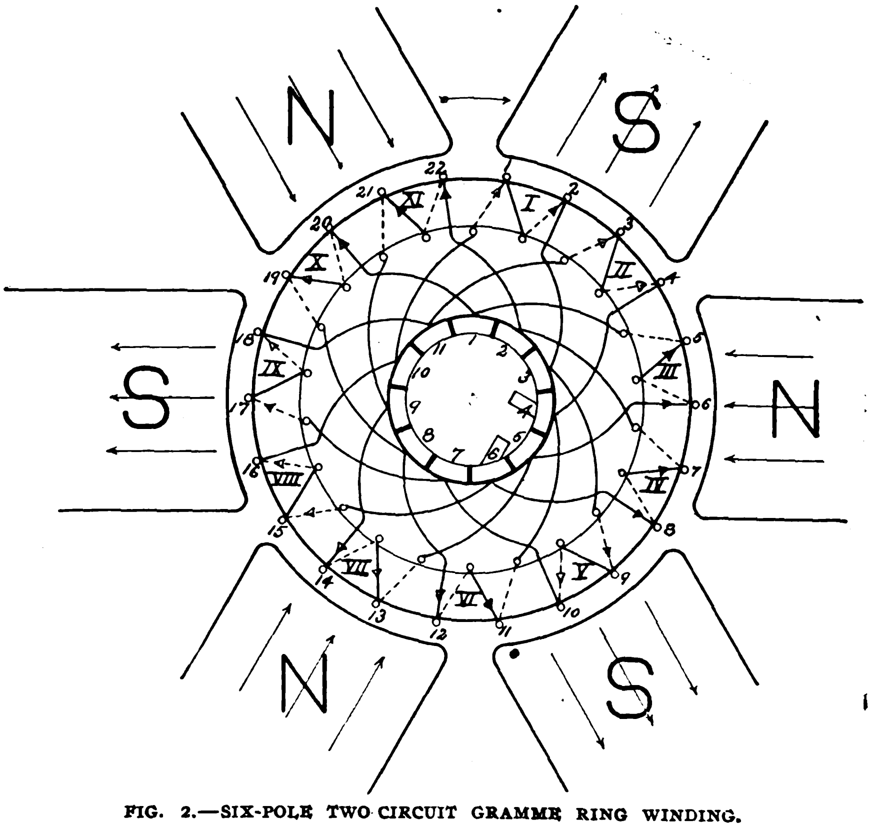

FIG. 2.—SIX-POLE TWO CIRCUIT GRAMME RING WINDING.

The brushes would go on bars 4 and 6 as shown in Fig. 2. The conductors are, as in Fig. 1, connected into two circuits, and there is the same unbalancing. The brushes are, of course, nearer together on the commutator than in Fig. 1—much nearer than would be allowable in practice. This would take care of itself in a properly designed machine, since the number of bars and coils—here shown absurdly small, for the sake of clearness in the diagram—would be greatly increased.

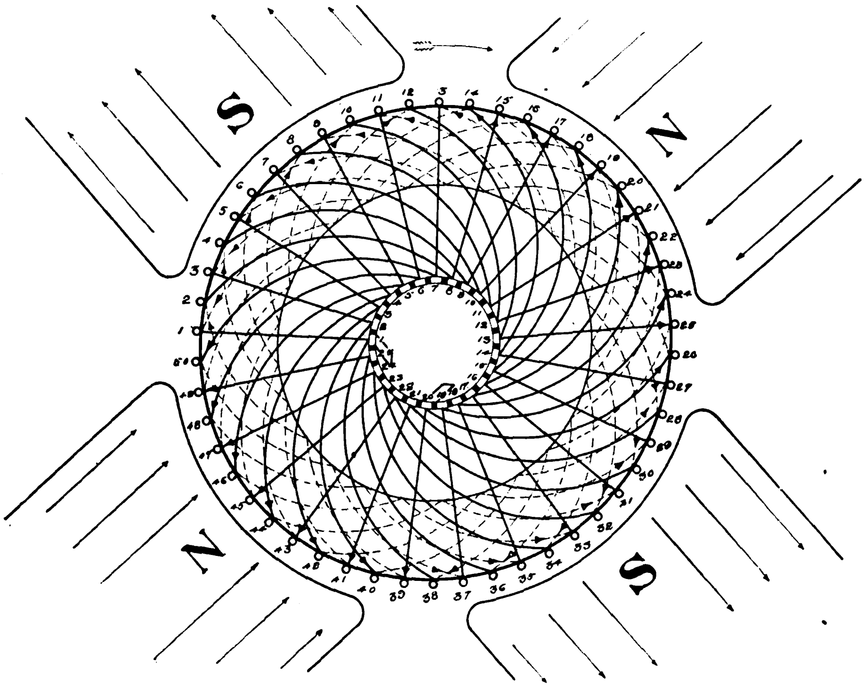

FIG. 3.—FOUR-POLE TWO-CIRCUIT DRUM WINDING.

In the case of drum armatures, the wave winding is the only form used for two circuit connections; hence the equation of condition for wave windings must be always satisfied; that is, number of conductors—number of circuits = number of poles × average pitch. Suppose it be desired to wind up 50 conductors into a two-circuit armature for a 4-pole dynamo. 50 — 2 = 4 × pitch; 48 = 4 × pitch; pitch = 12 or 52 = 4 × pitch; pitch = 13. Using 12 will give a retrograde winding, dropping back one bar on the commutator at each two connections; 13 will give a progressive winding, advancing one bar at each two connections. Let 13 be chosen; then connections will be from bar 1 to conductor 1, to conductor 14, to bar 14, to conductor 27, to conductor 40, to bar 2, to conductor 3, and so on, as shown in Fig. 3. The brushes are found to belong on bars 1 and 20, and are at 25 ÷ 4 = 6¼ bars apart. In passing from bar 1 to bar 2, the one adjacent, four conductors are joined up; as there are 6¼ bars between brushes, there will be 6¼ × 4 = 25 conductors between brushes. This is half the conductors on the armature, therefore the winding is a two-circuit winding. This method of testing is always a good one to ascertain whether a proposed winding fulfills the required condition as to the number of circuits in parallel. The unbalancing noted in the case of Fig. 1 and Fig. 2 is present here, but, as there, it will not be sufficient in a commercial armature to do any harm.

Suppose it is desired to wind the same armature for a six-pole machine. 50 — 2 = 6 + pitch; 52 or 48 = 6 × pitch; the average pitch must be 8, as 52 is not divisible by 6. Let the windings be in two layers, as is common in commercial work. Then, since the odd-numbered conductors are all in the outside layer and the even-numbered ones in the inside, it will be impossible to pass from one layer to the other with an even number for actual pitch, since the sum of an odd number and an even number is always odd, and of two even numbers always even.

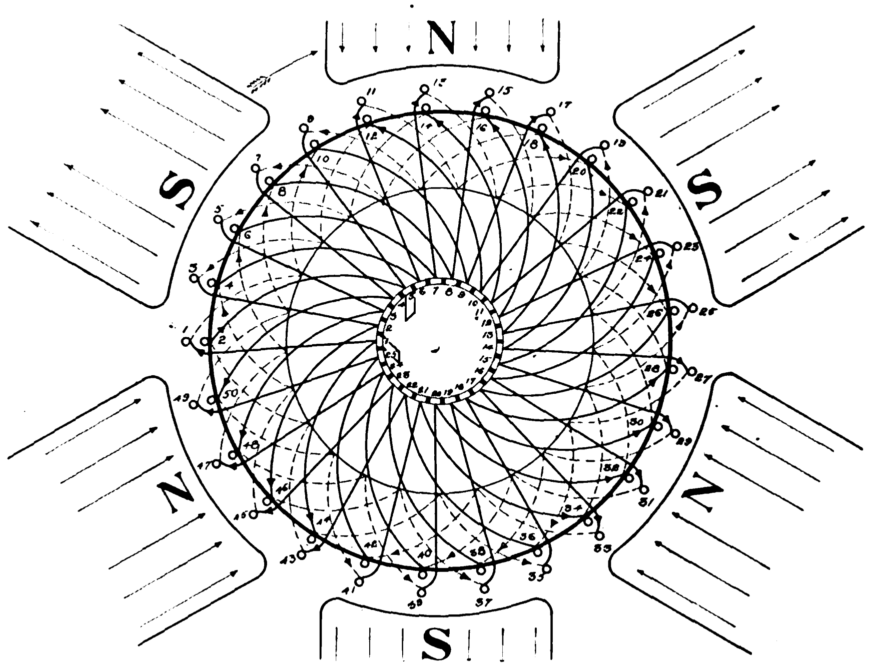

FIG. 4.—SIX-POLE TWO-CIRCUIT DRUM WINDINGS.

It is desirable to connect an outside conductor to an inside conductor to form a coil for the sake of symmetry and easy winding; therefore, it will be necessary to use unequal odd values for front and back pitch, such that the average shall be 8. Take 7 for the front and 9 for the back; then bar 1 connects to conductor 1, then on back to conductor 10, on front to conductor 17 through bar 9, on back to conductor 26, on front to conductor 33 through bar 17, on back to conductor 42, on front to conductor 49 through bar 25, and so on, as shown in Fig. 4. The brushes go on bars 1 and 5 at 25 ÷ 6 = 4 1-6 bars apart. In going from bar 1 to 25, which is next it, there are joined in 6 conductors; 6 × 4 1-6 = 25, or half the conductors on the armature are in one path between the brushes and there will be two circuits as intended. The unbalancing always brought in by connecting as a two-circuit winding is present, but otherwise the winding fulfils the requirements.

Since the two-circuit winding is to be used in order to allow of running high voltage machines at a low speed, it is desirable to be able to use the same parts for both high and low voltage machines. With a smooth-bodied armature core there is no difficulty in winding any number of conductors for which there is room on the armature; and the field coils can be wound of such size wire as will give a resistance suitable for the voltage to be used. But it is not possible to use the same commutator for parallel and series winding unless some of the bars are short-circuited so that the number of bars in use will correspond to the number of coils used.

With a toothed armature the problem is more complicated. The number of coils is regulated by the number of slots and cannot be changed; but one or more of the coils may be left unused. Suppose that it is desired to wind a toothed Gramme ring armature with 24 slots and bars into a two-circuit armature for a four-pole machine. By the condition given in the April number: 2 x 24 + 2 = 4 x pitch; 50 or 46 = 4 x pitch. This will not do, as neither 50 nor 46 is divisible by 4. If, however, one of the coils be left unused, then: 2 x 23 + 2 = 4 x pitch; 48 or 44 = 4 x pitch; and pitch = 12 or 11. Let 11 be chosen. One coil and one bar will have to be left unused. The unused, or "dead" coil, is wound in place to give mechanical balance, but is left with one or both ends unconnected. The unused bar is short circuited to the one adjoining, so that there shall not be a break in the circuit as the brushes pass that bar. The coil which would be number 24 is chosen (Fig. 5) for the dead coil; the dead bar must be one of those which would have connected to coil 24 in the winding; in Fig. 5 one end of the dead coil is shown connected and the bar to be made dead is thus determined; the other end of the coil is bent back on itself and covered with insulation. For the sake of short leads, coils which are to be joined are connected to a bar half way between them.

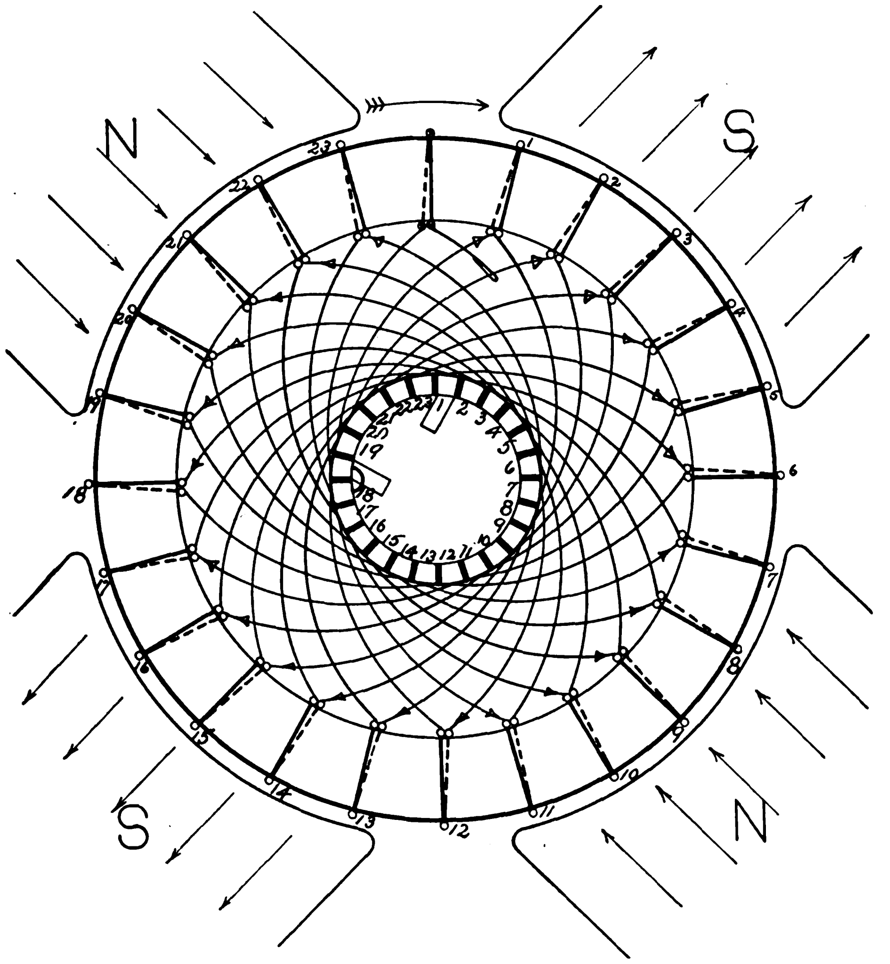

FIG. 5.

The back lead of coil 1 is joined to bar 19, the front lead is connected to coil 12—11 coils ahead—through bar 7; thence to coil 23 through bar 18. This gives two coils between adjacent bars. The front lead from coil 23 would go to the bar numbered 5, if all the bars were to be used and a strictly symmetrical arrangement were to be followed; but the coil which would connect to bar 6 is left dead and the bar next to 18 is short circuited so that the front lead of all coils from 13 to 23 must be set ahead one bar as shown. Practically this reduces to short circuiting the bar to which the back end of the dead coil connects and skipping that bar in making the connection of front leads. The front lead of coil 23 connects, therefore, to bar 6, then to coil 11, to bar 17 and so on.

One brush is found to belong on bar 1, so that the current may come into the armature at that point: Since it is a four-pole machine, the other brush must be at 90 deg., or on the dead bar. The direction of e.m.fs. would place it on bar 18, but bar 18 is connected to the dead bar, so that the current can pass to the brush and thence out to line.

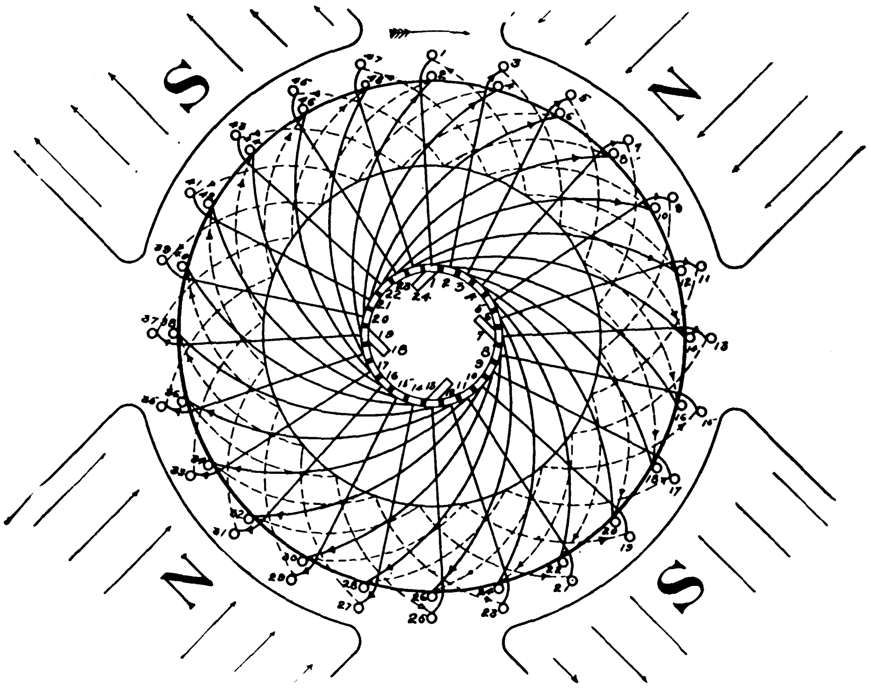

FIG. 6.—TWO-LAYER, FOUR-POLE LAP WINDING.

Between bars 18 and 19 there were found to be two coils; there are six bars between brushes, therefore there will be 6 x 2 = 12 coils in one circuit, and there must needs be 11 in the other, since there are 23 active coils in the winding. By examination, it will be seen that the circuit from bar 18, through coils 23, 10, 21, etc., has 11 coils; the one through coils 12, 1, 13, etc., has 12. Of course, this will produce some slight unbalancing, both of e.m.fs. and of resistances, but it is not found in practice to be of serious importance.

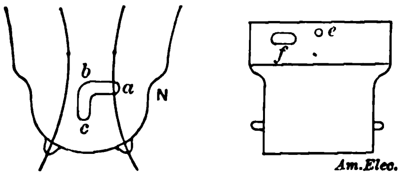
ENGINEERING EDUCATION.

At a recent meeting of the Western Society of Engineers, Mr. J. C. Bley read a paper on engineering education, which led to a discussion showing the usual wide difference of opinion concerning the relative proportion of practical and theoretical instruction. In the course of the discussion Prof. Ricketts, of the Rensselaer Polytechnic Institute, was quoted as regarding manual training of dubious value. His experience was that there were a great many boys who, while they had bright but lazy minds, much preferred to develop their fingers to their minds, and if permitted to go into the manual training schools they applied themselves very diligently to making a little engine or something of that sort, to the detriment of their mental training. For that reason Prof. Ricketts thought that parents and guardians should exercise very great care in sending their children to manual training school. Three of those joining in the discussion of the paper thought workshop training was necessary before or during the intervals of college or theoretical training. Another considered that a scientific man gets more out of an experience than a practical man and will beat him in the long run, and all appeared to agree that an engineer should be a good mathematician and able to use the calculus.

Among our Foreign Contemporaries.

Edited by CHARLES T. CHILD.

New Method of Attaching Lamp Bases.—An ingenious method for attaching bases to incandescent lamps without the use of plaster has been used for some time by M. Larnaude of Issy-les-Moulineaux, France, and is described in "L'Industrie Electrique." On the head of the lamp small grooves of the form shown at, a, b, c, in the figure are blown diametrically opposite each other, and arranged to engage with the projections, e, of the brass base. When the base is slipped on and given a turn so that the projection, e, is at the end, a, of the groove, the oval hole, f, in the brass is brought opposite the vertical part, b, c, of the groove. A drop of special solder put into the hole, f, is sufficient to secure the base tightly to the lamp. The disadvantages of plaster are specially noticeable in damp situations, and it is said that lamps provided with these all-metallic bases are better able to withstand moisture.



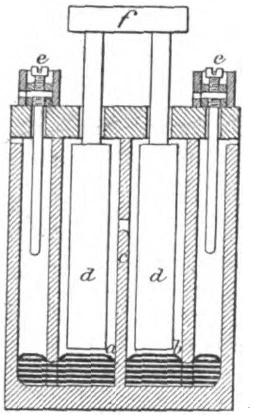
A LAMP BASE WITHOUT PLASTER.

A New Material for Fluorescent Screens.—According to "L'Industrie Electrique," MM. Ducretet and Roger have discovered that the white celluloid used for making collars and cuffs, fluoresces brightly when exposed to X-rays. This material is loaded with zinc-white, to which, doubtless, its fluorescent properties are due.

A Substitute for Platinum in Incandescent Lamps.—The "Electrician" states that experiments lately made in German show that iron-nickel alloys of various proportions have widely different coefficients of expansion, and that such an alloy containing 45 per cent. of nickel possesses the expansion rate of platinum. It is stated that experiments made at the Reichsanstalt confirm this and it has been proposed to use the alloy to replace the platinum leading-in wires of incandescent lamps.

Electricity at the Paris Exposition.—Electricity will play a large part at the Paris Exposition of 1900, says the "Revue Technique." No less than 15,000-h.p. will be used for lighting and 5,000-h.p. for furnishing electric power to the various parts of the grounds. As far as possible all the machinery exhibited will be shown at work and for this purpose electric conductors will be laid down to all points on the grounds. The boiler plant will be located at the end of the Champ de Mars, and will occupy two spaces of 130 x 390 ft. each, one being devoted to French boilers and the other to those of foreign makers. This plant will be, in itself, a very interesting exhibit. It is proposed to provide a capacity for evaporating not less than 440,000 lbs. of water per hour.

A New High-Tension Switch.—At a recent meeting of the Societe Internationale des Electriciens some new forms of switches for handling high-tension currents, invented by M. Bouchet, were described. The illustration clearly shows the principle upon which they work. An insulating case contains two cavities filled to the same level with mercury and separated by an insulating partition, c, in which is a hole normally above the level of the mercury on the two sides. Plungers, d, d, are manipulated by the cross-head, f, so that when they are forced down into the mercury its level rises, contact being made with the two electrodes attached to the terminals, e, e, and through the hole in the insulating partition. When the plungers are withdrawn the level falls and contact is broken at the hole and also at the tips of the electrodes attached to the binding posts, e, e. It is stated that no arc is formed, the surface tension of the mercury preventing it. The apparatus being entirely inclosed there is no oxidation. An interrupter of this type has been successfully used at Paris for a current of 12 amps. at 3,000 volts.

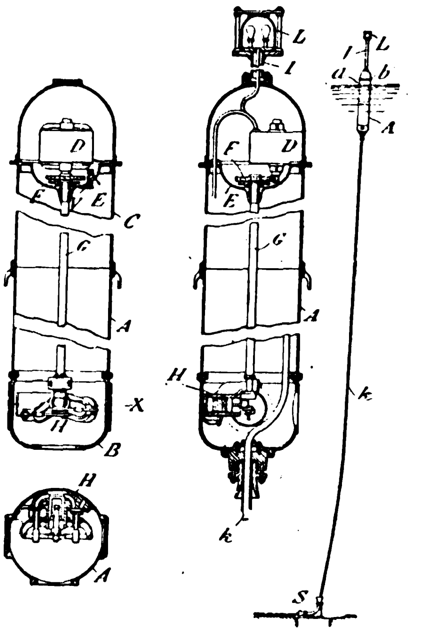


A NEW HIGH-TENSION SWITCH.

Engine Room and Shop Floors.—On account of the vibrations due to engines and other machinery the ordinary cement concrete floor has not been found entirely durable. An advantageous composition, according to "Erfindungen und Erfahrungen," is made of lime, sand, cement and clinkers, which should be used in thicknesses of at least 10 ins. The best mixture is said to be: Portland cement, 1 part; unslaked lime, ½ part; sand, 3 parts, and sifted clinkers, free from ashes, from 7 to 8 parts. For a top dressing of finer mass the composition should be 1 part cement, 3 parts sand and 2 parts of finely ground and sifted clinkers, the dressing to be well rammed and rolled after laying. Floors constructed in this way are said to be practically indestructible.

A New Incandescent Lamp.—Professor Nernst of Gottingen University has invented an incandescent lamp having an efficiency of 1.1 watts per candle. Up to the present, says the "Electrician," no particulars of the construction of the lamp have been published, but short articles in the German technical papers have described the principles of the invention. When magnesium oxide is heated to redness it becomes an electrolyte. A hollow rod of this material is used as the incandescent body of the lamp. It has first to be heated to incandescence by an outside source and then supplied with current to keep up its temperature and offset the losses due to radiation, conduction and convection. An alternating current must be used to avoid decomposing the magnesia rod. A cylindrical rod ¼-in. long and 1-6-in. diameter, glowing in air, is stated to have given 26-c.p. with 27 watts.

Disappearing Electric Buoys.—In a most interesting series of descriptions of applications of electricity in navigation and on shipboard, "L'Eclairage Electrique" includes an account of an ingenious channel buoy, devised by Siemens, which can be made to sink at will. This property would be useful in cases of a threatened invasion by an enemy, as a harbor could be cleared of these finger posts of navigation in a few minutes. The buoy consists of the usual metallic case attached by cables to an anchor and carying incandescent lamps on its upper part for lighting the channel at night. A small polyphase induction motor in the buoy is coupled to a centrifugal pump, which fills or empties the buoy according to the direction of its motion. This pump has a very large clearance, so that if it is operated after the buoy is discharged



AN ELECTRIC DIVING BUOY.

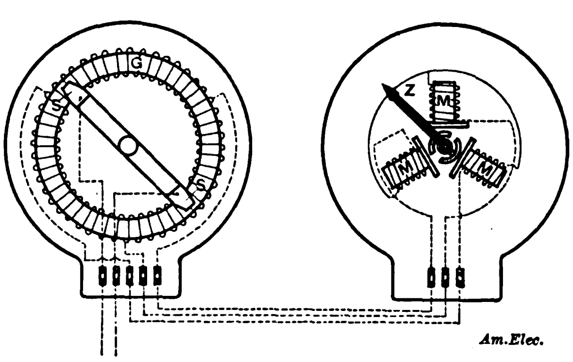
of water it will not create a partial vacuum in the case and cause the water to again enter and sink the buoy when the motor stops. The motor is in a chamber partitoned off from the rest of the case, so that it is not liable to be wetted by the submergence of the machine. By using a three-wire three-phase circuit two of the wires can be used at all times to carry current for lighting the lamps.

A 100-Mile Transmission Project.—A plan has been devised in Stockholm, according to the "Frankfurter Zeitung," for the utilization of part of the power of the waterfall of Elfkarleby, situated 100 miles from that city, where about 100,000 h.p. is continuously wasted. The idea of transmitting part of this power to Stockholm has, it is said, taken definite shape, and several engineers have been retained to work out the scheme. Their report is now ready. It is proposed to begin by utilizing 20,000 h.p., the estimated cost of the installation being given as follows: Power station, including all the machinery and works, $890,000; transmission line, $1,165,000; buildings and transformers in Stockholm, $145,000; the total being $2,200,000. It is estimated that the full load loss will be 25 per cent., and that 15,000 h.p. will be available for rental in the city, the price being fixed at a little over $11 per year per horse-power.

Electrochemical Equivalent of Carbon.—"L'Electrician" gives in brief the results of M. A. Coehn's researches upon the electrochemical equivalent of carbon. When carbon is used as the anode in the electrolysis of a liquid liberating oxygen, it disintegrates. This phenomenon is due partly to chemical action and partly to mechanical causes. At the first glance the action seems to depend upon the electrolyte used. Thus, if the action produced upon carbon anodes by electrolysing, in connection with platinum cathodes, under a current of about 0.12 amp., solutions of sulphuric acid in 1, 10, 20, 50, 100 and 500 parts of water, is studied, at the end of about ten hours it is noticed that the most concentrated solution is clear while the weakest is strongly colored, intermediate solutions showing intermediate degrees of darkening. By accounting for the particles of carbon mechanically detached and substracting their weight from the total loss of the electrode, 2.7 to 3.0 is obtained as the electrochemical equivalent of carbon, and this figure is independent of the concentration or temperature of the electrolyte.

Electric Conductors and Powder Magazines.—A committee of the Academie des Sciences was formed at the instance of the French Minister of War to investigate the question of fixing electrical conductors in or near powder magazines, and their report has been presented. They make no distinction between telephone and telegraph wires, and electric light and power conductors, since all these may be exposed to lightning. According to "Industries and Iron" the report may be summarized as follows: All underground electric conductors as well as gas and water pipes must be kept at least 30 feet away from the magazine. Aerial lines must be arranged so that they will not fall upon the magazine if broken, and it is recommended that none be allowed within 60 feet of the magazine. If light be required inside the magazine all wires are to be in strong metallic pipes and all switches, fuses, etc., are to be placed on the exterior of the building. Only fixed lamps are permissible, and these must be protected by a second envelope of glass. No voltages over 110 are to be used. Any electric bells required must be placed at least 12 ft. from the powder and only types using very small currents are permitted.

Signaling with the Rotating Field.—An interesting variety of signaling, due to Dr. L. Weber, is described and illustrated in "L'Elettricita." The principle of the apparatus may be readily understood from the accompanying illustration. The signal system is intended to replace the step-by-step systems now used for many purposes, but especially for signaling from the bridge or pilot-house of a vessel to the engine room. In apparatus of this character similar dials are used at the extremities of the line, the signal being given by moving an index lever over the dial at the sending end and this causing a corresponding movement of an index hand over the receiving dial. Dr. Weber's apparatus uses a rotating magnetic field. The sending instrument is shown on the left in the illustration. A direct current is led to the extremities, S, S, of the index lever which rest upon opposite points of a commutator connected to the resistance coil, G. This is tapped at three equidistant points, these being connected to three equal and equally spaced magnets in the receiving apparatus, as shown in the illustration. A small two-pole armature of soft iron carrying an index needle completes the apparatus. When the signalling lever, S, S, is moved the distribution of magnetism in the three coils, M, M, M, moves correspondingly, carrying with it the index needle, Z. For use on shipboard the apparatus is made reversible by combining the sending and receiving mechanism at each end so that the engineman can signal back to the bridge his receipt and understanding of the signal. The apparatus has some points of superiority over the step-by-step system, being less complex and less liable to derangement by the movement of the ship or, in the case of naval vessels, by the shocks of battle.



ROTATING FIELD SHIP SIGNAL.

Gas Engines for Poor Gases.—In a contribution to the "Memoires de l'Union des Ingenieurs de Louvain," M. E. Heirman discusses the working of gas engines with poor gases and describes a new cycle which possesses many points of advantage. The mixed gas and air is introduced under pressure behind the piston at the beginning of the stroke, cut off by a valve at any desired point, and simultaneously ignited. Expansion thus takes place up to the end of the outward stroke. During the return stroke the products of combustion are entirely expelled, as there is no clearance space or compression chamber in the cylinder. In this way two important objects are attained, an explosion for every revolution and an automatic cut off like that of a steam engine. The mixture of gas and air is maintained at constant proportions for the best efficiency and its initial compression (effected outside the working cylinder) can be carried to any desired point. Accurate regulation is secured and the size and weight of the engine for a given output considerably reduced. M. Heirman thinks that the possibility of using furnace gases and other poor gases in engines of this type opens a very broad field for the extension of the gas engine.

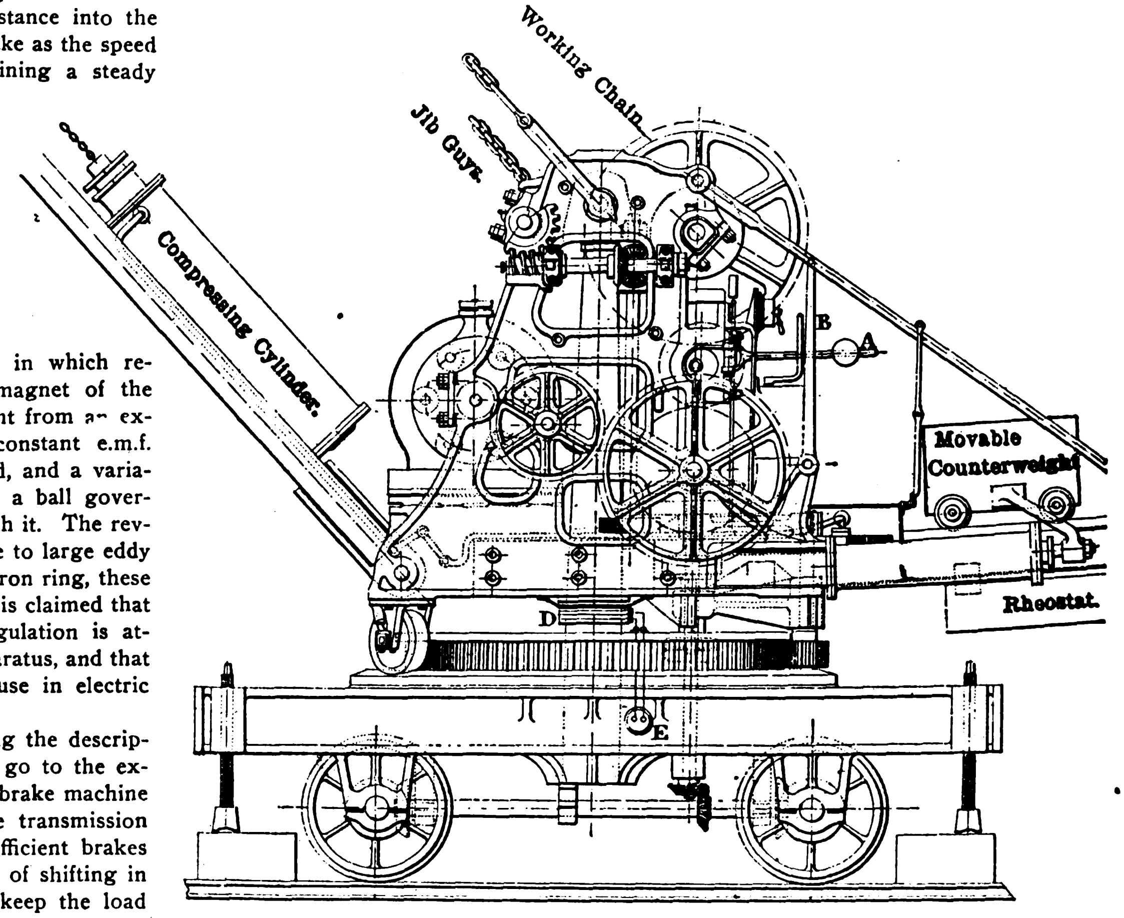
The Electric Arc as a Telephone.—Some exceedingly curious experiments are described in a paper by Herman Simon in "Wiedmann's Annalen" which go to show that the arc can act as a telephone receiver or transmitter. The primary of a small step-up transformer was connected in circuit with the arc, which was, of course, maintained by a steady direct current. The circuit with the secondary of the transformer was connected a microphone and its battery. Whistling, singing and even speech were distinctly transmitted and reproduced at the arc, a common glass funnel held near the arc and supplied with a rubber ear tube acting as the collector. When the arc is lengthened the sounds emitted become louder and more distinct, this being due to the increase in the resistance of the arc and the amount of energy expended in it by the current. The explanation of the curious action is, of course, the heating of the arc vapors by the alternating microphone current, thus altering the volume of the arc space and setting up corresponding sound waves in the air. The apparatus is reversible, as the effect of sounds upon the arc are to cause an alternate increase and diminution of its volume, and hence its resistance, and so modify the supplying current.

The "London Electrical Review," in commenting upon this experiment, says: "We do not recommend this invention for commercial use; the language transmitted through the present telephone is usually heated enough; at least there is no necessity for passing it through an electric furnace."

Electric Brakes as Turbine Governors.—A novel system of regulation for water wheels, due to M. E. H. Rieter, is described at great length in "L'Electricien." It consists of an electric brake of peculiar construction, driven by the water wheel, and controlled by a ball governor which switches more or less resistance into the energizing circuit of the brake as the speed falls or rises, thus maintaining a steady load upon the wheel. Of this form of regulation is only useful where there is no desire to economize the water, as the wheel works continually at full open gate. The brake consists of a cast iron ring, having a corrugated outer surface to better its heat radiating qualities, in which revolves a multipolar field magnet of the Brown-Boveri type. Current from an exciter or other source of constant e.m.f. is used to energize this field, and a variable resistance controlled by a ball governor is included in circuit with it. The revolution of the field gives rise to large eddy currents in the mass of the iron ring, these being dissipated as heat. It is claimed that very close and accurate regulation is attained by the use of this apparatus, and that it is specially adapted for use in electric power transmission plants.

One wonders, after reading the description, why it is necessary to go to the expense of building a separate brake machine when the dynamos of the transmission plant are themselves most efficient brakes of the same class. The idea of shifting in and out dead resistance to keep the load steady on a water wheel driven generating plant and thus to maintain a steady speed, is by no means new, and such arrangements are in use in several parts of the United States. It is unnecessary to have a ball governor, even, as an electromagnetic device in the working circuit will manipulate the resistance as required and will even compound the plant, so to speak, by allowing a somewhat higher speed at heavy working loads. Just why it should be considered necessary to go through the complicated cycle of energy transformation used in this form of governor when the water wheel is driving a dynamo, is hard to see, but the machine would probably prove of excellent use in the regulation of wheels driving other than electrical machinery.

An Electric Crane.—M. Emile Evers contributes to the Memoires of the Societe des Ingenieurs Civils de France an account of an electric crane possessing some novel and ingenious features. The crane is of the type used about docks, consisting of a platform running on rails and surmounted by a rotating part carrying the motor, with a jib and its guys on one side and a counterweight on the other. The principal novelty in M. Evers' design is the automatic adjustment of the counterweight to balance whatever load is suspended from the jib in the various positions the latter may take. The main working chain of the crane goes over a pulley at the end of the jib, through a block to which the load is attached, back through another pulley on the jib, and is anchored to the piston of a cylinder containing some fluid such as oil. This cylinder communicates by appropriate pipes and valves with one or more cylinders on the other side of the main pivot of the machine, to these being attached the movable counterweights. As the pressure on the first cylinder increases it is transmitted to the counter-weight cylinders and forces the counter-weight further away from the pivot for heavier loads on the crane. The track upon which the counter-weight runs is inclined upward in a curve, so that the position of equilibrium is determined by the weight on the end of the jib. When the load is released the counter-weight descends by gravity to its initial position, also pulling in the end of the main chain and leaving the whole machine ready for another load. The operation of this crane is said to be very successful.



AN ELECTRIC CRANE.

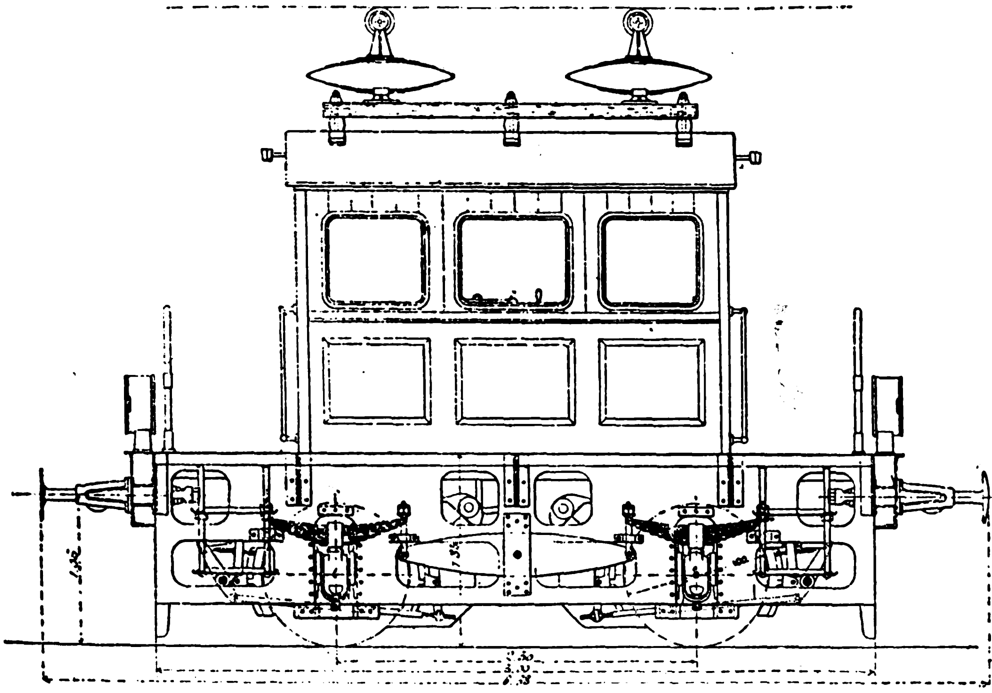
Phosphorus by the Electric Furnace.—"L'Industrie Electro-Chimique" notices three recent processes for the manufacture of phosphorus in which electricity plays a part. The Gin and Leleux process consists of heating, in an appropriate electric furnace, a mixture of phosphate of lime and coke. The two ingredients should be finely powdered and the mixture should be homogeneous. When, under the action of the heat, the mass becomes pasty, all the openings of the furnace are hermetically sealed except that for the passage of the phosphorus vapor, which is distilled out and collected in the usual way.

In the Boublique process iron phosphide is decomposed by electrolysis, this salt being produced by fusion of phosphate of lime with a salt of iron. The disengaged phosphorus vapors are carried away by a current of some inert gas.

The Collardeau process consists of the preparation in the electric furnace of a mixture of calcium carbide and phosphide. By using a mixture of 310 parts of phosphate of lime, 260 parts of quick-lime and 160 parts of coke nearly all the phosphorus goes into combination as calcium phosphide. The phosphuretted hydrogen obtained from this product is led through a tube filled with fragments of coke and maintained at a red heat, the gas breaking up into hydrogen and phosphorus.

The Hulin Alkali Process.—An interesting dry electrolytic process for the manufacture of caustic soda and bleaching powder from salt is described in the "Electrician" by Mr. John B. C. Kershaw. The process is due to M. Leon Hulin, and is a modification of the Vautin process which was unsuccessfully tried in England some years ago. In the latter process a cathode of molten lead was used, it being expected that the liberated sodium would alloy itself with the lead and thus be removed from the electrolyte, which consisted of fused salt. The difficulty encountered was the formation of a crust of the lead-sodium alloy on the surface of the cathode which was impervious to the passage of the sodium ions, and these were forced to escape at the surface of the bath where they burned. The compound of the fused salt, lead and free sodium also attacked the materials of the crucibles and the process was on these accounts unsatisfactory. M. Hulin's method is both simple and effectual. A certain percentage of lead chloride is maintained in the crucible by the diversion of a part of the electrolyzing current through a lead anode, and the electrolysis of this produces ions of lead at the cathode simultaneously with those of sodium. The two immediately alloy and are regularly and easily dissolved in the molten cathode. By the action of water upon the metal of the cathode after the electrolysis of the charge a solution of very pure caustic and spongy lead is obtained, hydrogen being liberated; or the alloy may be heated in a current of air, oxidizing both the lead and the sodium, and the caustic recovered by lixiviation, lead peroxide remaining. Both the spongy lead and the peroxide are valuable by-products, and doubtless some use can be found for the nascent hydrogen liberated. The current density in the cells may go to nearly 1,000 amps. per square foot, but the best results are obtained with a density of 700 amps. This process requires more energy than others for the production of the same quantity of caustic and chlorine, but the by-products are very valuable. A plant is now being erected at Clavaux, Isere (France), where a water power of 5,000 h.p. will be used, the turbines being direct coupled to 375-k.w. direct current dynamos.

A German Electric Locomotive.—A new type of electric locomotive has been constructed for service on the Prussian railways, and it is fully described in the "Annalen fur Gewerbe und Bauwesen." The locomotive, as may be seen from the accompanying illustration, is symmetrical in design and adapted to run either way equally well. It weighs 20 tons and can haul a 120-ton train at a speed of 31 miles per hour on a level track. Two motors are carried, one geared by a 3 : 1 gearing to each axle. The truck is a rectangle of stout steel plate, the buffers and draw-head being attached directly to it. The weight of the superstructure is borne by four leaf springs, as the illustration shows. The cab is of wood, with windows in all sides. Control is effected by the usual series-parallel arrangement, a resistance being used at starting. The trolleys are two bronze rollers supported by carriage springs, and a double trolley wire is used in order to increase the area of contact, both wires being of the same polarity. At 500 volts the locomotive has a speed of 30 miles per hour and a current consumption of 125 amperes, giving 84 h.p.



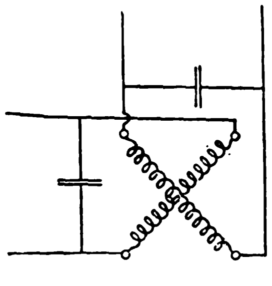
SIDE ELEVATION OF A GERMAN ELECTRIC LOCOMOTIVE.

An Electric Idyl.—They do things gracefully in some parts of Europe. Here is a literal translation of the report of the inauguration of a new electric lighting system in the little Swiss town of Grand-Saconneux, appearing in the "Journal de Geneve":

"The village inaugurated its new system of electric lighting last Tuesday evening by a charming little improvised festival. The town Council was assembled to take possession of the new installation and to see its perfection. Around them, on the Town Hall square, the village brass band and nearly the whole population assembled. After two pieces of music and a few words by the mayor praising the excellent workmanship of the installation and thanking those who had contributed to so handsomely light the village, the officials and sub-officials of the electrical department, the procession set itself in motion, the band in front, to get acquainted with the different street lamps. At each end of them a well garnished table immediately appeared and a representative of that part of the village expressed in a few simple words the satisfaction of the public. This joyful journey accomplished, not having neglected the mayor's house by the way, the crowd, still compact, returned to the Town Hall square. This must now be rededicated, so, to the gay strains of the faithful band, the young people organized a charming bal champetre and took possession of their new territory by joyfully frolicking there."

All very proper and lovely. "L'Energie Electrique," commenting on this idyllic tale, says that "there were 200 street lamps, from which circumstance the gayety of the crowd after refreshing itself at the 199th can be imagined."

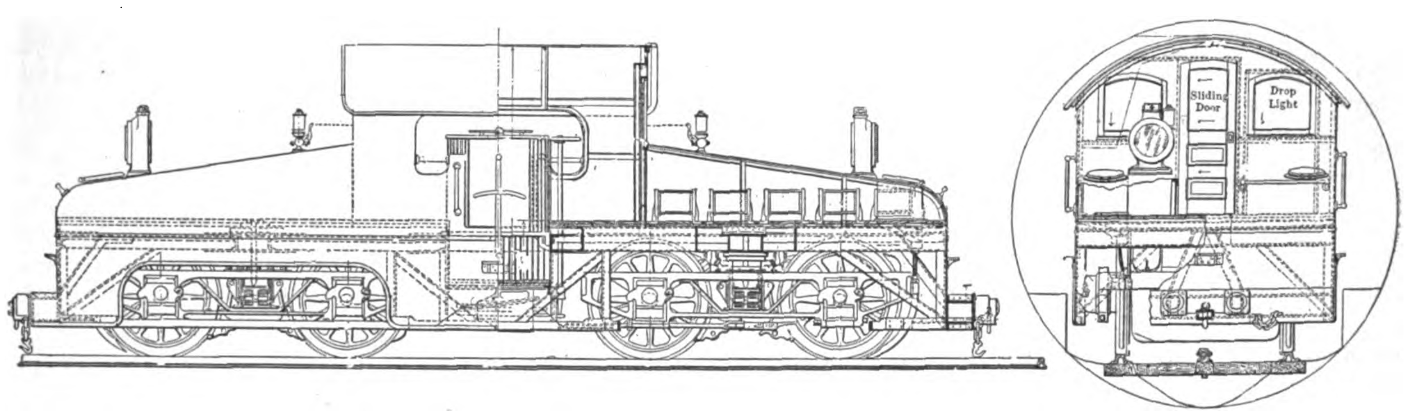
Commercial Condensers.—Some interesting facts regarding condensers are contained in a paper lately presented to the Societe Internationale des Electriciens by M. Boucherot. His experiments were confined to condensers constructed with paraffined paper as the dielectric, his experience having led him to think this the best material for the purpose. A great deal depends upon the quality of the paper, by which is meant its capacity to resist puncture and cracking at high electrostatic stress. Resistance to puncture, according to M. Boucherot, seems to depend on the mechanical strength of the paper rather than upon its specific insulating quality. As all dielectrics are more or less conducting there is always a certain amount of loss in a condenser which makes itself manifest as heat, the temperature attained depending on the radiating power of the case of the apparatus and the C^2R losses in it. These latter increase with the square of the voltage, so that a condenser that is very satisfactory at a given potential difference may heat and be destroyed at a higher voltage. If the "power" of a condenser is taken to be the product of the effective voltage at its terminals by the apparent current flowing into it the prices of condensers vary with the frequency at which they are used and the tension. For a frequency of 40 cycles per second condensers for 600 volts cost $30 per kilowatt, and for 3,000 volts $20 per kilowatt. For 120 cycles per second they cost, for the low and high voltages respectively, $10 and $6.50 per kilowatt. Apparently the most fatal defect of condensers of this type is the enormous decrease of the insulation resistance of paraffine with increasing temperature. Paraffined paper which shows a resistance of more than 10 megohms per square centi-



CONDENSERS IN ALTERNATOR EXCITING CIRCUIT.

meter (at 19 Centrigrade) falls to about ½ megohm at 99.

An interesting application of condensers shown by M. Boucherot is that of furnishing exciting current for alternators. The condenser excited machine he exhibited consisted of two similar parts, both armatures, so to speak, alike as to number of poles and winding, one of which was fixed while the other revolved. If this machine be connected to condensers, as shown in sketch, and turned it will furnish alternating currents in the two circuits of its armatures. The explanation of its action is that the condensers furnish a current leading in phase a quarter-period ahead of the e.m.f., while, in an alternator, e.m.f.s. are produced lagging in phase a quarter-period behind the magnetic flux. Hence the condenser current is in phase with the magnetic flux and can produce it. In the machine described a rotating field of half the angular velocity of the moving armature is maintained between the two by the condensers. It is not impossible that this very interesting type of machine may find practical uses, since it has no collector rings or brushes; but it unfortunately needs to be "started" every time it is desired to use it, as it holds no residual magnetism.



ELECTRIC LOCOMOTIVE FOR CENTRAL LONDON UNDERGROUND RAILWAY.

The Central London Railway.—The new underground railway, now under construction in London, is to be operated by electricity throughout and will present one of the most complete and well worked out systems of electric traction extant when it is finished. An interesting description of its engineering features appears in the "Railway World," from which the accompanying illustrations are taken. The road is underground throughout, at a deep level in order to be well out of the way of sewers, etc., and extends from Shepherd's Bush to the Bank, a distance of 10,163 yds.. Including the terminal tracks electric traction is provided for over 6.47 miles of double track. Thirty-two electric locomotives are under construction, each capable of hauling seven double truck saloon carriages, the train exclusive of the locomotive weighing (loaded) 105 tons and seating 336 passengers. The average speed called for by the schedule is 14 miles per hour, including 20-second stops at each of the thirteen stations. The tracks at each station are level, but fall away at a considerable grade on each side so that the trains are aided in starting and stopping by the grades. The generating station is at the extreme western end of the line. Steam is supplied by sixteen water-tube boilers automatically stoked, a coal storage tank of a capacity of 1500 tons being provided. Each pair of boilers is piped direct to one engine, a main header being also provided so that the boilers may be connected together in the usual way. The six engines of the first installation are of the cross-compound Corliss type, each of 1000 i.h.p. They are direct coupled to three-phase generators of 850 k.w. each, giving a voltage of 5000 direct from their stationary armatures. The main circuit high tension switches are so arranged as to break circuit simultaneously on both sides of the board, thus obviating any danger of arcing across their terminals. There are now being installed three sub-stations, but a fourth will be needed when the two-minute headway eventually contemplated is introduced. At each of these sub-stations, there will be three stationary transformers of 300 k.w. each and a rotary converter of 900 k.w., supplying direct current at 500 volts to the track conducting system. These sub-stations are located at the bottom of the elevator shafts at three stations. The stationary transformers are of the air blast type, the warm air being blown up through sheet iron pipes in the center of the spiral staircase that gives access to the stations. A third rail of channel section, weighing 80 lbs. per yard, is used as the working conductor. This is bonded with two bonds aggregating 420,000 c.m. at each joint, but it is not provided with fish plates. The track rails are of 100-lb. section and are bonded with both crown and plastic bonds.

As the tunnels are only 11 ft. 6 ins. in diameter inside, the construction of the locomotives presented no little difficulty. Each has two trucks, each of the two axles of each truck being provided with a motor, mounted direct without gearing. The total power of each locomotive is 260 h.p., at a speed of 27 miles per hour. The tractive effort at 22 miles per hour is 8000 lbs.

It is very interesting to note that the greater part of this fine installation is American. The boilers, coal conveyors, steam piping and valves, engines, dynamos, rotary converters, locomotives, rail-bonds, elevators at the stations, air-brakes and other minor features are all American. The contract price for the complete work, including the tunnels, was $16,200,000.

British Machine Shop Methods.—A new dynamo and motor works has been recently opened near Glasgow, with an elaborate plant of machinery, and is described at length in several of our English contemporaries. The praise bestowed upon certain new methods inaugurated in this well planned works throws a strong light upon average British machine shop practice, and seems curious to an American reader. For example, a marked innovation is the installation of a tool room where tool-makers are kept constantly busy in making and keeping in order standard tools, so that the machinists are not compelled either to stop their machines to make or grind their own tools or to wait for this to be done for them. This departure is spoken of as a novelty, and this fact illustrates strongly how conservative the older regimen of such shops has been. The differentiation of labor that has been carried to so great a length in this country and that has been productive of such excellent results, has apparently been opposed on the other side by the conservatism that is a marked feature of English character, and it is only now that the valuable object lesson taught by the accurate and cheap output of American shops is beginning to impress itself there. Attention is called in these articles to the fact that the main shop is heated in winter by the exhaust from the engines used, and this provision for the comfort of the men is thought praiseworthy. A curious difference in methods from those obtaining here is illustrated by the fact that the slots in all the armatures made by the new works are milled from a core built up of plain circular discs. It is claimed that this method gives better spacing and alignment of the slots than the usual practice of stamping out the teeth of the disc. It certainly seems to be a laborious and expensive process. In the light machines for brass working, etc., to quote one of the descriptions: "Advantage has been taken of the most modern improvements in American design and the result is an immense improvement in the economy and accuracy of the product."

Throughout the works the electric transmission is used, there being no line-shafting anywhere. As in many similar foreign installations a concentric cable is used for the transmission circuits, the inner core being positive and the outer cylindrical part being left bare and grounded.

New Types of Polyphase Motors.—Two very interesting types of polyphase motors were described by M. Boucherot before the Societe Internationale des Electriciens at a recent meeting. In the ordinary types of induction motors using a short-circuited rotor the difficulty of starting them, especially under load, without enormous rushes of current, rapidly increases with the size of the motor. The well known method used to avoid this difficulty—connecting a variable resistance in circuit with the rotor winding—necessitates the use of collector rings, and also requires that the winding be of a sufficiently great number of turns to give a reasonable voltage at the collector rings. The simplicity and mechanical excellence of the "squirrel-cage" cannot be made available when the size of the motor necessitates this opening of the rotor circuit for the introduction of resistance. To start an induction motor on a load and to operate it efficiently at speed require different windings. Except in the case of motors working centrifugal pumps, fans, etc., where the load at starting is practically nothing, the interposition of a resistance in the rotor winding is almost invariably necessary. It has been for a long time a great desideratum to rid the motor of this cumbersome and costly auxiliary and to make it self-contained. M. Boucherot's solution of the problem is extremely simple and elegant. He combines on the rotor two windings; the first such that, if it acted alone, the curve of torque and speed would be similar to that of I, Fig. 1, and the other such that its corresponding curve, when acting alone, is like II, Fig. 1. With the first winding there is a large starting torque which rapidly falls off as the motor approaches synchronism, so that the slip at full load would be excessive and the efficiency and output correspondingly low. The second winding possesses an extremely feeble starting torque, but this increases with the speed, and at full speed is sufficient to keep the slip low and the efficiency of the two give rise to a torque and speed curve like III, Fig. 1, showing a high starting effort and a satisfactory running torque at full load and speed. Of course these windings may be of any of the usual forms, but the squirrel-cage is preferred for mechanical reasons. The first winding should have as high a resistance and as low a self-induction as possible, while the second should be of low resistance and very great self-induction. Instead of the simple case of two windings here described, there may be combined any number of separate windings differing in their time-constants in the proper manner, but it is found in practice that two, or at most three, such windings are sufficient for all ordinary purposes. Fig. 2 shows an end elevation and axial cross section of such a rotor. A first series of holes, $T_1T_1T_1$, is provided near the periphery of the rotor as in the ordinary squirrel-cage construction. Through the body of the rotor another series of holes, $T_2T_2T_2$, is also provided, the numbers of holes in the two sets being the same. Narrow, slits, FF, connect the two so as to augment the magnetic resistance of the annular spaces comprised between the two series of holes and to diminish the dispersion of lines of force and compel them to pass through the second circle of holes. In the outer tunnels are copper bars connected at their extremities to the rings, C_1C_1, or iron, ferro-nickel, German silver or other high resistance metal. The copper bars in the inner series of holes are connected to the two rings, C_2C_2, of copper. At starting when the inducing magnetic flux traverses the rotor at high frequency (that of the supply circuit), even a small portion of it penetrating the interior of the inner winding suffices to set up large currents in it, tending to oppose the passage of the flux in this part and restrict it to the annular space between the two sets of windings. Thus the high resistance outer squirrel-cage works practically alone in starting the rotor, giving a high initial torque. As the speed increases the frequency of the flux relative to the windings diminishes, more and more of the flux passing through the inner winding and bringing that into play, until, at full speed (nearly synchronism), the rotor is running on the low resistance winding like an ordinary induction motor.

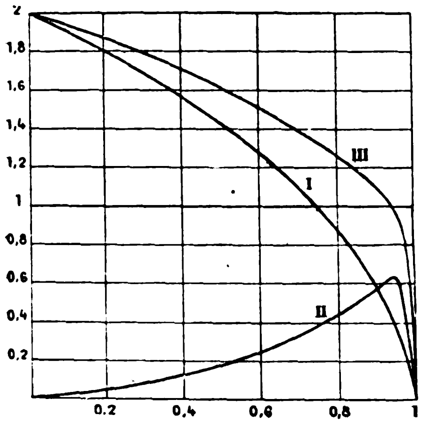


FIG. 1.—CURVES OF TORQUE AND SPEED.

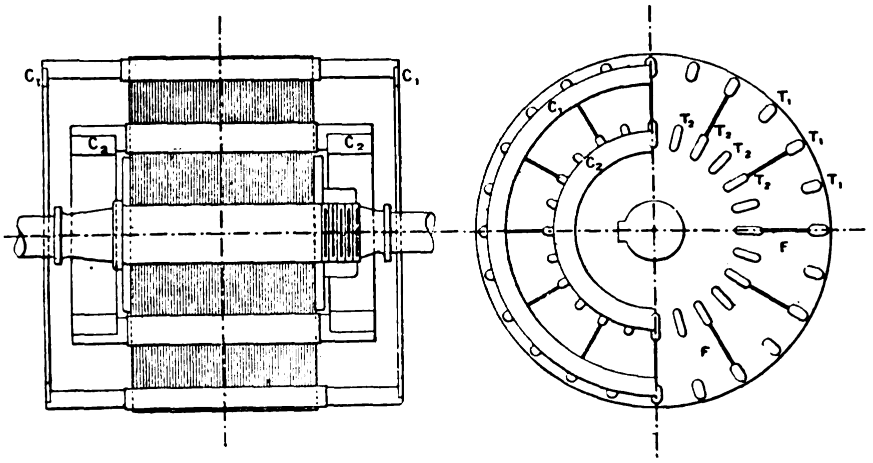

FIG. 2.—ROTOR OF SELF-CONTAINED INDUCTION MOTOR.

M. Boucherot meets the greatest objection to this type, that of the increase of wattless currents due to the second winding and the consequent lowering of the power factor of the machine, by saying that in most cases this makes no difference. The type of motor described is said to be particularly well adapted to operation from a distance, since it is entirely self-contained.

Another type which accomplishes practically the same results in a different way consists of the combination of two identical fields or stators, one of which is fixed in place on the frame of the machine, while the other is free to rotate between the positions of coincidence and opposition with it. The armature or turning part consists of two similar rotors, with slots near the surface, mounted on the same shaft, the copper bars of the squirrel-cage running through both. At the outer ends these are connected in the usual way by heavy copper rings, and in the middle they are connected by an iron or other heavy resistance ring. At starting the two fields are placed in a position of opposition so that the currents developed in the two halves of the bars of the rotor are opposed. These currents combine in parallel through the high resistance ring, giving the needed starting torque. As the speed increases the movable field is turned into the position of coincidence with the other and the motor then becomes an ordinary induction motor. The turning of the movable field is accomplished either by an endless screw or other appropriate mechanism, and the switch is combined with it so that the starting current cannot enter the stator except when it is in the proper position.

These solutions of the problem of starting induction motors are so ingenious and simple that it seems thankless to criticise them, but the decreased power factor seems to be a considerable objection. It is the low power factor of induction motors more than anything else that has limited their usefulness.

REGULATION IN CENTRAL STATIONS.

BY WM. H. CHAPMAN.

"An ounce of prevention is worth a pound of cure." This is a good maxim to set out with in any line of work, but a point is soon reached along any path of progress where the stubborn fact appears that after all possible efforts have been put forth in the way of prevention, many evils still crop out for treatment in the way of cure.

In no line of business does this appear more emphatically than in central station work, where electric currents are generated and supplied for various commercial purposes, requiring in some cases constant potential with varying current, and in other cases constant current with varying potential. To generate currents of just the kind needed and so prevent variation at the outset is one thing; and to correct variations as they occur is another thing. In practice we are compelled to work along both of these lines, and while the first is the most desirable to attain, yet we are compelled to resort to the second.

The all important factor in the preventive problem is constancy of speed at the generator, even under widely varying conditions of load. Accordingly, the most persistent efforts of steam engine designers have been for years devoted to this task of fine speed regulation, with results that are even better than could have been expected. The same is also true of water wheel governors, and we have in this line machines of marvelous ingenuity combining sensitiveness with power. And yet, as if to mock the efforts of these persistent workers who have really accomplished so much, electrical generators have the unhappy characteristic of exaggerating the faults of others, and while the variation of speed may not exceed two per cent., the resulting variation of voltage may be as high as four per cent.

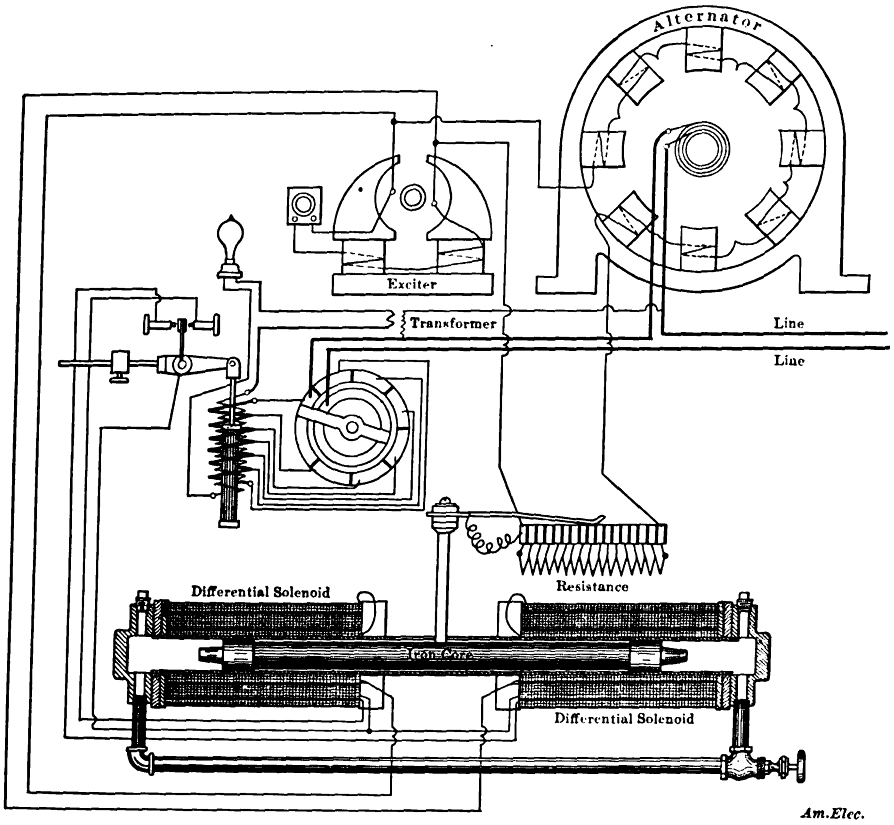
The variation of voltage in a generator due to changes of speed is not simply proportional to the speed, but is much more than that, and in some cases is more nearly as the square of the speed. To avoid the evil results of this law of rapid increase, generators sometimes have their field magnets excited by a dynamo driven from a separate and independent source of power. This, however, is not always convenient or even possible, as is shown by the usual practice of self excitation or excitation from a dynamo driven from the same line of shafting as the generator.

Variations of voltage due to armature reaction may be well taken care of by proper compound windings on the field magnets, yet the success of this presupposes a constant speed, and after all has been done that can possibly be done to prevent variation, there still remain a great many causes that can only be dealt with when their results begin to appear.

The one universal primitive way of meeting the necessity is a rheostat, a voltmeter, and a man to serve as a connecting link between the two. In most cases the man acts as a mere machine, and his duties could be performed better and with more uniformity by the substitution of a very simple form of regulator having a pair of platinum contacts in place of eyes, and magnetic force in place of muscular force. However, his duties are not always so simple, since he may have to take note of a multitude of feeders and mains, distributing centers and potential wires, and armeters as well as voltmeters, but in every case his final controlling action is performed at the rheostat, and by strict attention to business he may at the rheostat accomplish the regulation of the system in a very satisfactory manner. The action of the man from day to day and hour to hour, is, however, performed with a systematic regularity that convinces us that the most complicated systems of electrical generation and distribution may with great advantage be placed under automatic control, subject to the determination of the operator only as to what kind of regulation is applied to certain circuits at certain portions of the day.

The first requisite of a system of automatic regulation is a sensitive device to detect slight variations of voltage or of current, or of both at the same time, according as the basis of regulation is respectively constant potential at the station, or constant current, or constant potential at some given distant center of distribution. The device also must not only detect the variation, but must also be able, without interfering with its sensitiveness, to direct a power sufficiently great to operate a rheostat for the correction of the variation.

In such a device either one of two principles may be adopted—the expansive force of a hot wire or electromagnetic force. The hot wire principle has the advantage of great force of movement when contracting, but the disadvantage of involving a large time element, so that the corrective force is not applied instantly. Magnetic force, on the other hand, can be applied in a way to practically eliminate the element of time, and is, therefore, much more satisfactory. An arrangement, which in my experience has been very successful, is shown diagrammatically in the accompanying cut, and may be briefly described as follows:



Am.Elec.

DIAGRAM OF CONNECTIONS.

It consists of a solenoid having a fine winding for constant potential service, and a coarse winding for constant current service; a switch connected to the coarse winding serves to connect more or less of the convolutions of the coarse winding into the main circuit of the generator. The solenoid may be used on either direct or alternating current circuits. It has a laminated iron plunger or core supported by one arm of a lever, which has a counterbalancing weight at the other end, the counterbalancing weight being adjustable along the lever arm. The movement of the lever one way or the other from its normal position closes a pair of electrical contacts at one side or the other.

In operating such contacts where alternating current is used in the solenoid, it is found to be necesary to give the contact which is attached to the lever an elastic support. This may be done by mounting the platinum contact piece on one end of a short strip of thin spring brass, the other end of which is secured to the lever. When supported rigidly, the jar due to the alternations actually prevents the obtaining of an electrical connection at the contacts, even when the contact surfaces are apparently pressing hard together.

Having thus constructed a variation detector, we now need a connecting link between this and the rheostat, and here we require a uniform force of some considerable amount acting through a wide range, and one that can be controlled by the platinum contact points without undue sparking and burning. An ordinary magnet or solenoid large enough to do the work produces an induction spark at the contacts that is very formidable to deal with and actually forbids its use in practical work, but two differentially wound solenoids having a common core entirely overcome this difficulty.

Each solenoid has two windings, which are exactly alike, but connected in opposition to each other. Normally each solenoid has a current in only one of its two windings, and the iron core is, therefore, subjected to a magnetization by both solenoids and to two forces tending to pull it in opposite directions; but these forces balance each other and it remains at rest indifferently in any position where it happens to be. Now when the second coil in either solenoid is put in circuit by the contact points, the effect is to exactly neutralize the force of that solenoid and allow the other solenoid to move the core into itself; and when the circuit of the second coil is again broken at the contacts, there is no decrease in the magnetization of the iron core, but on the contrary a slight increase, and consequently there is no inductive spark.

It is really surprising to observe how effectually all spark can be removed from a set of contacts by this balancing of coils against each other; accordingly, the contact points are subjected to very slight wear, even though they may be controlling a large force. Of course, solenoids worked differentially and opposing one another, involve the expenditure of a double quantity of energy as compared with a simple solenoid, but it is perfectly feasible to operate the field rheostat of a 250-k.w. generator with a pair of differential solenoids, using only 42 watts of energy normally, and only 56 watts when moving the core. The question of watts wasted, is, therefore, trivial when compared with the immense advantage gained by a sparkless condition at the platinum contact points.

With any form of solenoid it is necessary to use some kind of retarding device, or it would move the rheostat too quick and cause racing. A most convenient and effective retarding device is obtained by mounting the two solenoids on a brass tube, inside of which the core is fitted as a piston. The tube is closed at each end and has a small pipe leading from one end to the other, with a hand valve in it. The tube and pipe are completely filled with oil or other liquid. The valve then serves as a means of adjusting the quickness of the movement, because the core can only move as it displaces the liquid in front of it.

Some electrical generators respond much more quickly than others to the movement of a field rheostat. Those with laminated fields respond quick, while those with massive solid fields respond slowly, and the question of quickness of regulation in every instance reduces to that of the quickness of response of the generator field, which may be one second and it may take several seconds. Alternators being usually constructed with laminated fields of comparatively small mass, are exceedingly susceptible to quick regulation and also to accurate regulation, by reason of the mechanical jar caused by the alternations in any coil through which they pass. The jar effectually removes the element of friction from pivots, and renders the variation detector exceedingly sensitive.

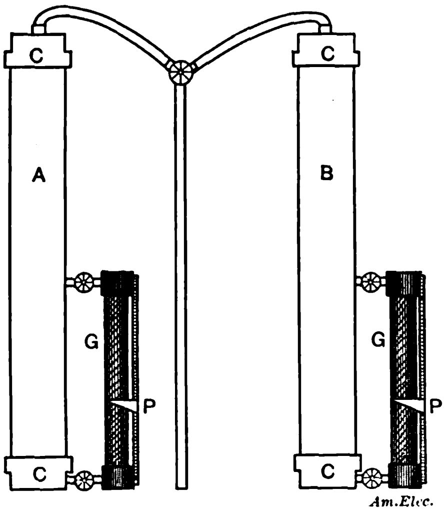
To render the detector solenoid free from temperature error it is important and feasible to put in circuit with it a resistance, which is a great many times as large as that of the solenoid itself, the resistance being made of material having a low temperature coefficient, like German silver, or else, one with a negative coefficient, like carbon, as the negative coefficient is favorable to sensitiveness.

In the case of alternating currents the resistance must be non-inductive, and the more there is of it the less liability there is of errors due to change of frequency, for change of frequency may easily prove a formidable source of error in plants subject to considerable speed variations, unless this matter of non-inductive resistance is carefully observed.

RELATIVE STEAM PIPE CONDENSATION TESTS.

BY REESE HUTCHISON.

While a student of the electrical and mechanical engineering course of the Alabama Polytechnic Institute, and following the suggestion of Prof. John J. Wilmore, professor of mechanical engineering, I made some tests to obtain the relative amount of steam condensation in two exactly similar iron pipes, except that one was highly polished and the other left rough.



STEAM CONNECTIONS.

Two 3-ft. 4-in. lengths of 2-in. iron pipe, A and B, were provided with caps, C. Each was provided with a 12-in. water glass gauge, G, having the customary valves for draining and cutting off from pressure. All joints were tight, and no loss of condensed steam was lost by leaks of any description.

Each pipe was clamped vertically in a vice and its water glass graduated to heights of water in the pipe, it being introduced in one fluid ounce quantities. One of the protecting rods of each glass was provided with a movable rider, the rod being marked at the successive heights of water in the glass. Before this graduation was started, each pipe was filled with water until the level was visible in the glasses. The amount and height in each pipe was the same.

When connected to the source of steam supply, all leading in pipes were inclined so as to allow any condensation in them to drain back from the test pipes.

A 5-h.p. test boiler, located in the foundry of the institute was used, a small auxiliary engine being run light to aid in pressure regulation. The steam passed to the test pipes through a 1-in. inclined pipe, and the test pipes were protected from draughts.

The steam pressure was kept constant at 100 pounds, it not varying ½ pound either way during the test. The height of water was also kept constant, thus rendering the steam practically of the same saturation in all tests.

As a preliminary, the pipes were "warmed up" by letting steam blow through the drain valve of each glass for at least twenty minutes. Then the bleed cocks were closed and water condensed to equal heights in the two pipes by means of a wet piece of waste. The test was begun by cutting off the glasses and allowing the steam to stand in the pipes for twenty minutes. Five tests were made for each condition, a mean being then taken. The rough pipe was provided with different qualities of commercial pipe covering, kindly furnished by the manufacturers mentioned below. More extensive experiments were prevented by the close of the scholastic year.

PIPE CONDENSATION TEST.

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.

Duration each test, minutes...	20	20	20	20	20	20
Mean steam pressure, lbs..... ..	100	100	100	100	100	100
Condensed steam, oz.:						
P'lish'd pipe	6½	6½	6¼	10.58	7	6¾
Rough pipe.	10⅛	4½	4¾	8.16	4.62	6.083
Ratio of condensation of rough to polished...	1:1.558	1:1.44	1.1.315	1:1.296	1:1.515	1:1.109

CONDITION OF PIPE TESTED.

No.	Condition Rough Pipe.	Material of Covering, etc.
1	Uncovered.	
2	Covered.	Asbestos Sponge Moulded Covering. Mfg. by H. W. Johns Mfg. Co.
3	Covered.	Firefelt Asbestos, Ditto.
4	Covered.	Not Branded—Philip Cary Mfg Co.
5	Covered.	Not Branded—Ditto.
6	Covered.	Cinders retained around pipe by iron jacket.

From these tests it might be inferred that the usual practice of equipping lubricators with polished water column pipes is against the scientific principles, as a rough pipe of shorter length would give similar results.

Electrical Journals.

To the Editor of American Electrician:

It is not quite correct to state, as does your corespondent John Horn, in your issue of April, that "the 'Telegrapher' was the pioneer journal" in the line of electrical or telegraphic information or news.

Edward Caldwell in your February issue is nearer the mark when he says it "was the first really successful paper in the United States devoted to the interests of the Electric Telegraph."

Exception may, however, be taken even to this statement, as it turns on the meaning and scope which each one of us may give to the word "successful."

The whole story of early American electrical journalism is told well, and with substantial accuracy, by James D. Reid in Chapter XLVII. of his "Telegraph in America," edition of 1879.

There, it is truly stated that three periodicals of this kind appeared before the "Telegrapher." The first of these was "The American Telegraph Magazine." A bound volume of this magazine is now before me, from which I learn that it was a monthly periodical, published in New York by Donald Mann; that Volume 1, No. 1, was published October, 1852; and that the last number, 6, having become a quarterly, asserts itself as being for April, May and June, 1853. Henry Brooks O'Rielly was supposed to be the editor, and the history of the magazine is told at length in the "Telegrapher," Volume 2, p. 75.

Next, came a quarterly, bearing the name of the "National Telegraph Review," edited by James D. Reid. It expired after four numbers had issued, forming a substantial volume of 400 pages. I have never been able to get hold of this, although I should like to; and so far as I can ascertain, there is but one copy now extant.

Then came a rather pretentious quarterly entitled "Shaffner's Telegraph Companion." Of this I have a copy. The first number is dated, January, 1854, and the last October, 1855.

These periodicals are all of great interest as preserving a record of facts and current news, of which otherwise there would be no account.

From 1855 to 1864, I believe no other attempt at telegraphic journalism was made. Then at a meeting of the National Telegraphic Union, an association of operators, the "Telegrapher" was founded. It became a good paper, was well run throughout, and existed until February 3, 1877. There are twelve volumes, all of which are in my business library.

It was the success of this paper which inspired some one behind Jerry Borst, to start the "Telegraphic Journal." As stated by your correspondents, everybody at that time believed the Western Union Company to be the inspiring influence in question. It was shortlived. Born March 7, 1867, and issuing weekly, it died in the arms of its friends in November of the same year.

From its ashes sprang the "Journal of the Telegraph," which from its incipiency was avowedly the organ and official instruction medium of the Western Union Telegraph Company. It was for many years a trustworthy and instructve journal of electrical events, and news; but with the advent of independent electrical journalism, and the widening field of electrical application, it gradually withdrew from its position as an electrical newspaper; retaining its functions as a tariff circular. I have also a complete file of this.

The "Operator" was started March 1, 1874, and has developed into the "Electrical World."

In conclusion I may say that it might be a good thing for that portion of the electrical public which interests itself in the historical side of the science, if Mr. Horn, your correspondent of April, would communicate with George C. Maynard of Washington, (who is Secretary of the Telegraphic Historical Society) with reference to his compilations regarding early telegraphic history; as that Society, I believe, wishes to get together, anything and everything it can, about the History of the American Telegraph.

Boston, Mass.

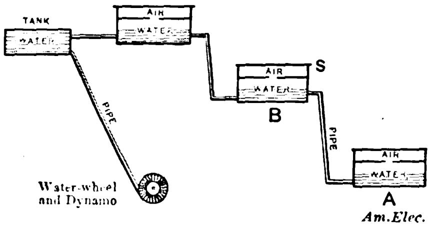
THOMAS D. LOCKWOOD.

A Sun Storage Battery.

To the Editor of American Electrician:

I have read the article entitled "Electricity," in the March issue, very carefully, and it seems to me to be in every way a most excellent one, and in marked contrast to the sensational and erroneous matter which has often been published under this heading. I concur entirely with the views expressed, and am glad occasion was taken to publish them, for the article will undoubtedly clear away the misconceptions which many have on this subject.

In one respect, however, I think a few words might have been said, i. e., in reference to the fact of the great trouble in handling chemicals for batteries, which make it appear to me that it would be preferable to attempt to use the sun's heat direct. As Langley has found, the sun radiates about 3 watts per sq. cm. per minute. Taking half of this we get 1,000,000 h.p. per sq. mile. Now, there are, even at present, means of utilizing a part of this. Take, for instance, a set of cells, shown in the accompanying sketch. W W are tanks of water, inclosed in glass roofed houses, like conservatories; S S are screens. First, open the screen of B, and close that of A. Let air in both. Then, open screen A and close the screen of B. The water will pass from A to B. If we assume the air in the glass roofed houses to reach a temperature of 50 deg. above the air, by painting its bottom and walls black, we may easily reach an efficiency of 5 per cent., the theoretical thermodynamic efficiency being about 15 per cent. Or, in other words, we might get about 50,000 h.p. per sq. mile in this crude way, which would have some slight advantages, as a pond of water at the top of a hill is the best kind of a storage battery, and more efficient than the forms now used, as 80 per cent of the power can be got back. I should be less surprised to see some plan like this used in certain cases, at first, than any other, though, of course, the above is only a very crude suggestion.



THERMAL STORAGE.

REGINALD A. FESSENDEN.

Allegheny, Pa.

Electricity.

To the Editor of American Electrician:

The article on "Electricity," which was printed in the March number of the "American Electrician," is admirable from many points of view. Among other timely things the author asserts that "electricity is popularly considered a mystery which has defied all the powers of science"; that "it is generally believed that marvelous developments await the answer to the question, What is electricity?"; that "the popular cry for a solution to the great mystery of electricity usually arises from the misconception that electricity is a substance, while in reality it is a mere word expressing nothing definite."

These assertions are true. And their truth emphasizes only the fact that the average electrical text-book is wofully inconsistent and misleading. The popular misconception that electricity is a "juice" is deplorable; but its existence will end only when students are no longer nursed on the nipple of the water-in-the-pipe bugaboo. As the writer stated in a serial on "Electrified Matter," which was begun in "Electricity" July, 1897, the real import of the terms volt, ampere and ohm is much more comprehensible when thus expressed:

Volt—Unit of effort to electrify.

Ampere—Unit of degree of electrification.

Ohm—Unit of persistency to remain unelectrified.

When we electrify a body we excite a conditional change therein; namely, we impair the cohesion of its molecules. The impairment of cohesion is induced by the impairing effort of the poles in contact with the body; the degree to which the cohesion is impaired by a given effort is dependent upon the resistance of the body, which consists of the persistency of its molecules to maintain their normal degree of compaction. Hence,

$$\text{Degree} = \frac{\text{Effort}}{\text{Resistance}}$$

Why should we labor over current when there is no current, over pressure when there is no pressure, or over the resistance to the passage of something when nothing is passing? The terms of electrical expression may be thought immaterial by some persons who understand the subject —and the subject is very much more understood than is popularly supposed. But Dean Alford's motto, "Call a spade a spade, not a well-known oblong instrument of manual industry," is a good thing for us to memorize.

HARVEY L. TYLER.

Corning, N. Y.

LIBRARY

ANNUAL REPORT OF THE GENERAL ELECTRIC COMPANY.

The following is an abstract of the eighth annual report of the General Electric Company, which was received too late for inclusion in the body of the paper:

PRESIDENT'S REPORT.

Schenectady, N. Y., April 25, 1898.

To the Stockholders of the General Electric Company:

The past year witnessed a revival in business which increased rapidly in activity and volume during its latter months. In the last annual report attention was called to the fact that your company began the year with less orders on hand than previous seasons. As a result of this the actual output of your work has been slightly smaller than in previous years, although the orders received during the period have shown a marked increase. This increase will be reflected in the shipments of the ensuing year.

A careful scrutiny of the assets of your company, other than its patents, leads to the belief that previous values were conservatively fixed and no changes of any significance have been necessary. The patent account of the company has been kept at substantially the same amount on its books since the organization of the company. The question of a revaluation of patents is one to which consideration should be given at the proper time.

The business of the year, given in detail elsewhere, has resulted in a reduction of the deficit of previous years by $1,231,852.37.

In addition to the purchase of $2,000,000 of debentures referred to in previous annual reports, your company has purchased during the year just ended $2,000,000, and the entire $4,000,000 have been destroyed. Since the books were closed $290,000 additional have been acquired and are now held in the treasury of the company. An increase is shown in the amount received from interest and dividends from securities owned. It is expected that the income from this source will still further increase from year to year, unless considerable sales of such securities should be made by the company.

The growth of your business has made it necessary to make further expenditures for additions and changes at your factories and in acquiring much additional machinery. Plans have been prepared and contracts partially closed for a new foundry and a large and important machine shop, the largest buildings yet erected by your company. In anticipation of the investment in the construction and equipment of these new shops, which it is estimated will cost about $500,000, the sum of $250,000 has been deducted from the profits of the past year and carried to the factory reserve account. It has been the practice of the company to write off the amounts expended for additional factory facilities. It is thought that these allowances are not more than are required to properly provide for depreciation in all your factory plants taken as a whole.

At the annual meeting of the stockholders, held four years ago, the question of reducing the company's share capital in the manner prescribed by law was referred to the directors. Since that time the matter has had the earnest attention of your board, and it is their hope that a plan will be submitted for your consideration at an early date, designed to provide for a suitable reduction of the share capital of the company, with a view to the resumption of dividends.

The patent situation has not materially changed since the last report to the stockholders. The company has secured many important patents during the year, by inventions of its engineers and experts and by purchase.

One of the Van Depoele trolley patents which had been uniformly sustained by the courts up to last summer has been adversely passed upon by the Court of Appeals for the Second Circuit. This decision was on a motion for preliminary injunction and is not final. The invention was an important contribution to the electric railway art, and no court has questioned its great merit. There is reason to believe that the technical objections to the claims of the patent, upon which was based the decision of the Appellate Court over-ruling that of the Circuit Court in favor of the patent, will be found upon full consideration at final hearing to be insufficient to defeat the patent. In view of the fact that nearly all of the railway companies in the country that would be likely to use the overhead trolley system are now electrically equipped, and that the third rail and underground conduit methods are being rapidly adopted for the important new enterprises, an adverse decision in this case will have but slight effect upon the business of your company. Many other cases based upon patented inventions of great value, including a number on the overhead trolley system, are being pressed against infringers, in which early and, it is believed, favorable decisions are expected.

Your directors desire to express their appreciation of the valuable service of your admiable engineering and commercial staff, as a result of whose ingenuity and vigilance the company has more than maintained its position of pre-eminence in the varied and constantly increasing applications of electricity.

By order of the Board of Directors.

C. A. COFFIN, President.

FIRST VICE-PRESIDENT'S REPORT.

Schenectady, N. Y., April 19, 1898.

C. A. Coffin, Esq., President:

I submit herewith a condensed report of the operations of the Sales Department for the fiscal year ending January 31, 1898:

Total sales (amount billed to customers)	$12,396,093
Cost of goods sold, general expenses and taxes, including sundry losses and allowances for losses	10,896,578
Profit on sales	$1,499,515

From this profit should be deducted debenture interest, etc., as shown in the report of the second vice-president.

I stated in my last report that "the orders actually booked in 1896 were considerably less than the orders secured in 1895." As a result, we entered upon the last fiscal year with less unfilled orders on hand than usual. Our orders during the first six months of the year were far from satisfactory; the second six months showed a very marked increase in orders, and as we were not able to increase our output to such an extent as to fill these orders within the limits of the fiscal year, we enter upon the present year with a larger list of unfilled orders on hand than ever before. "Sales" include the total billed amounts for goods actually shipped. "Orders" include business secured, and become sales only when the material is shipped and billed. Our sales for 1897 are somewhat less than our sales for the previous year, while our orders are considerably in excess of the orders secured in 1896. The following figures are based on orders secured and not on sales:

Lighting Department.—We have received during the past year orders for 60,826 k.w. capacity of arc and incandescent lighting machines as against orders for the year 1896 of 57,476 k.w. capacity, an increase of 5.8 per cent. Among the important lighting contracts secured during the year may be noted the equipment for the new station of the Brooklyn Edison Company and the equipment for the new station of the Boston Electric Light Company.

Railway Department.—Orders received (money value) for railway apparatus has shown an increase of 33⅓ per cent over 1896. Orders for railway generators aggregated over 60,000 k.w. The average size of the railway motor has increased to 34.7 h.p., while the average railway generator for 1897 was 484.3 h.p., as against 356.3 h.p. in 1896.

Among the important railway contracts secured during the year may be noted, the equipment of the Metropolitan Street Railway of New York City, the large motor order for the additional service of the Boston Elevated Railway (Lessees of the West End Street Railway), and the contract for the substitution of electric traction for cable traction on the entire system of the Capital Traction Company, of Washington, D. C. The development of interurban electric railway service has been a marked characteristic of the past year. This is well illustrated in the Cleveland & Lorain, the Akron, Bedford & Cleveland, and the Cleveland & Eastern Roads, each of which is equipped with powerful motors operated at speeds up to, and at times exceeding, 60 miles per hour.

Power and Mining Department.—The growth of business in the class of electrical apparatus handled by this department is strikingly shown by the following comparison of orders received for various years past:

Orders for 1893 were 36 per cent in excess of orders for 1892
" " 1894 " 126 " " " 1893
" " 1895 " 10 " " " 1894
" " 1896 " 60 " " " 1895
" " 1897 " 60 " " " 1896

Orders for direct current and induction motors aggregated

19.531 h.p., as against 15,171 h.p. in 1896. Orders for multiphase generators aggregated 49,902 h.p., as against 25,007 h.p. in 1896. Total transmission lines installed in connection with GE apparatus aggregated 326 miles, as against 232 miles in 1896.

Supply Department.—The supply department has handled 114,229 separate orders during the year, or 43 for each working hour. The "orders received" in 1897 exceeded by 20 per cent those of 1896. The supply stocks carried at our local offices have been decreased about 7 per cent during the year, and of the present total 90 per cent consists of active supplies, a great improvement over previous years.

The following are some of the principal articles handled by the supply department:

Wattmeters.—Total number ordered during the year, 36,874, an increase of 42 per cent over 1896.

Measuring Instruments.—Total number ordered during the year, 3369, an increase of 38 per cent over 1896.

Transformers.—Total number ordered during the year, 11,499, an increase of 36 per cent over 1896.

Arc Lamps.—Total number ordered during the year, 24,158, an increase of 75 per cent over 1896.

Sockets and Receptacles.—Total number ordered during the year, 2,357,629, an increase of 36 per cent over 1896.

Foreign Department.—The orders of the Foreign Department have shown a gratifying increase over the orders for 1896. Several notable contracts have been placed with us by our foreign companies—the equipment of the Central London Underground Railway, and the equipment of the street railways in several European cities.

Incandescent Lamp Sales.—The incandescent lamp orders for the year aggregated 6,857,239, of which 6,706,624 were shipped. This is an increase of about 10 per cent over the year 1896.

The success of the sales department is, in a great measure, due to the administrative ability and untiring energy of the department managers, and I desire to particularly commend their good work to your notice. Respectfully submitted,

EUGENE GRIFFIN, First Vice-President.

THIRD VICE PRESIDENT'S REPORT.

C. A. Coffin, Esq., President:

I submit herewith a report on manufacturing and engineering for the fiscal year ending January 31, 1898:

Our increased business in foreign countries has disclosed the fact that in design, cost and efficiency our machinery compares most favorably with that of European manufacturers. Valuable data, drawings, patterns and tools, necessitated by the large amount of special apparatus which we have successfully designed and manufactured in the past, are now frequently available in the construction of new apparatus, thus reducing the cost of developing such apparatus.

Engineering.—The number of undertakings requiring machinery of large capacity and special design has increased materially during the past year. This has been due largely to the application of electricity to the operation of underground, suburban and interurban railroads, and also to the concentration of power in large units due to the demonstrated economy of our three-phase machinery and the rotary converter mentioned in previous reports. A most notable and important installation is that of the underground Central London Railway, which we are equipping with three-phase generators, rotary converters and thirty-two large electric locomotives. Another remarkable undertaking is that of the mammoth new station of the Metropolitan Street Railway Company, of New York. From this station enormous electric generators will operate, through the medium of rotary converters and other machinery of our design and manufacture, the electric street cars throughout nearly the entire Borough of Manhattan.

In my last report I called attention to the value of our rotary converter, a species of connecting link between the alternating and continuous current systems which enables existing continuous current plants to add the advantage of alternating current generation and economical transmission to the simplicity and effectiveness of the continuous current distribution. The economies which thus result from the substitution of a single large alternating current power station for a number of small stations is well illustrated in a notable installation of such apparatus made during the past year by the Brooklyn Edison Company, using our three-phase generators, rotary converters, synchronous motors and other appliances.

The number of long distance transmission plants has greatly increased during the past year, so that we have now a total generating capacity in such plants of over 100,000 h.p., and among these some twenty installations are operating at potentials of over 10,000 volts and transmitting a total of some 50,000 h.p. to distances varying from ten to forty miles. The 5000 h.p. plant at Ogden, Utah, has been in operation for nearly a year, transmitting power to Salt Lake City, a distance of 36½ miles, at a potential of 16,000 volts. We have now under construction apparatus intended for the transmission of over 4000 h.p. from a distant water power 80 miles to the city of Los Angeles, Cal., at a pressure of 33,000 volts. The St. Anthony Falls plant, mentioned in my last report, has been completed and is now in regular operation, furnishing power to the street railways of Minneapolis and St. Paul, Minn. In the city of New Orleans, La., we shall soon have in operation a novel plant of some 4000 h.p., which will be used to operate pumps for the drainage of the city. Three-phase machinery will be employed. The driving of all machinery in cotton mills and factories by electric motors is increasing rapidly, even where the original source of power is a steam engine located in or near the mill or factory itself. The United States Navy is adopting the electric drive in place of steam or hydraulic machinery for ventilating, pumping and hoisting on shipboard and for lowering and elevating guns and for turning turrets on the warships. This is in addition to the recognized use of electricity for lighting and small power work.

We shall soon be operating our Schenectady works from a distant water power. We have contracted for a supply of 2000 h.p. from the Falls of the Hudson River at Mechanicsville, 10 miles from Schenectady. A novel feature of this transmission is that the generators, each of 1000 h.p., have been constructed by us to produce directly a pressure of 12,000 volts, thus saving the cost of the usual intermediate step-up transformers.

Our older transmission plants, such as Portland, Ore., and Fresno, Cal., operated with great success and have largely increased their capacity, demonstrating the advantages of our system and apparatus in the electrical utilization of water powers. There has been a great improvement in the efficiency and quality of our numerous small articles of manufacture, such as arc lamps, transformers, meters, switchboards, etc., many features of novelty and value having been developed by our engineers. Our business in this line has shown a gratifying increase. We have continued to protect our new and important engineering designs as far as possible by application for letters patent.

The efficient work of the factory managers and the unequaled ingenuity, skill and industry of our engineers, are worthy of special commendation. Respectfully submitted,

E. W. RICE, Jr., Third Vice-President.

SECOND VICE-PRESIDENT'S REPORT.

From the report of Second Vice-President J. P. Ord the following figures are taken and comparison made with reports of previous years:

CONSOLIDATED BALANCE SHEET.

Dated Jan. 31.	1895.	1896.	1897.	1898.
ASSETS.				
Patents and franchises	$12,059,263	$8,000,000	$8,000,000	$8,000,000
Factory plants		3,468,002	3,400,002	3,400,002
Real estate (other than factory plants)	423,787	453,585	643,016	586,529
Stocks and bonds	5,329,011	5,479,332	8,545,796	7,455,873
Notes and accounts receivable	5,508,499	6,584,123	4,578,601	4,537,301
Work in progress	846,291	961,386	517,866	283,832
Inventories	3,913,787	4,219,884	4,034,753	3,860,553
Cash	404,236	879,656	703,484	1,425,875
Miscellaneous, including Ft. Wayne Claims	1,176,666			
Profit and loss	14,294,717	13,917,071	12,957,413	11,725,561
Totals	$43,956,257	$43,963,069	$43,380,931	$41,275,526
LIABILITIES.				
Capital stock, common	$30,460,000	$30,460,000	$30,460,000	$30,460,000
Capital stock, preferred	4,252,000	4,252,000	4,252,000	4,252,000
5 p. c. gold coupon debentures	8,750,000	8,750,000	8,000,000	6,000,000
Accrued interest on debentures	72,917	72,916	66,666	50,000
Accounts payable	421,341	428,153	402,265	263,526
Mortgages			200,000	
Reserve for extension to factory plants				250,000
Totals	$43,956,257	$43,963,069	$43,380,931	$41,275,526

CONSOLIDATED PROFIT AND LOSS ACCOUNT.

Years ending Jan. 31.	1896.	1897.	1898.
EARNINGS.			
Sales	$12,730,058	$12,540,934	$12,396,093
Royalties and sundry profits	585,609	279,402	128,845
Interest and discount	100,784	88,336	90,371
Dividends and interest on securities owned	320,257	282,144	299,418
Profit on sales of stocks, bonds		79,817	116,356
Discount on debentures purchased and canceled		57,139	14,015
Balance forward	13,917,071	12,957,413	11,725,561

Totals	$27,653,779	$26,285,245	$24,770,660

NOTES.

The Van Depoele Trolley Patent.—The U. S. Circuit Court of Appeals, Second District, has declared invalid the two claims of the celebrated Van Depoele under-running trolley patent, which had survived previous litigation, thus bringing to a close the most important episode in electric railway patent litigation. The patent contains sixteen claims, and the final ones annulled relate to the pivoted trolley arm, movable on both a vertical and a transverse axis. The grounds upon which the decision was based were that the two claims at issue are for the same combinations specified in some of the claims which have been declared void. The owners of the patent state that they will push the case to final hearing, the present decision having been made under proceedings for a preliminary injunction.

The Electrical Exhibition.—The New York Electrical Exhibition, which will have opened its doors by the time this issue reaches many of our subscribers, gives every promise of securing a success highly creditable to the industry represented. The special features arranged for are so numerous that their mere mention would require more space than is at our disposal, and it is perhaps sufficient to say that a visitor to the exhibition will find, aside from the trade exhibition, enough to keep his attention occupied for hours. One of the latest features arranged for is a series of eight tableaux designed to mark the more important successive stages of early electrical development. The tableaux have been executed and arranged by the Eden Musee Company under the direction of Dr. Park Benjamin and Prof. F. B. Crocker, and will include scenes including Gilbert, Stephen Grey, Benjamin Franklin and others. A complete model exhibit will be made of the Edison magnetic iron ore separation process, together with samples of material in its various stages. In the instrument department Dr. Shelden will have a loan exhibit of electrical standards, including some from the German Reichsanstaldt.

Charges for Electric Power.—The Cataract Power and Conduit Company, of Buffalo, which will distribute Niagara power in that city, has established the following rates for power service: First, a "service charge" of $1.00 per k.w. on the amount of power which the user may require the company to keep available and ready for use—this amount corresponding to the "maximum demand" of the Wright system of charge. Second, a "power charge," depending upon the actual amount of power used, as determined by meter. This charge per k.w.-hour is as follows: Not exceeding 1000 units, 2 cents per unit; exceeding 1000 units, but not exceeding 2000 units: for 1000 units 2 cents per unit, and for the excess 1.5 cents per unit. Exceeding 2000 units, but not exceeding 3000 units: for 2000 units 1.5 cents per unit, and for the excess 1.2 cents per unit. Exceeding 3000 units, but not exceeding 5000 units: for 3000 units 1.2 cents per unit, and for the excess 1 cent per unit. Exceeding 5000 units, but not exceeding 10,000 units: for 5000 units 1 cent per unit, and for the excess .8 cent per unit; exceeding 10,000 units, but not exceeding 20,000 units: for 10,000 units .8 cent per unit, and for the excess .75 cent per unit. Exceeding 20,000 units, but not exceeding 40,000 units: for 20,000 units .75 cent per unit, and for the excess .7 cent per unit. Exceeding 40,000 units, but not exceeding 80,000 units: for 40,000 units .7 cent per unit, and for the excess .66 cent per unit. Exceeding 80,000 units: for 80,000 units .66 cent per unit, and for the excess .64 cent per unit.

Philadelphia Electrical Exhibition.—Besides the other many special features of the Philadelphia Electrical Exhibition, arrangements are being made whereby the most attractive features of the New York exhibition will be transferred to Philadelphia, the exhibition there opening at the conclusion of the one in New York. Special arrangements have been made for the elaborate decoration of the building, and the managers hope in this respect to surpass anything that has yet been done. An electrical cataract is almost completed, which is a reproduction of one used with great success at the Opera Ball in Paris. Among the attractions will be the kinetoscope, the cinematograph, and an X-ray apparatus, which will be constantly in operation in connection with a screen. An electrical fountain, with kaleidoscopic effects produced by rapidly moving lights, is now being built. Arrangements are being effected for the use of large quantities of decorative foliage plants in connection with electric lights. Phonographic speeches have been secured from distinguished inventors and electricians, and these will be reproduced at regular intervals. The exhibition will open on June 6.

Treatment for Electrical Burns.—The New York "Medical Journal," in a recent issue, printed an account of the treatment of a severe case of electrical burn, which we reprint below. Through the kindness of Mr. S. A. Rickard, of Saratoga Springs, New York, we are enabled to add two illustrations, showing the condition of the patient before and after treatment. Following is the account of the case, as furnished to our medical contemporary by Dr. J. F. Weathers, of New Albany, Ind.: An electrician employed in the electric plant used to furnish power to the city street-car line and to the arc and incandescent lights for the city accidentally brought his back in contact with the positive and negative keys of the switchboard of arc line furnishing ninety-six street lamps and carrying 4000 volts of electricity. He became impaled, so to speak, on those keys, until he was released by the tissues being burnt away in two pits about 3 ins. in diameter and down to the bony structures. The intervening space between these pits, which were 10 ins. apart, was roasted, and after the lapse of a few weeks was lifted out. It weighed 2½ lbs. I was called to see him immediately after the accident, which was on April 12, 1897. I applied linseed oil and limewater, equal parts, pouring the charred cavities full and covering them over with absorbent cotton. I kept this up some days. I administered opiates to relieve pain, which was quite severe. The sloughing was something awful; the cotton, bandages, clothing and bed were saturated in pus. I turned my attention to some dry dressing, and first used boric acid and bismuth subnitrate, but this produced too much pain. I then tried the antiseptic known as vitogen, sprinkling the powder lightly over the surface, and over all a cloth saturated with linseed oil was laid. The effect was marked; quietude and sleep followed without the administration of an opiate. This dressing was repeated generally twice a day for many days, and one remarkable feature is that I saw no more pus, and on undressing the wound there was visible no vitogen powder. This treatment was never departed from until September 1st, when the patient was discharged. I used 18 ozs. This man withstood 4000 volts, as all the arc lamps were extinguished for the time.

The Electrical Exhibition.

The electrical exhibition which opens May 2 in Madison Square Garden, New York, promises to be by far the best electrical show yet presented to the public, both electrical and non-electrical. Aside from the commercial exhibits, the former will find many special features of interest, including models of the open conduit electric railway system adopted in New York and Washington, the third rail system in use on several New England roads, the Sprague multiple unit system, a working exhibit of the Marconi wireless telegraph, etc. The educational features for the general public are particularly numerous and well conceived, in this respect the exhibition performing a worthy work in the better interest of the electrical industry.

Heat Storage.

In another column will be found an interesting letter from Prof. R. A. Fessenden on heat storage, which points out one method whereby in the far future the heat of the sun may be stored for final transmission into electrical energy. In this connection it may be remarked that Ericsson spent the latter years of his life working on the problem of the industrial utilization of the heat of the sun directly, having in view, he said, not present needs, but the time some centuries hence when the world's supply of fuel shall be exhausted. The method suggested by Prof. Fessenden has a present interest as an illustration of a simple transformation of the energy heat into work.

The War.

Warfare, besides its beneficial effects in stimulating, when waged in a good cause, the nobler nature of a people, has also in these days when every branch of engineering is represented in the art of war, its technical lesons to teach. Next to contractors, yellow journalists and jingo politicians—though in not so selfish a relation—electricity has the most promise of material benefit from the war now upon us, for one of the lessons that will undoubtedly be taught in naval action is the desirability of further extensions of electrical power aboard ship. A few auxiliary steam pipes severed by shot will involve an object lesson not to be passed by; and the monstrous ventilating systems installed on some ships, with their conduits of a square foot or more sectional area and passing through water-tight bulkheads, may lead to disaster in case of the flooding of a compartment that will bring about a full recognition of the advantage of an electrical blower service. An impetus will also be given to electrical signalling without wires, at least one promising system of which has already been submitted to war officials. It is also gratifying to electricians to know that one of the most powerful defensive means on a modern warship is the electric searchlight, without which night would be a time of terror aboard a naval vessel, comparatively defenceless as she would be against torpedo attack.

Condenser Action and Synchronous Motors.

When the transmission of power first began to assume importance, it was thought that line inductance would be a serious factor, owing to the loss of voltage through inductive drop. Happily it has been discovered that where synchronous motors can be used, this drop may not only be nullified, but also ohmic drop and, in fact, that the voltage at any desired point may be regulated within considerable limits independently of the generator voltage. Since the rotary converter, as usually designed, is a synchronous motor with respect to the alternating current line side, this method of regulation has a wide field of application. While a complete explanation of the principles involved would be difficult to give in simple terms, the understanding of the action is easy if it is borne in mind, first, that a condenser current leads the impressed e.m.f., and, second, that in connection with an inductance a condenser may act as a step-up transformer.

In a synchronous motor circuit there are three e.m.fs.—the impressed e.m.f., a motor counter e.m.f., and an e.m.f., due to the inductance of the armature, and the current flowing will be a resultant of these three factors. Now, if such a motor is so designed that the resultant of these e.m.fs., and, consequently, the current, will lead the line e.m.f., then the motor will be analogous to a condenser in circuit. The field of a synchronous motor is maintained by a direct current taken from a source independent of the source of the armature current, or, in the case of a rotary converter, from the commutator circuit, and in either case its value may be regulated at will. On the other hand, the armature of the motor must run at a speed fixed by the frequency of the alternating current line. We thus see that the counter e.m.f. factor can be regulated at will, and it happens that for a given load (or any smaller load) it may be varied between wide limits without affecting the working of a machine. It has been shown by Steinmetz in "Alternating Current Phenomena" that with a field excitation having a certain relation to the impressed and inductive e.m.f., a synchronous motor may be made to take a current having a definite lead over the impressed e.m.f. That is, such motors may be designed so as to have a condenser effect and thus be capable of regulating the line e.m.f. entirely independent of the generator.

In the following article it is shown how a condenser in series with an inductance may act as a step-up transformer. In the case here considered, the inductance may be that of the line between the generator and motor, in which case the latter, if so designed, will raise the voltage at a point immediately on the other side to an equality with the generator voltage. Or, by placing an additional inductance in the generator side of the line, the voltage beyond the motor can, with a proper design of the latter, be raised to compensate also for the ohmic drop, or even to a voltage above the generator voltage. Moreover, by varying the motor field excitation, the amount of the voltage increase may be varied within limits. In the case of the plant at St. Anthony's Falls, a description of which appears elsewhere in this issue, the line voltage is thus over-compounded by means of inductances in connection with rotary converters.

Inductance and Capacity.

Were it possible to make condensers as reliable as, say, transformers, an entirely new field and a most interesting one would be opened up in alternating current working. While experience with condensers in commercial working has hitherto been unsatisfactory, one would be rash indeed to assert that the defects they have developed cannot be overcome. Thus far what work has been done in the attempt to adapt the apparatus to alternating current working appears to have closely followed old lines of construction, and owing possibly to the supposed recondite nature of capacity phenomena, the subject has received but little attention from the professional inventor. There is scarcely any branch of alternating current working in which the condenser could not be commercially applied with benefit, and it is to be hoped that its commercial perfection will soon receive the attention that its importance warrants, and which in the past it has not received.

To appreciate the role of the condensers in alternating current working, the relation between inductance and capacity must be understood. Whenever an alternating current flows in a circuit, a counter e.m.f. is set up, due to the cutting in and out of the circuit of the lines of force corresponding to the successive values which the current assumes. As the current varies in value the number of lines due to it also varies, so that at one instant the circuit will contain more or less lines than at the preceding or succeeding instant, the resultant effect during an entire cycle being the generation of an e.m.f. counter to the impressed e.m.f. The case may, in fact, be considered exactly analogous to that of the generation of counter e.m.f. in the armature of a constant current motor. In each case an e.m.f. is generated by the cutting of a conductor by lines of force—the conductor being movable and the lines fixed in that of the motor, and the conductor fixed and the lines movable in that of the alternating current circuit. We here speak of the resultant effect, for whereas while the current is increasing the inductive e.m.f. is counter to the impressed e.m.f., when decreasing it is the same direction. Were there no difference in phase between the impressed and inductive e.m.f., what would be lost in one part of the cycle would be gained in the other, and no counter e.m.f. would result. It can, however, be very simply shown, first, that the inductive e.m.f. must differ in phase from the impressed e.m.f., and, second, that this difference gives rise to a resultant opposing the impressed e.m.f., but this will here be taken as granted.

The action of a condenser in an alternating current circuit might also be explained with reference to lines of force, but it is perhaps simpler to view it from another standpoint—the capacity of a condenser for absorbing current when the difference of potential is raised between its terminals, and discharging current when this difference is lowered. For example, as the e.m.f of an alternating current containing a condenser is increased, the difference of potential between the condenser terminals is also increased, and a charge flows into it corresponding to its capacity, the frequency and the change in potential. Now, this charge is in the same direction as the main current, and consequently is equivalent to the introduction into the circuit of an e.m.f. in the same direction as the impressed e.m.f., and corresponding in value to the condenser current thus set up; on the other hand, when the circuit e.m.f. decreases, a current is discharged into the circuit against the main current, which is equivalent to the introduction of an e.m.f. opposing the fall of impressed e.m.f., and corresponding in value to the condenser current. As, however, the impressed and condenser e.m.f. differ in phase, the resultant effect during an entire cycle will be, as in the case of an inductance, an e.m.f. opposing the impressed e.m.f., its value depending upon the capacity of the condenser for a given frequency.

From the above it will be seen that while with a rising e.m.f. an inductive e.m.f. opposes the impressed e.m.f., a capacity e.m.f., on the contrary, acts in the same direction; and that with a falling e.m.f., while the inductive e.m.f. acts in the same direction as the impressed e.m.f., a capacity e.m.f. acts in the opposite direction. If this relation is borne in mind, every application of the condenser in alternating current working may be clearly understood.

For example, suppose we take for illustration the case of a choke coil placed between the mains of a 100-volt constant potential circuit. Furthermore, assume that the ohmic drop due to the current passing is relatively negligible and that the current flowing through the coil is 2 amps. If now we place in series with the coil a condenser, since the e.m.f. set up in the latter is, with both a rising and falling current, opposite to that set up in an inductance, part of the inductive e.m.f. will be nullified, and consequently more current will flow through the circuit, say 4 amps. But as the inductive e.m.f. between the terminals of the coils varies directly with the current flowing through it, this will have become 200 volts, or double that of the circuit. Suppose now that a condenser is chosen of such a capacity that for the same current flowing through both the condenser and coil, the inductive e.m.f. will equal the capacity e.m.f. Then when placed in series, the e.m.f. of one will nullify that of the other, and the current flowing will be that corresponding to the ohmic resistance alone. If this is 1 ohm in the above case, the current will be 100 amps., and consequently the e.m.f. between the terminals of either the condenser or choke coil will be nearly 5000 volts, though that of the circuit is but 100 volts. If there were no resistance in circuit, the current and both the inductive and capacity e.m.fs. would be infinite, or the circuit would be a so-called resonant circuit—though why this particular name should be given is not clear, since it is merely made a short circuit through the reactance being reduced to zero.

From what precedes it will be seen that by the use of a condenser of proper capacity in series with an alternating current motor, the inductance of the latter may be nullified so that to the passage of an alternating current no more resistance will be opposed than if it were a direct current; and it can be shown that the same effect will be produced by inserting a condenser in parallel with the motor. Similarly, a condenser may be used in connection with an inductance as a step-up transformer. If placed in an alternating current line, the inductive drop may be nullified, or both the inductive and ohmic drop, or even the voltage at the end of the line raised above the generator voltage. Where concentric conductors are used this latter effect, in fact, may occur through the high capacity due to such an arrangement of conductors. Another interesting application of condensers and inductances, following to the principles herein explained, will be found on page 222.

A UNIVERSAL MOTOR AND DYNAMO.

The majority of amateurs and experimenters are so situated that they are unable to command a supply of both alternating and direct current, and many of them have neither at hand. It is principally for the benefit of those who are so circumstanced that the little machine described here was designed, since it seems to combine in a small compass ability to serve most of the purposes of the experimenter, and, at the same time, requires no great mechanical skill for its construction. Its cost, especially when most of the work upon it is done by the owner, should be very small considering its usefulness and capacity.

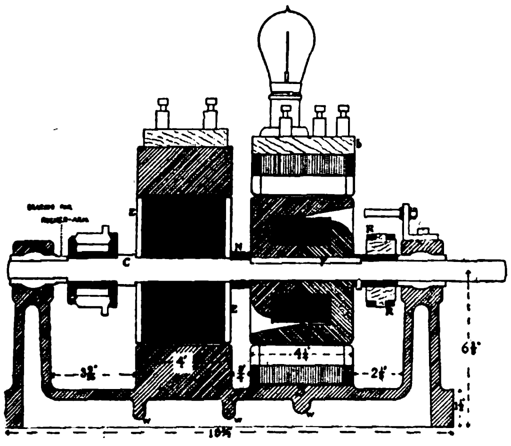

FIG. 1.—LONGITUDINAL CROSS SECTION—WINDINGS NOT SHOWN.

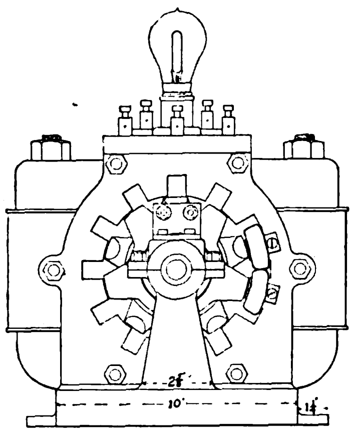

FIG. 2.—ELEVATION OF ALTERNATOR END—TWO COILS OF A. C. ARMATURE SHOWN IN PLACE.

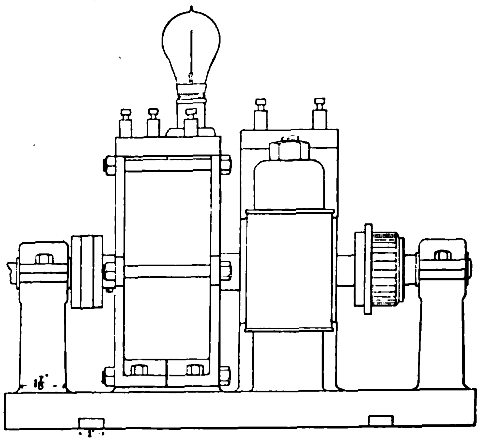

FIG. 3.—SIDE ELEVATION—D. C. BRUSHES, A. C. AND D. C. ARMATURE WINDINGS AND COLLECTING BRUSHES NOT SHOWN.

The machine consists of a small alternator and a direct current motor or dynamo of equivalent dimensions, coupled together and furnished with a pulley for applying or withdrawing power. With the dimensions and windings here given it can be put to the following different uses:

1. Direct current 110-volt 1-h.p. motor.

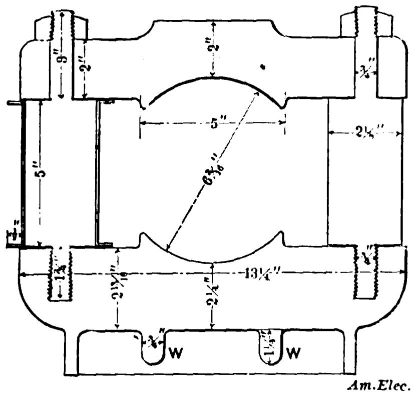

FIG. 4.—CROSS SECTION OF FIELD D. C. PART, SHOWING ONE SPOOL IN PLACE.

2. Direct current dynamo, giving 110 volts and 8 amps.

3. Motor dynamo, taking 100 volts and 10.8 amps. direct current and giving 110 volts and 6 amps. (single-phase) alternating current at 7200 cycles per second.

4. Alternating current, self-excited generator, giving 110 volts and 6 amps. (single-phase) at 7200 cycles per second.

5. Synchronous motor, giving about ¾ h.p. at 1200 r.p.m. with proper single, two or three phase alternating current supply.

6. Motor dynamo, taking alternating current and giving direct current at 110 volts.

7. Double-ended dynamo, giving at the same time both alternating and direct currents.

8. As generator, synchronous motor, motor dynamo in either sense, or double-ended generator, giving or taking two-phase or three-phase alternating currents.

Its construction is clearly indicated by the accompanying engravings. Fig. 1 is a longitudinal cross-section, Fig. 3 is a side elevation and Fig. 2 an elevation of the alternator end.

The base casting carries the two pedestals for the bearings and the lower yoke of the direct current end. Its design may, of course, be modified to suit the taste of the maker, but that given in the illustrations is simple and strong, and easy to cast. It would be better on some accounts to make the pedestals carrying the bearings separable from the bed casting, but this would involve planing four surfaces, boring and tapping eight holes and considerable care in the fitting and alignment of the parts, so that the pedestals are shown, for the sake of simplicity, cast integral with the bed. The webs W W (Figs. 1 and 4) should run entirely across and lengthwise of the bed, respectively, serving to stiffen it and to avoid any deformation due to unequal cooling in the mould. The hollow pedestals might, with advantage, be closed at their bases and provided with small drain-cocks, so that the oil used in the bearings, after passing through them, may collect and be used again. The surface S (Fig. 1), upon which the stationary alternator armature rests, should be cast about ⅛ in. higher than it is to finish, and planed off to a proper height for lining up the machine when it is assembled, as will be described below.

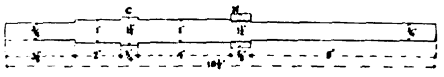

FIG. 5.—THE SHAFT.

The bearings may be of any convenient form, that shown being a simple self-lining variety, the brass bushing carrying a spherical central part fitting in seats milled, or coned with the point of a large twist-drill, in the pedestals and the covers. The bushing at the commutator end is made ½ in. longer than the other, and turned down, as shown, to form a bearing for the brush-holder rocker arm. This should be straight and may be of any convenient design, as may also the brush-holders. Copper leaf brushes should be used, set at opposite points on the commutator. The lines of commutation will be nearly horizontal.

The shaft is of good machin[illegible]teel, its dimensions being given in Fig. 5. It is easily made by turning down a piece of 1½-in. shafting, or a piece of 1⅛-in. may be used, and the collar C pinned or shrunk on; but this construction is not so good as the other. The nut N is an ordinary hexagonal nut, which is turned off round after the armature is assembled ready for winding.

The direct current armature core is composed of two stout end pieces of steel or brass (E E Fig. 1) and charcoal iron discs, 6 ins. in diameter and not more than 1-32 in. thick. It is slotted with thirty-six slots parallel to the shaft (Fig. 6), each slot being 9-32 in. wide and ⅜ in. deep, and is provided wth a key-way ¼ in. wide by ⅛ in. deep. The slotting may be easily done on a milling machine, the discs being first assembled on the shaft (which should be steadied with blocks at each end of the armature core to prevent its springing) or the discs may be

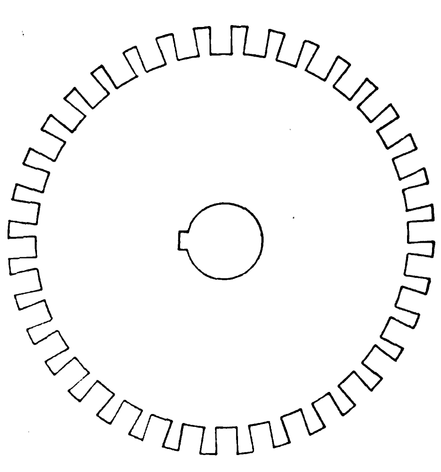

FIG. 6.—AN ARMATURE DISK.

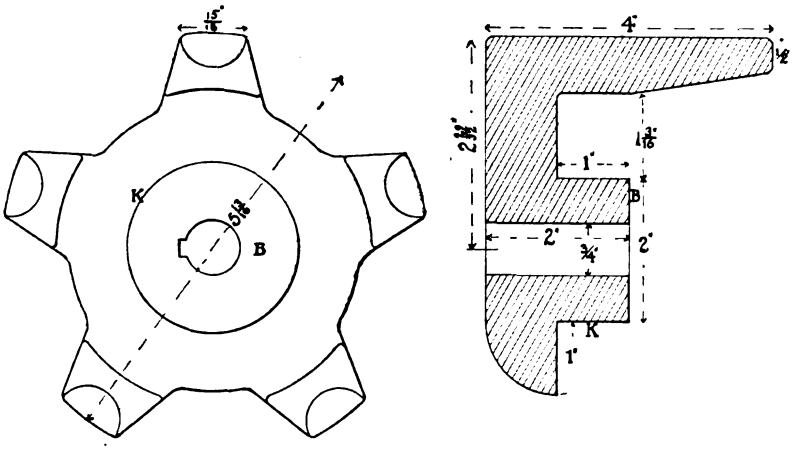
bought of the proper shape. If they are milled the core should be taken apart and the discs annealed, after brushing off any burrs due to the milling, by heating them to a dull red heat and cooling slowly. They should then be shellaced or japanned lightly and reassembled, the nut N being set up as tight as possible without stripping the threads, and then turned off round and smooth to the size given in Fig. 5. The sharp edges of the slots in the end plates should be brushed off with a file and the whole core given a coat of thin shellac and baked (a cooking-stove oven answers admirably for armature and coil baking, but should not be made too hot).



FIGS. 7 AND 8.—ELEVATION AND CROSS SECTION OF ONE PIECE OF A. C. FIELD.

The cores of the field magnet are made of round iron shafting, the softest that can be had, 2½ ins. in diameter. Two pieces, each 9⅞ ins. long, are cut off and turned up and threaded, as shown in Fig. 4. Holes are drilled and tapped for their reception in the lower yoke of the bed casting, as shown, and the upper yoke casting bolted in place. The surfaces of both upper and lower yokes, where the shoulders of the field cones abut, should be planed flat, and extra care in fitting these will be well repaid by the better performance of the machine. The top of the upper yoke is tapped to receive countersunk screws holding the hard-wood or fiber base for the four binding-posts shown in Figs. 1, 2 and 3. Spools for the field winding are made of brass, using thin mandrel-drawn tubing for the cylindrical part, or, if this cannot be had, 1-32 in. sheet brass, bent to shape around the core, and soldered. The ends are brass rings, soldered on, all four being easily made at the same time by soldering together four pieces of ⅛-in. sheet brass, boring out the center, mounting them on a mandrel, turning down the outside and melting them apart. The spool should be covered with about two layers of cotton cloth, put on with thick shellac, and well baked before winding. The ends should not be less than ⅛ in. thick, and should be scored 1-16 in. deep to form a channel for bringing out the inside end of the winding.

The commutator has thirty-six bars, 1 in. width of face and 1 in. bore. It should be not less than 3 ins. in diameter and is best bought, though the amateur can make it if he has the time and necessary tools. It is held fromturning on the shaft bya feather (not shown in the drawings) and sufficiently held endwise by the wires soldered in it. It should go flush against the shoulC of the shaft.

The alternator is of the type described by Professor Henry S. Carhart in "The American Electrician" of November, 1897, and is here modified from his excellent design only in size and to adapt it to the purposes of this machine. It is urgently recommended to those who construct this machine that they first read Professor Carhart's article.

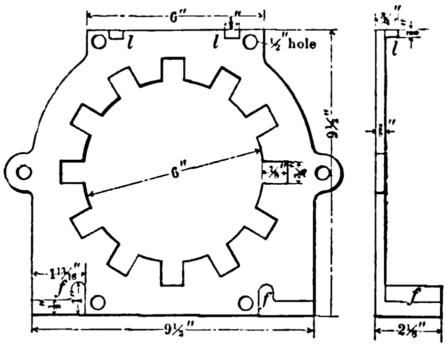
The field revolves and consists of two five-pointed star-shaped iron castings (Figs. 7 and 8), exactly alike, mounted facing each other on the shaft with their fingers interlaced. A key-way is cut in each to receive a feather on the shaft (F Figs. 1 and 5), so that the ten fingers are spaced at exactly equal intervals around the circumference when the field is assembled. The abutting surfaces, B, Figs. 7 and 8, should be turned off true in the lathe, and the outer surface of the core, K, Fig. 8, should be turned off to size to receive the spool carrying the winding. This spool is made in the same way as those already described, its dimensions being 2 ins. inside diameter, 2 ins. long over all, and 1⅛ ins. deep to contain the winding.

After assembling this 10-pole field its exterior should be turned off to a diameter of 5 13-16 ins. All sharp corners should be neatly chamfered off with a file after it is turned up.

The two collector rings, R R Fig. 1, are of brass, about 3 ins. outside diameter, turned up smooth and driven on a hub or hard-wood or fiber; wood being the better because it is less liable to shrink. They may be pinned in place, but a little bicycle tire cement will be found to hold them excellently. The hub should be trued up in the lathe after it is in place on the shaft, and given a coat of shellac to keep out moisture. The two ends of the field coil are led in small rubber tubes (⅛ in. diameter may be had at most drug stores) and soldered into small holes in the edges of the collector rings. Of course one wire goes through the hub to the side next the bearing to connect with the outer ring.

The alternator armature is stationary, and is wound with twelve coils. It consists of soft iron discs, held between two cast iron end plates, shown in elevation in Figs. 9 and 10, Fig. 9 showing the side next the discs. These end plates are provided with feet (f f Figs. 9 and 10), which abut when the two plates are drawn together by the six bolts connecting them. At the upper part of the end plate are two lugs (l l Figs. 9 and 10), which are tapped to receive the screws holding the wooden block b (Fig. 1), which carries the eight binding posts and lamp socket shown in the drawings. The discs are 6 ins. inside and 9½ ins. outside diameter, and may be bought of this size. They should not be heavier than No. 24 gauge. To assemble the armature the lower surfaces of the feet f f should be planed true, and their abutting surfaces finished off, the bolts put in place in one of the end plates, the discs laid in the cage formed by the six bolts, and the other end plate put on and bolted up tight. The nuts should be tightened evenly all around the circumference until the feet abut fairly against each other, the whole being set on a flat plate and gently tapped with a mallet, so that all four feet will bear evenly. The twelve slots, each ¾ in. wde and ⅞ in. deep, should then be milled out and the discs taken apart and treated in the same way as those of the direct-current armature described above. A score should be filed or sawed in the bottom of one of the slots before the discs are dismounted for annealing, etc., so that they may be put together in the same way when reassembled.

If the shop in which the work is done has no milling machine, the slot may be planed out or worked out on a small shaping machine. It is possible to get very satisfactory results with a hack-saw and chisel, by sawing two cuts of the right depth for the side of each slot and chipping out the metal with a sharp chisel ground off to the right width. If care and time be taken, a very neat job can be made by this primitive means.



FIGS. 9 AND 10.—INNER SIDE AND EDGE ELEVATIONS OF A. C. ARMATURE FACING CASTING.

After the bearings are in place, the direct curent field should be put together and bored out. A boring bar running in the bearings is by all odds the best tool to use for this. To make this bar take a piece of 1½-in. shafting 24¾ ins. long, turn down the ends to a diameter of ¾ in. for 8½ ins. at one end, and 6½ ins. at the other, so that it may run in the bearings of the machine and at the same time slide through them endwise. Cut a slot through the bar, for the reception of a lathe tool 3 ins. from the shoulder next the long bearing surface, and put in a set-screw to hold the tool. Then block up the machine, with the boring bar in place, in the bearings, on the the carriage of the lathe, so that the boring bar may be driven in centers, the dog being put on the long bearing end. Very light cuts are taken, the diameter of the bore being finished to 6 3-16 ins. All resulting sharp corners and edges should be filed off. Of course the field may be bored in other ways than that described, but it will be found that the method given is accurate and easy.

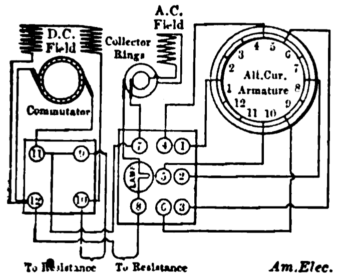


FIG. 11.—CONNECTIONS, BINDING POSTS AND CIRCUITS.

The surface S (Fig. 1), on which the base of the alternator armature rests, may now be planed down and the armature set on it and lined up. It is advisable to have the holes in the feet of the armature somewhat larger than the cap screws which fasten it to the bed, to allow a little adjustment sideways.

The windings for 110 volts at the direct current end and the same voltage (single phase) at the alternator end, with a speed of 1200-r.p.m. and a corresponding frequency of 7200 cycles per second are as follows:

1. Direct Current Field: Fill each of the two spools neatly full of No. 24 B. & S. gauge double cotton-covered wire, putting in not less than 18 layers on each. The spools should be covered with cotton cloth, well shellaced and baked, before winding. About every third layer of wire should be shellaced and the finished coils should be baked at a low temperature for several hours. They must be put on the field cores with the ends of the winding uppermost, the outer end of one coil and the inner end of the other being connected to the two binding posts, numbers 10 and 12 (see Fig. 11), and the other two ends connected together, the connection being covered with a piece of ⅛-in. rubber tubing. It is a good plan to solder a piece of No. 16 wire a few inches long to the inner end of the coil winding, running this down through the score in the spool head to the cylindrical part and allowing the small wire winding to begin there. This obviates the danger of breaking off the inner end of the coil.

2. Alternator Field: This spool is also wound full of No. 24 double covered wire, at least 34 layers being put on. It is connected directly to the two collector rings as has been described above.

3. The Direct Current Armature: This is wound with 36 coils, each containing 8 turns of No. 16 wire, making 16 wires in a slot. The slots are first insulated with little gutters of thin micanite or fibre, shaped around a square cornered bar and forced into the slot. The heads of the armature under the slots and the shoulder C and nut N on the shaft are covered with cotton cloth shellaced on. The simplest winding is the best. Commence at the commutator end of any slot, making first a small loop in the end of the wire to identify the inner end of the coil, and wind over the armature endwise and through the opposite slot four turns, always going to the same side of the shaft, then four more turns going to the other side of the shaft. The first four will fill the bottom of the slot and the next will go in on top of them. Then turn the armature over and begin another coil in the slot next to that opposite the first slot. When 18 coils have been wound every slot will have 8 wires in it. Proceed with 18 more coils on top of these and the armature winding is finished. If the slots are numbered consecutively 1 to 36, the coils will begin as follows:

Coil	1	in	slot	1	Coil	19	in	slot	19
"	2	"	"	20	"	20	"	"	2
"	3	"	"	3	"	21	"	"	21

"	18	"	"	36	"	36	"	"	18

As each coil is wound the two ends may be twisted together for the moment. When all 36 have been wound there will be 36 pairs of ends sticking out, one end of each pair being distinguished by a loop to indicate the beginning or inside end of the coil. The commutator is now put on, and into the slot in the tail of each bar is soldered the inside end of one coil and the outside end of its next neighbor in regular order around the armature.

Where the coils cross each other on the ends of the armature strips of muslin should be laid between them. Each coil should be shellaced as it is wound, and when the first 18 are completed it is advisable to bake the armature for an hour. It is to be borne in mind that absolute cleanliness is an essential to good armature winding. It should never be attempted in a machine shop or where there are filings, etc., and dust in the air, but should always be done in a clean, airy place. The wires may be forced straight in the slots with a hard-wood wedge, but care must be taken not to injure the insulation. Above all, don't be afraid to use the shellac.

The soldering of the wires into the commutator should be done with rosin, not acid, as a flux, and any globules of solder that fall on the butt of the commutator must be brushed out. It is well to put a piece of asbestos paper over the head of the armature next the commutator before beginning to solder in the connections.

4. The Alternator Armature: This is much simpler than the direct current armature. The winding consists of 12 coils, exactly alike, made in a former and slipped over the poles. Two of them are shown in position in Fig. 2.

The former for winding these coils is made of three pieces of wood and is shown in Fig. 12. It will save time to make two or three of them. A piece of strong, thin paper is laid in the groove of the former (to prevent the coil sticking to the wood) and shellaced lightly on its inner surface, that is, where the wires are to lay. On this the coil is wound, 98 turns of No. 18 B. & S. gauge double cotton covered wire, 14 turns to a layer, 7 layers. Thick shellac should be applied to each layer. As each coil is finished loosely twist the ends together and put the former carrying the coil into the oven to bake. By having several formers it is possible to bake several coils at once and thus save time. After baking take the former apart and remove the coil. Tear off the loose edges of the paper and tape the coil neatly with ½-in. white silk ribbon, or cotton tape, well shellaced. The inner end of each coil should be marked when it is wound, and all should be wound in exactly the same way.

In putting the coils on the teeth of the armature care must be taken to see that all are put on in the same way, otherwise confusion is sure to result. Then connect the inner end of coil 1 to the inner end of coil 2; the outer end of 2 to the outer end of 3; the inner end of 3 to the inner end of 4; the outer of 4 to the outer of 5; and so on all around the armature, finally connecting the outer end of 12 to the outer end of 1. Any coil may be chosen as the first in this series. If the connections are properly made a direct current sent through all the coils in series before the last connections is made will magnetize the armature teeth alternately north and south. The coils are held in place by small L-shaped pieces of sheet brass screwed to the armature end-plate, as shown in Fig. 2.

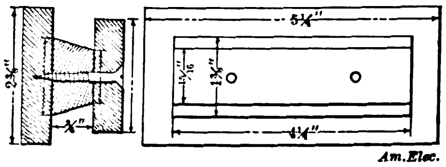

FIG. 12.—FORMER, CROSS SECTION AND PLAN, TOP REMOVED.

Leads should be taken off from the connections between coils 1 and 2, 4 and 5, 5 and 6, 7 and 8, 9 and 10, and 10 and 11, and brought to the binding posts, as indicated in Fig. 11. Running at 1200 r.p.m. the machine, either driven by the direct current motor end or by outside power, will give 110 volts, single-phase, from terminals 1 and 2; two-phase currents, 110 volts on each side, from terminals 1 and 2, and 4 and 5; and three-phase currents, 95 volts on each side of the triangle, from terminals 1, 3 and 6.

The lamp shown is used as an external resistance in the alternator field, it being impossible to put on enough wire of a reasonable size in the limited winding space of the rotating field to secure the needed resistance. It is a 50-volt, 3½-watt 16-c.p.

lamp, or may be of a higher resistance, this depending, as the performance of the machine in most respects will, upon the quality of the cast iron of the two fields and the width of the air gaps. For this reason it is not possible to predict very exactly the performance of the machine, except to say that efficiency has not been especially considered in its design.

Current in D. C. armature, about	8.8 amperes
Current in D. C. field	1 ampere
Current in alternator field (50 volt lamp in circ.)	1 ampere
Total direct current input, about	1,188 watts
Current delivered by alternator armature, about	6 amperes
Volts at alternator terminals, single-phase	110
Total output	660 watts
Efficiency at full load, about	55 per cent.
Speed	1,200 r.p.m
Frequency	7,200 cycles per min.

The above table gives the constants of the machine approximately, assuming it to run as a motor dynamo transforming from direct current at 110 volts to single-phase alternating current at same pressure.

AMERICAN TELEPHONE PRACTICE.

BY KEMPSTER B. MILLER.

THE EXPRESS SYSTEM.

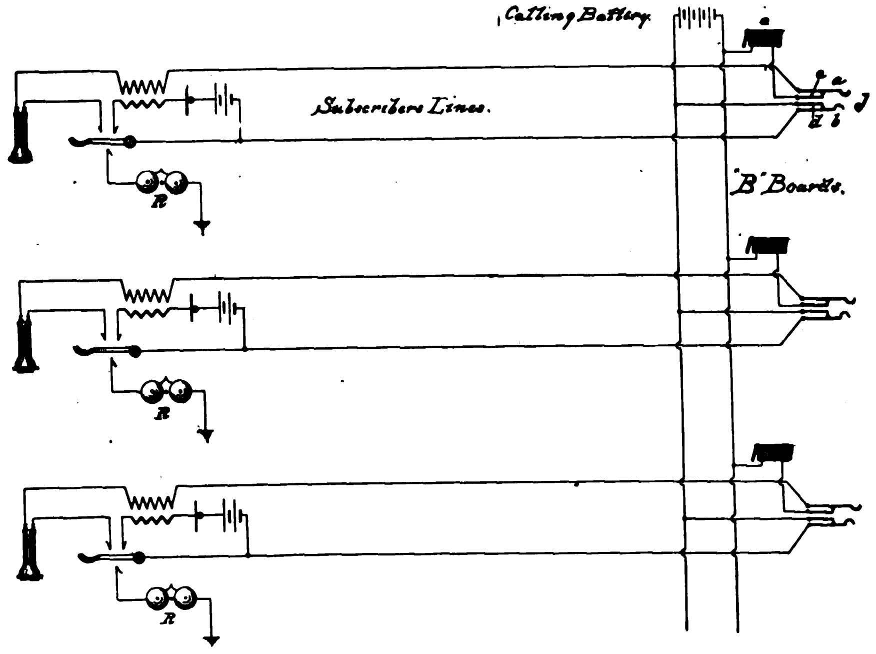
So far the only systems described in this series for handling large exchanges have been those of the multiple type; that is, systems, wherein each line runs through a spring jack on every section of the board in the entire exchange. While one form or another of this general type of board is used in nearly all of the large exchanges in this country, and in fact the world over, there are notable exceptions, and the success of some of these, coupled with the inherent difficulties due to the very nature of the multiple board, leads me to believe that the coming system, while it may in some degree embody the plan of the multiple jacks, will depend for its action on other ideas already developed to a very considerable extent.

In the multiple switch board the cost of installation increases approximately as the square of the number of the subscribers. When a new section containing, say, 200 spring jacks, annunciators and other apparatus is added to an exchange, the increase does not end there. Two hundred multiple jacks must be added also to each of the sections already existing in the exchange. This is clearly an objection, which increases in seriousness as the exchange grows. A multiple board having a capacity for 6000 lines would probably be divided into 30 sections of 200 lines each. On each section would be placed the 6000 multiple jacks, plus the 200 answering jacks belonging to the particular 200 lines whose annunciators were located at that section. This would make a total of 6200 spring jacks on each section, or 186,000 in all. The first cost is, therefore, large, increasing the board is excessively expensive, and cost of maintenance is necessarily heavy.

When, in addition to these facts, it is considered that each jack may be the cause of an open circuit, or a short circuit, which is worse, and that other electrical difficulties pointed out in previous articles also exist, it will be evident that the multiple board is not the perfect system. It has met certain requirements with a fair degree of success, better perhaps than any other known system has shown its capability of doing; but with such grave defects, the existence of which are due solely to the very nature of the system, are we to suppose that the multiple board can survive long in this age of constant improvement?

The enormous multiplying of jacks in the multiple system is for one purpose—to enable each operator to have within her reach a terminal of every line in the exchange, to the end that she may be able herself to complete any connection called for over any one of the lines under her immediate supervision. That is, that she may be able to answer any call arising at her section, and, without requiring the aid of any other operator, make the connection called for. In other words, in a 6000 exchange, 186,000 spring jacks would be used, instead of only 6,000, in order to accomplish this result.

Clearly, if multiple jacks are not used, two operators or more will have to be instrumental in making a connection between two subscribers whose lines terminate on different portions of the board. It would seem at first thought that this would be a considerable disadvantage, and would result in a slower system. On further consideration, however, why should it be more of a disadvantage to divide the labor of manipulating a switchboard between several operators, than it is to apportion the labor of making a pair of shoes or any other manufactured article among a large number of operators, as is now done in all large factories?



SUBSCRIBERS' CIRCUITS, EXPRESS SYSTEM.

The loss of time required by one operator having to repeat an order to another, or, as is the case in some systems, of the subscriber having to repeat his own order, is or should be fully compensated for by the gain in simplicity over the multiple system.

One of the most successful efforts to do away with the multiple jack system is that embodied in the express system, due to Messrs. Sabin & Hampton of San Francisco. This system has been used for several years in San Francisco, and has demonstrated its capability of handling with success an exchange having over 6000 subscribers.

The system is so radically different from anything so far described that its consideration in detail should be a matter of much interest. One striking feature in it is that no magneto generators are used at the subscriber's station, and when it is considered that approximately one-third of the cost of a complete telephone set of the ordinary type is in the magneto, it will be seen that this is a saving of considerable moment. The doing away of the magneto, however, is not an essential feature of the express system, but is one of the advantages incident to its use.

Briefly stated, the underlying ideas of the express system are as follows: The boards are divded into two classes, termed for convenience "A" and "B." Similarly, the operators at the respective boards are termed "A" operators and "B" operators. There is but one line jack for each line in the exchange, and these are divided into groups of one hundred each and are placed only at the "B" board. At the "A" boards, which are entirely removed from the "B" boards (they may even be in another exchange), are placed plugs which form the terminals of other trunk lines leading *from* the various "B" boards; and also jacks forming the terminals of other trunk lines leading *to* the "B" boards.

The former trunk lines—that is, those terminating in plugs at the "A" boards—also terminate in plugs at the "B" boards. These are termed "A" trunk lines. The latter trunks—that is, those terminating in in jacks on the "A" boards—terminate in plugs on the "B" boards, and are termed "B" trunk lines. When a call is received it attracts the attention of one of the "B" operators by displaying an annunciator in an ordinary manner. The "B" operator at whose board the call is received pays no further attention to it than to insert one of the plugs of an "A" trunk into the jack of that line, thus transferring the call to an "A" operator, who answers it with a listening key in the ordinary manner. No means whatever are provided for a "B" operator to listen in on a subscriber's circuit, this duty being confined solely to the "A" operators.

The "A" operator having learned that the subscriber calling desires to be connected with a certain other subscriber, conveys this information, by means of a special order wire, to the "B" operator at whose board the called-for subscriber's line terminates. The "B" operator then tells the "A" operator what "B" trunk line to use and the "A" operator then inserts the plug of the "A" trunk line used into the jack of the "B" trunk line thus designated. This brings the connection as far as the board of the second "B" operator; that is, the "B" operator at whose board the called-for subscriber's line terminates. This operator, in order to complete the connection, simply inserts the plug of the "B" trunk used into the jack of the called-for subscriber's line, and presses a ringing key in order to call that subscriber.

It will be seen that the connection has really been handled by three different operators, but that the first of these operators do no more than to insert a plug into a jack, giving the matter no further attention.

All signaling between the subscribers and the operators and between the various operators, whether it be for establishing or clearing out a connection, is entirely automatic, and therefore not dependent upon the volition of the parties concerned.

The accompanying figure shows the arrangement of the circuits at the subscriber's stations, and also the arrangement of spring jacks and annunciators on the "B" boards. One side of the line wire at the subscriber's station is normally grounded through the polarized ringer R. This means that calling a subscriber from the central office must be accomplished over one limb of the line wire and ground, instead of over a metallic circuit, as in case of talking and other signaling in this system. The other circuits and apparatus at the subscriber's station are of the ordinary arrangement and type, the only difference being that the magneto generator is omitted entirely. The line wires of each subscriber terminate in two springs, a and b of their spring jack J. These springs normally rest on two anvils, c and d, one of which connects through an annunciator, e, with a heavy wire leading to one pole of the calling battery, and the other of which leads to a similar wire connecting with the other pole of this battery.

This annunciator, e, has a shutter which is simply lifted by the attraction of the armature, and again dropped into its normal position when the armature is released. It is, therefore, the simplest type of self-restoring drop. The circuit of the call battery is normally open only at the subscriber's station. It is automatically closed through the receiver and secondary winding of the induction coil at the subscriber's station whenever the subscriber removes his receiver from its hook. This allows enough current from the calling battery to pass through the drop, e, to raise its shutter, and thus attract the attention of the "B" operator at that board.

The shutter remains raised until the operator inserts the plug of one of the "A" trunk lines in order to transfer the call to the "A" operator. The insertion of this plug, however, lifts the springs a and b from their anvils c and d, thus cutting off the battery and allowing the shutter of the annunciator, e, to drop to its normal position, and the "B" operator therefore pays no more attention to it.

The advantages of this part of the system are numerous. It is simplicity itself. A single battery is made to serve for actuating the signals of every line in the exchange, no matter how great their number may be. Storage batteries are used for this purpose, ten cells being connected in series so as to give a pressure of about twenty volts. It is said that the average flow of current from this battery is about one and one-half amperes, and never exceeds two amperes in the San Francisco exchange of approximately 6000 subscribers. It will be thus seen that the cost of maintenance of these batteries is very trifling.

Another good feature of this arrangement is that, should a "B" operator by mistake withdraw a plug from a jack before a subscriber has finished talking—that is, before he has hung up his receiver—she will be at once notified of her mistake by the display of the signal belonging to that line.

The other circuits and parts of apparatus relating to the trunking signaling between the operators will be considered at length in the next article of this series.

CENTRAL STATION WORKING.

THE CARE AND TESTING OF ALTERNATING CURRENT RECORDING METERS.

BY R. H. STERLING.

The recording meters of an electric lighting company may be compared to the weighing scales of any mercantile business, for they measure the amount of electric energy used by a customer, and should, therefore, be accurate and reliable, and are, in no small measure, a factor in the dividends of the company.

The meter once installed on a consumer's premises is apt to be a case of "out of sight, out of mind," and is too often left to care for itself year in and year out, and during that time acquiring all manner of friction losses, which, in a large number of meters, amounts to many dollars that should have gone to the company's earnings.

It is proposed in this article to take up the recording ampere-hour meter for alternating current, which is probably more extensively used than the recording watt meter, and we will deal with the Shallenberger type, it being the most familiar and the oldest in use. This class of instrument being less complicated and delicate than the wattmeter, is for this reason unfortunately often considered not to require much care and attention, but it will amply repay all the good treatment shown it.

These meters are frequently taken from the packing boxes, when received from the factory, and placed in position for immediate duty without first ascertaining, by tests, whether they have been altered in their adjustment in transit. A very important reason why meters of this type, having the retarding air veins, should be tested on receipt from the factory, is that in higher altitudes than that where they are manufactured and standardized, they will record considerably faster. This is owing to the lighter air of high altitudes having less retarding effect on the aluminum vanes. In altitudes of 5000 ft. above sea level an increase of 10 per cent will be found over the adjustment of sea level.

The selection of the size of a meter for a given installation deserves careful consideration, owing to the fact that the light-load accuracy is not as great as half and full load, and the failure of the large units to start at all on very light loads.

This question of size is more especially important in residence lighting, for a house may be wired for thirty lights, but in practice not more than five or ten lights will be burning at any one time, except it may be on the occasion of an entertainment, and then not more than twenty turned on. A 10-amp. meter is large enough for an installation of this size. It would carry the overload all right, but would cause some slight drop with this number burning.

The most serious loss with large meters installed in dwellings and even stores, is when a night light is kept burning, for it is seldom that a meter of 40 amps. capacity and over will move on one lamp, more especially if it has been up for any length of time and has accumulated dust and grit, or the jewel has become worn.

Take the case of one night light left burning after 10 P. M. till daylight, or an average of eight hours per night for 365 days, and at 1 cent per ampere-hour, this would mean a loss of revenue of $29.50 per annum. In cases like this it will pay, oftentimes, to put in a separate wiring for night lights and a small meter, or divide the lights into two sections, with a smaller sized meter on each, to prevent such loss.

Now, the question as to how often a meter should be taken down, overhauled and adjusted, depends a great deal on circumstances. The location the meter has been placed in is an important factor, for as their cases are not airtight, and consequently not dust or vapor proof, if placed in a position where much dust can be blown into the cases, a year's time will cause signs of friction to appear. A meter placed in the kitchen of a restaurant will in a short time have its mechanism so clogged with grease, seemingly deposited on it from the atmosphere, that it becomes sluggish. Meters placed in bathrooms or laundries have their steel pivots rusted in a short time, this also causing retardation. A meter set up where it is subject to much vibration and jar should be under suspicion.

Meters brought in for inspection, if gone through in a systematic manner, about to be described, can be cleaned, repaired,

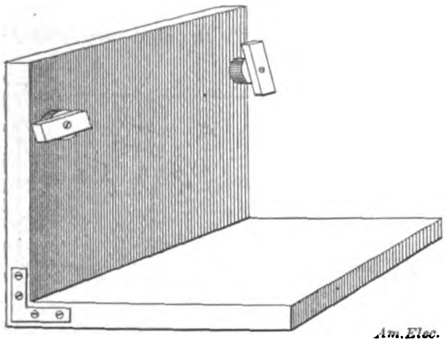
tested and standardized in a very short time, and at very little expense; and it will more than repay the care and time given to them in the saving in revenue that will be effected.

The first step is to provide the proper tools and appliances. Procure from a dealer in watchmakers' supplies a pair of long nose pliers, a pair of tweezers, a swivel-top screw driver, a clock hand set (small tool for forcing on dial hands), a bunch of orange wood sticks and a fine-haired watch brush. A low bench facing a good light is the best place to work. A cradle or frame should be provided to hold the meter in an upright position after the case has been removed. The accompanying sketch shows a convenient form, which can be 9 ins. high and about 10 ins. wide, with two turn buttons set out from the back to engage in the ends of the wooden cleat on the back of the meter frame.

Now proceed as follows: With a small hand bellows blow out all the dust from around the movements; then remove the three brass screws holding the decimal train to the frame, and take off the cap that closes the oil cup on top of the meter shaft, and place the whole set of gears in a large-mouth jar, half filled with gasoline; a Le Clanché battery jar, with a wooden cover, answers this purpose well.



CRADLE FOR HOLDING METER FRAMES.

While the gears are soaking in the gasoline to remove all grease and dirt, the rest of the meter is gone over. First, loosen the set-screw holding the vane on the shaft, and slide the vane up as far as it will go, letting two of the wings go in between the two field coils; now, with a small wrench remove the cap of the jewel and with the point of a fine needle passed over the surface of the jewel, feel for any roughness. If the slightest trace of unevenness is felt, the jewel has become worn, and a new one must be inserted in its place, taking care first before removing the old one, to measure its height from the arm holding it, and adjust the new one to the same distance. If the jewel has become much worn, it is best to either renew the shaft or repolish the end of the old shaft in a lathe with fine rouge, for in the wearing of the jewel its roughened surface has worn away the polished surface of the steel shaft, which in its turn would injure a new jewel, if it were not repolished.

The wearing out of jewels in this class of meters is not frequent, owing to the light weight of the shaft and armature revolving on it. If the best sapphire jewels are used, they will have a long lifetime. The old jewels need not be thrown away, but when enough have accumulated they can be repolished by a lapidist. The jewel having been inspected, the vane is now replaced and the wings carefully straightened, and the teeth of the small gear on the top of the shaft cleaned with the brush.

Before removing the train of gears from the bath of gasoline, swash them about a few times to dislodge all traces of foreign matter, and then while inspecting the dial hands, the gasoline will evaporate, leaving everything clean and bright. The dial hands should all be carefully gone over with the set, and with a light tap driven down tightly. Nothing is so annoying as to have a loose hand cause an error in a reading, as it frequently does. Hold the dial on a level with the eyes and see that none of the hands touch the enamel dial; if they do, bend them away with the tweezers. It is a good plan to turn the hands to zero; this will prove the adjustment of them all, and show that none has lost its relative position. The enamel dial should be wiped clean with a soft cloth, as well as both sides of the glass face.

In placing the train back on the frame, the tweezers will be found convenient in pointing the end of shaft back into its bearing, which bearing should first be reamed out with the sharp pointed end of a piece of orange wood. With everything in position once more, start the shaft revolving by blowing on the vane, and notice if there is any wabble in the armature, or scraping of the wings against the frame or fields. The armature should run perfectly true.

The question of oil now comes up. It was once considered essential to have oil on the moving parts of a meter, especially on the jewel. If the oil is used at all, none but the best quality of watch oil is permissible, and that only in the smallest quantities. It is better to err in having too little than too much. A small pointed brass wire, dipped in oil and shaken, carries sufficient oil to go over the whole meter by touching each part lightly. It is found best to use no oil on a well-polished jewel and pivot.

The meter is now ready for testing, but a preliminary test should be given it to ascertain its starting qualities on a light load, or to see to what degree friction has been eliminated by the cleaning just given it. A meter case should be provided with a glass face inserted opposite the veins, so that their motion can be seen, for air currents would otherwise disturb the test if made without the case.

Now have a bank of lamps containing three or four 16-c.p. 50-volt lamps; one 8-c.p. 50-volt, and one 8-c.p. 100-volt lamp. Five and ten ampere meters should start on the 8-c.p. 100-volt lamp; 20 amps. with the 8-c.p. 50-volt, and a 40-amp. on two 16-c.p. lamps, but occasionally one of this size will start on one lamp; an 80-ampere meter requires from three to four lamps to start it. If a meter fails to start on the lamps mentioned, there is some binding or friction taking place, and it should again be gone over. Frequently a meter has to be entirely taken apart and each pivot hole reamed out with the orange wood, and the gear wheels thoroughly polished with the brush, and pivots polished, before it will start on the proper load here prescribed. This is usually the case with meters that have been in a moist atmosphere and have become oxidized badly.

There are several methods of testing a meter for accuracy. The most common method is to have standard meters of each size, and to place twenty or thirty in series with a standard meter of the same capacity, and let 100 ampere-hours pass through them and compare at the end of the run their registration with the standard meter; then those that have proved too fast or too slow are adjusted by turning the movable coil slightly to the right or left—toward the right hand lessens the speed of rotation, to the left increases the speed. Those meters that do not come within 1 per cent of the standard should be run through a second time. The advantage of this method of testing is that after a day's work of cleaning and repairing a lot of meters, they can be left to themselves in the testing rack to run through the night and be ready in the morning to note the result; and where stations do not have a day service it does not require the long hours of night work necessary with the stop watch method, which will be described in following article.

◆

NAVAL MARINE ELECTRIC LIGHTING.

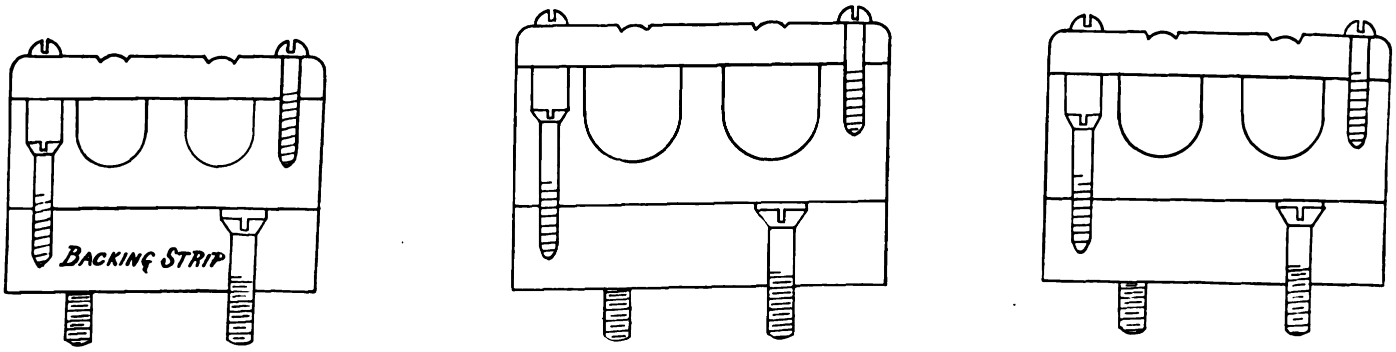
BY E. W. COUNTISS.

It is hard to conceive of a situation where an installation of electric light and bell work is put to such a severe test in actual everyday service as on one of our modern naval vessels. On the bridges and decks there is not only the inclemency of the weather to contend with and guard against, but also the seas that break over the vessel in heavy weather. In the fire and engine rooms there is the heat from the boilers and engines, as well as the moisture from sweating and escaping steam. To stand for any length of time the work must be done thoroughly, both electrically and mechanically, using none other than the best material.

Specifications covering the work in the electrical equipment of U. S. naval vessels are exceedingly complete, covering almost every conceivable point that may be raised, from the construction of the foundations of the generating sets to the size of the screws that secure the lids to the junction boxes.

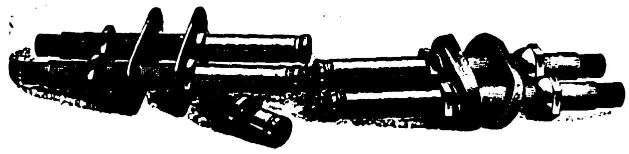
By consulting the illustrations accompanying this article, it will be seen, without detailed description, that the various accessories meet the requirements very fully. The details will be mentioned as we have occasion to use them during the progress of installation, and without quoting the specifications too frequently, we will give the "kernel" by adhering to their requirements.

There are two divisions of the circuits called "Lighting" and "Motor" circuits.

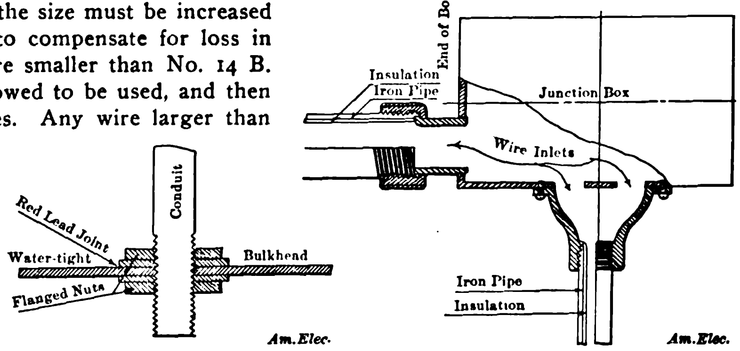


FIGS. 1, 2 AND 3.—MOLDINGS.

The lighting circuits are again divided into six divisions, according to the services required, namely, "Continual," "Battle," "General," "Sea," "Day," and "Special" services. While the divisions are so numerous, a number of them are but submains branching from the trunk lines, which start from the switchboard in the dynamo room. Each sub-division is controlled by a double pole switch of ample capacity, placed in a convenient location. For instance, the lights on the circuit for sea service are taken off the mains for continual service; the lights for day service are on a sub-main branching off from the mains for general service. The battle service mains have their own feeder and start at the switchboard, and carry current to the lamps lighting the magazines, handling rooms, ammunition hoists, central station, conning tower, and battle lanterns at the guns when in action.



FIGS. 4, 5 AND 6.—MAIN DECK, BULKHEAD AND PROTECTIVE DECK STUFFING TUBES.



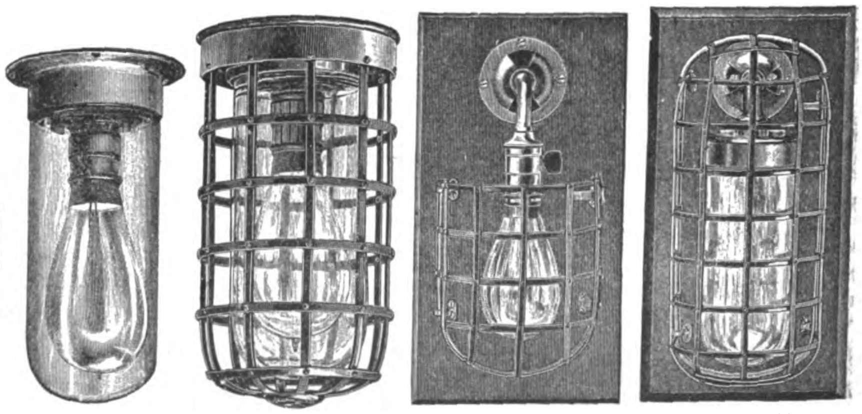
FIGS. 7 AND 8.—IRON-ARMORED CONDUIT AND COUPLINGS.

The signal circuit leads directly from the switchboard, for the lighting of the binnacles, running lights, stay lights, stern lights, truck lights, Ardois signal hoist, and various others for general signal purposes.

The searchlights have their own independent leads, and are not connected to any other circuit.

The number of feeders leading from the switchboard is determined by local conditions and the load they carry. No circuit can carry over 75 amps. The circuits are divided up into decks, starboard and port, or forward and aft, and sometimes it is necessary to use both combinations to keep within the limits allowed or fixed by the construction of the ship. To keep the service intact, wherever possible, the feeders are run below the protective deck, and where occasionally space does not permit this to be done, then as far inboard as practicable. The vertical risers must be protected by such means as can be procured. To further carry out this system, a plan of connecting two feeders together by means of double-pole switches is used, so that in case of accident to one circuit, the neighboring one can be cut in.

FIGS. 9 AND 10.—CEILING FIXTURES.



FIGS. 11, 12 AND 13.—STEAMTIGHT AND BULKHEAD FIXTURES.

The least sectional area allowed is 1000 circular mils per amp., irrespective of length or load; but where the drop is over 3 per cent, then the size must be increased above this rate to compensate for loss in voltage. No wire smaller than No. 14 B. & S. gage is allowed to be used, and then only for branches. Any wire larger than this must be stranded conductor, varying in the number and size of strands according to area. Where feeders are cross-connected, the area per amp. must be at least 1500 circular mils, with the same correction for drop as before mentioned. The only exceptions to the foregoing instances are made in favor of the searchlight feeders, where 500 circular mils per amp. are allowed.

In figuring for size of wire for feeders, let us take a circuit carrying 30 16 c.p. lamps, taking .9 amps. per lamp, this being according to specifications, and corresponding therefore to 27 amps. Allowing 1000 circular mils per amp., the least size wire allowable is 27,000 circular mils. Suppose the distance in wire-feet from switchboard to feeding center is 500, then the drop at 80 volts (which is the voltage used), would be 5.5 volts, or nearly 7 per cent. A wire of at least 61,875 circular mils would be required to keep within the 3 per cent allowed; but the nearest size according to standard is 60,088 circular mils, and as this is yet too small, the wire to be used would be the next larger size, or 75,776 circular mils, which would have 37 strands of No. 17 B. & S. gage. The figures are approximate only, to illustrate the manner of determining the size wire to be used. Each circuit must necessarily be determined alone after the number of lights is decided upon for that circuit.

Having found the size of the wire, it determines the size of the molding (Figs. 1, 2 and 3), conduit and hard rubber bushings. Each size of wire has the diameter over braid, etc., specified. By reference we find the size of the bushing must be 13-16 in. inside diameter and 1 1-16 in. external diameter, which must have a hole 1⅛ in. diameter drilled to receive it. The molding must be 3⅛ ins. wide, with gutter ¾ in. wide and deep. Or, if we use iron-armored conduit, it must be 1 in. bore. Where we go through iron or steel bulkheads that separate the water-tight compartments from each other, we must drill and tap the bulkhead for the stuffing tube (Fig. 5), and pass from one compartment to the other through this tube, making it secure by means of a soft rubber bushing and stuffing nut. Where the wire passes through the decks, a plain deck stuffing tube is used (Fig. 4), or if on an inclined surface the protective deck tube (Fig. 6) is used in the same manner. Cuts of the several various sizes and styles of moldings are shown in Figs. 1, 2 and 3.

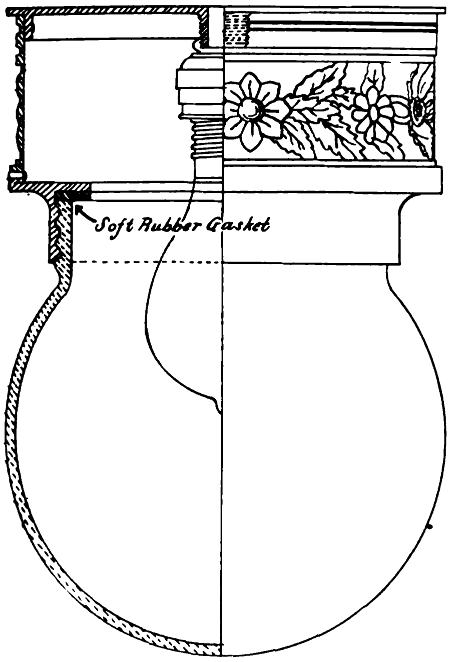


FIG. 14.—CEILING FIXTURE.

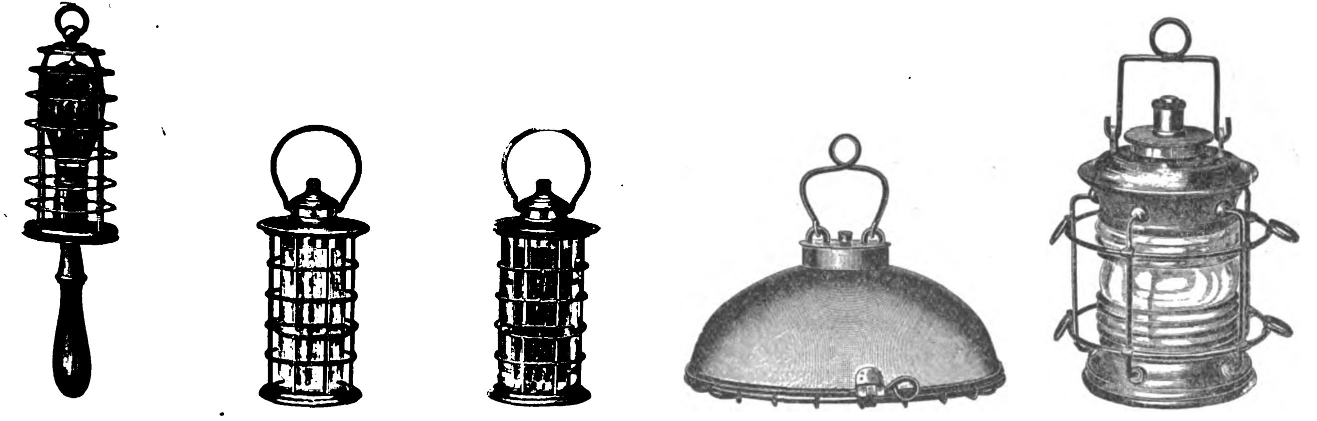
Taking for granted that the different styles of fixtures have been selected, and their location determined upon, the route the mains, branches and feeders must take now demands attention. The line must be as straight as possible, and clear of bolts, nuts and rivets of unusual size; small detours are allowed to avoid these and other obstructions.



FIGS. 15, 16, 17, 18 AND 19.—PORTABLE LAMPS.

The wires are carried in molding or conduit. If molding is used it must be of the same wood as the surrounding joiner work, which generally is white pine painted. But if the bulkhead is finished in hardwood, the molding must correspond with it. A backing strip is laid in advance of the molding over metal surfaces, and secured in place by No. 14 flat-head brass machine screws, with 20 threads to the inch. They must be placed not over 12 ins. apart and staggered, being countersunk below the level. All molding and backing, except hard wood, must be thoroughly painted after being fitted and before being secured in place. Molding is to be used in the cabins, state rooms and officers' quarters generally. But in the water-tight compartments and on the spar deck, and under bridges and all exposed places, iron armored conduit must be used. The method used is fully shown in Figs. 7 and 8.

Let us next turn our attention to the different styles of fixtures used before we attempt to locate them. The ceiling fixtures shown in Figs. 9, 10 and 14 are installed in the cabins and ward rooms, in place of electroliers, which are no longer used. The ceiling fixture of Fig. 10, as well as the steam tight globe (Fig. 11), is used for general overhead lighting, the steam-tight fixtures being protected with a wire guard (Fig. 12), where liable to be broken.

The bulkhead lights (Fig. 13) are used for standing lights in all places except offices and officers' quarters. Where the steam-tight globe is too long on account of the guard, and a guarded fixture is necessary, the bulkhead fixture may be used. Where hammocks are swung the bulkhead fixtures are lowered until the top of the fixture block is about 3 ft. above the deck. This then dispels the shadows caused by the hammocks, and the lamps are in use all night, whereas the overhead lights are all turned off at 2 bells or 9 P. M.

The bunker-lights (Fig. 20) are to light up the coal bunkers. Portables (Fig. 15), decks (Fig. 16) and battle lanterns (Fig. 17), and cargo reflectors (Fig. 18), are used where standing or stationary lights would be almost useless, and are provided for general uses when a shifting light is needed. The battle lantern has a shield which can be rotated until the rays of light can be entirely cut off, and thus form a dark lantern. Racks with hooks are provided for the stowage of these close to where they will be needed. The signal lanterns (Fig. 19) are provided in three colors—red, white and green, and are used for various signaling purposes. One and two light brackets are used over sideboards and transom sofas, where other fixtures would be in the way. As the ceiling fixtures are quite flat, the greater part of the light is lost except directly under the fixtures, particularly when the beams are wide. In the latter case a block about 4 ins. thick is secured overhead, and the fixture screwed to it. This brings the lamp below the level of the beams and gives a greater illumination.

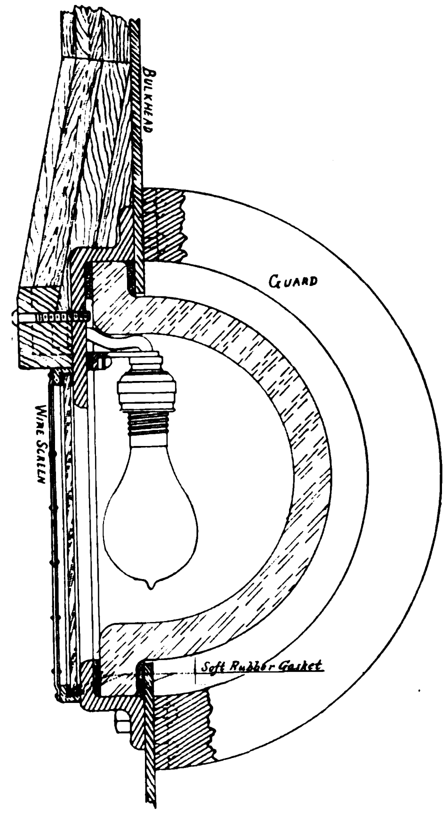


FIG. 20.—COAL BUNKER FIXTURE.

In a succeeding article the arrangement of other lights, the dynamo-room, searchlights, signals, etc., will be taken up.

INTERIOR WIRING.

BY CHARLES E. KNOX.

BRANCH CIRCUIT WORK.

Let us now select points for locating the cut-out groups or distributing centers. Up to this time we have considered the location of these centers solely with reference to architectural requirements, but now we must consider them in conjunction with the branch circuit work.

It frequently happens that after running the branch circuits on the plans, we find, in certain cases where these groups were located, that their positions may be changed to advantage, or sometimes certain groups may be dispensed with entirely and the circuits run to other points. We now see the wisdom of ascertaining from the architect where cut-out groups may be located, rather than selecting particular points for their location.

Having in view, then, the relation of these centers of distribution to the branch circuit wiring, we must bear in mind the following points when selecting their tentative location:

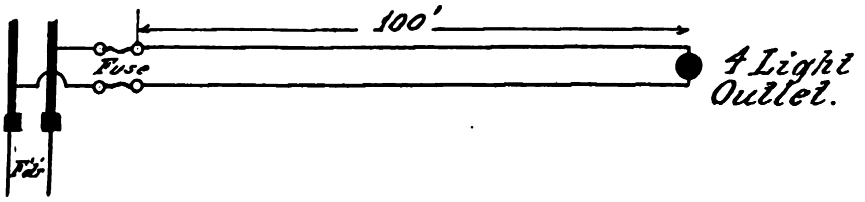

FIG. 1.—BRANCH CIRCUIT WITH GROUP OF LIGHTS.

1. As a rule, wherever possible, it is wise to limit the length of each branch circuit to 100 ft., and the numbers and location of the distributing centers should be determined accordingly.

2. Except in special cases, it is also wise to limit the number of circuits fed through any group of cut-outs to 25 or 30.

In regard to the first point, it may be stated that it is sometimes necessary and even desirable to increase the limit of length. One instance of this may be found in hall or corridor lights in large buildings. It is generally desirable in such cases to control the hall lights from one point, and as the number of lights at each outlet is generally a small number, it would not be economical to run mains for sub-centers of distribution. Hence, in instances of this character the length of runs will frequently exceed the limit named. In the great majority of cases, however, the best results are obtained by limiting the runs to 90 or 100 ft.

There are several good reasons for placing such a limit on the length of a branch circuit. To begin with, assuming that we are going to place a limit on the loss in voltage (drop) from the switchboard to the lamp, it may be easily proven that up to a certain reasonable limit it is more economical to have a larger number of distributing centers and shorter branch circuits than to have fewer centers and longer circuits. It is usual, in the better class of work, to limit the loss in voltage in any branch circuit to one volt. Assuming this limit (one volt less), it can readily be calculated that the number of lights at one outlet that may be connected on a branch circuit (using No. 14 B. & S. wire) 100 ft. long is four lights (see Fig. 1); or in the case of outlets having a single light each, five outlets may be connected on the circuit, the first being 60 ft. from the cut-out, the others being 10 ft. apart (see Fig. 2).

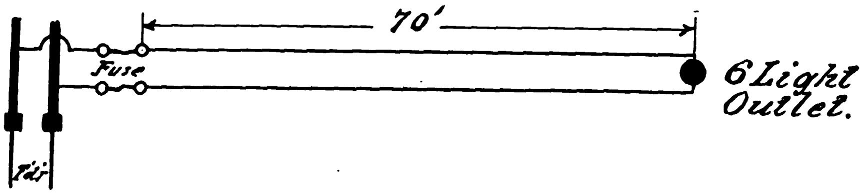

FIG. 3.—BRANCH CIRCUIT WITH GROUP OF LIGHTS.

These examples are selected simply to show that if the branch circuits are much longer than 100 ft. the loss must be increased to more than one volt, or else the number of lights that may be connected to one circuit must be reduced to a very small quantity, provided, of course, the size of the wire remains the same.

Either of these alternatives is objectionable, the first on the score of regulation, and the second from an economical standpoint. For if, for instance, the loss in a branch circuit with all the lights turned on is four volts (assuming an extreme case), the voltage at which a lamp on that circuit burns will vary almost four volts, depending on the number of lights burning at the time. This, of course, will cause the lamp to burn below c.p. when all the lamps are turned on, or else to diminish its life by burning above the proper voltage when it is the only lamp burning on the circuit. Then, too, if the drop in the branch circuits is increased, the sizes of the feeders and mains must be correspondingly increased (if the total loss remains the same), thereby increasing their cost.

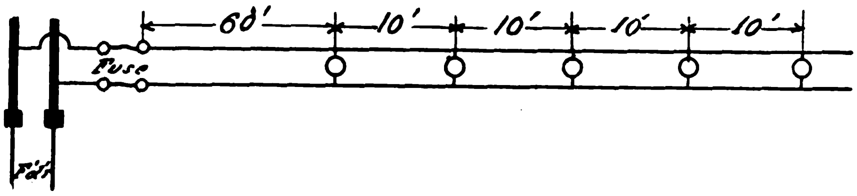

FIG. 2.—BRANCH CIRCUIT WITH DISTRIBUTED LIGHTS.

If the number of lights on the circuit is decreased we do not use to good advantage the available carrying capacity of the wire.

Of course, one solution of the problem would be to increase the size of the wire for the branch circuits, thus reducing the drop. Whatever slight saving this might cause (if any at all) is entirely offset by the fact that the number of amperes which may be fed through a branch circuit fuse is limited to six or eight; in order, therefore, to take advantage of the increased carrying capacity of the wire we must use fixture cut-outs, which, as we said before, is extremely objectionable. The better solution is to increase the number of cut-outs, thus shortening the length of the branch circuits and using No. 14 B. & S. gage wire.

We referred above to calculating the loss in a branch circuit. As this is a problem which continually arises in laying out branch circuits, it may not be out of place at this juncture to explain the method of calculating the "drop" in a branch circuit. Although it is a simple problem it has, nevertheless, frequently proved a very puzzling one.

For the benefit of the more practical reader, to whom mathematical symbols are more or less confusing, we will try to make the problem as simple as possible, and will, therefore, make the consecutive steps as gradual and detailed as may be necessary to gain this end.

We know that the resistance of a wire increases as the length increases and decreases as the size (i. e., the area or cross-section) varies. If we know the length (measured in feet) and the cross-section or area (measured in circular mils) of any piece of wire, we can calculate its resistance, provided we know the resistance of a wire 1 ft. long and 1 mil (i. e., 1-1000 in.) in diameter. The resistance of a "mil foot" (as it is called) of wire has been determined by tests, in the case of copper wire having a conductivity of 98 per cent of pure copper, and when measured at about 68 deg. F. (20 deg. C.) to be equal to 10.56 (international) ohms. (This is based on the copper wire table issued by the American Institute of Electrical Engineers in 1893.) In other words, the resistance of a wire measured in ohms is equal to the length measured in feet divided by the area measured in circular mils, this quotient being multiplied by 10.56, the resistance of one mil-foot; that is,

$$R = \frac{F}{\text{c.m.}} \times 10.56,$$

where R = ohms, F = feet, and c.m. = area in circular mils.

Now, from Ohm's law we know E = CR. Placing in this equation the equivalent value of R in the first equation, we get

$$E = \frac{C \times F \times 10.56}{\text{c.m.}}; \quad (1)$$

or expressed in words, formula (1) means that the difference in voltage ("drop") between any two points of a circuit is equal to the current flowing through that circuit, multiplied by the length (in feet) of the circuit, divided by the area (in circular mils) of the wire, and multiplied by the resistance of one mil-foot of wire.

Now, as the length of a circuit is generally given as the distance measured one way (i. e., one-half of the length of wire constituting the circuit) it would be simpler to substitute this quantity, which we will represent by the letter D, in the formula, F, of course, being equal to twice D; that is,

$$E = \frac{C \times 2 \times D \times 10.56}{c.m.} \quad (2)$$

Now, as we have two constants, namely, 2 and 10.56, it will make the formula simpler if we multiply them together; thus,

$$E = \frac{C \times D \times 21.12}{c.m.} \quad (3)$$

Remember, that D is the distance one way, or the length of one leg of the circuit, and that we still get the resistance of both legs of the circuit in the formula, because this distance is multiplied by the factor, 2, which now forms part of the constant, 21.12.

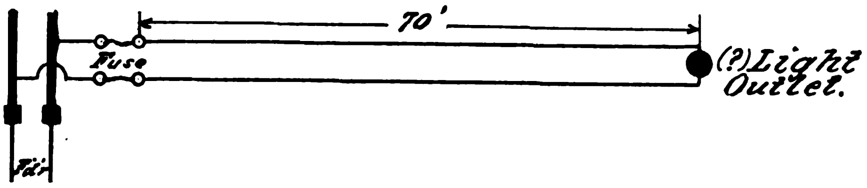

FIG. 4.—BRANCH CIRCUIT WITH GROUP OF LIGHTS.

The formula, as above expressed, is used where the current, A, to be carried the distance, D, and the area of the wire, c.m., are all known, and we wish to determine the loss in voltage in the circuit. If we wish to find the size of wire required where the loss, length of circuit and current carried are given, we can, by transposing the terms, get the formula in this form:

$$c.m. = \frac{C \times D \times 21.12}{E}; \quad (4)$$

or, if we wish to determine the current that may be carried through a certain size of wire, where the distance and loss are fixed, we would use the formula in the following form:

$$C = \frac{c.m. \times E}{D \times 21.12}; \quad (5)$$

in a similar manner, if we wished to determine the length that a circuit might be and produce a given loss with a given current in a fixed size of wire, the formula would be:

$$D = \frac{c.m. \times E}{C \times 21.12} \quad (6)$$

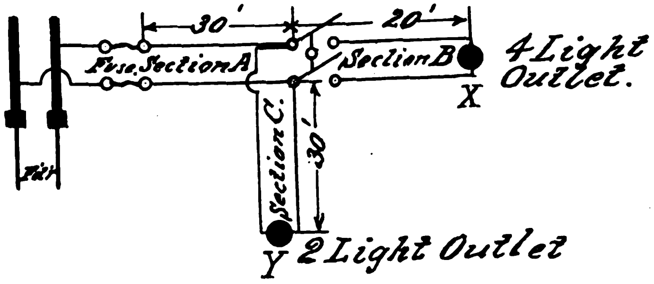

FIG. 6—BRANCH CIRCUIT WITH PARALLEL BRANCHES.

If, however, instead of dealing in amperes, we had lamps to consider in our calculations, it might be simpler (where a number of calculations, involving lamps taking the same quantity of current, were to be made) to substitute a value for lamps in formulas 3, 4, 5 and 6. The current in any case would be equal to the number of lamps multiplied by the current used by each lamp. In the case of a 16-c.p. lamp (using 3.5 watts per c.p.) the current required per lamp, burning at 116 volts, would be .48. Representing the number of lamps by L, formula 3 would become:

$$E = \frac{L \times .48 \times D \times 21.12}{c.m.} \quad (7)$$

To simplify the formula, we will multiply the two constant quantities (.48 and 21.12) together, and (7) becomes:

$$E = \frac{L \times D \times 10.14}{c.m.} \quad (8)$$

In similar manner formulas (4), (5) and (6) become:

$$c.m. = \frac{L \times D \times 10.14}{E} \quad (9)$$

$$L = \frac{c.m. \times E}{D \times 10.14} \quad (10)$$

$$D = \frac{c.m. \times E}{L \times 10.14} \quad (11)$$

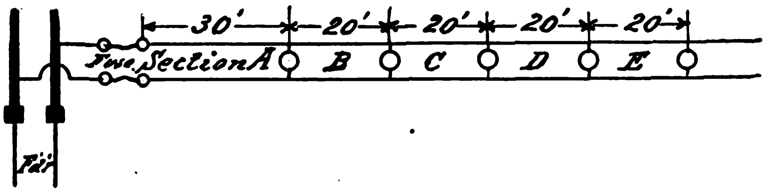

FIG. 5.—BRANCH CIRCUIT WITH DISTRIBUTED LIGHTS.

In a similar manner we could change the formula for lamps, taking any number of amperes or fractions thereof.

We have gone into the derivation of the above formulas with such minute detail as to run the risk of being wearisome, but wiremen who frequently have occasion to calculate the loss in circuits, either do not know the formula, or are so puzzled by terms of the formulas that they are unable to use it intelligently. Then again, many of those who use these formulas continually do not know what the constants signify, nor how they are derived.

Of course, there are tables, charts and slide rules innumerable, but as a rule they are either inaccurate or more difficult to use than the formula. Nearly all of them are good only within certain narrow limits of length, current and drop.

Having derived the formulas, let us now apply some of them. Suppose we have a circuit 70 ft. long, of No. 14 B. & S. wire, supplying a six-light chandelier (see Fig. 3). What is the loss or drop in voltage between the cut-out and the lamp?

Here D (distance) = 70.
L (No. of lamps) = 6.
c.m. (area in circular mils of No. 14 B. & S.) = 4106.

Substituting these values in formula (8) we get:

$$E = \frac{6 \times 70 \times 10.14}{4106} = 1.05 \text{ volts loss.}$$

Suppose we had a circuit 70 ft. long of No. 14 B. & S. gage (see Fig. 4), and we wished to limit the loss to .8 of one volt, how many lamps could we carry on that circuit? We would have by substituting in formula (10):

$$L = \frac{4106 \times .8}{70 \times 10.14} = 4.6, \text{ or } 5 \text{ lamps.}$$

Given a circuit having a number of outlets with one or more lights at each. How would you calculate the loss? It is evident in this case that you cannot take the whole length of the circuit and the total number of lights supplied, for the reason that the different sections of the circuit carry a different quantity of current and consequently the loss in each section will vary according to the quantity of current carried and the length of wire through which it flows.

Let us suppose we have a circuit, the total length of which is 110 ft., and which supplies five outlets having a single light each (see Fig. 5). The distance from the cut-out in this case to the first outlet is 30 ft.; the other outlets are 15 ft. apart. What is the loss to the last outlet?

The way to do this problem is to calculate the loss in each section (see Fig. 5) separately, and then add them together. Thus, taking section A from formula (8) we have, substituting the different values:

$L = 5$
$D = 30.$
$c.m. = 4106.$

$$E = \frac{5 \times 30 \times 10.14}{41.06} = .38$$

That is, the loss in section A, or the loss from the cut-out to the first lamp, is .38. In similar manner we find the loss in the other sections to be:

Section B = .15
" C = .11
" D = .075
" E = .038

.373
Total loss to last outlet = .75

Given a circuit where at a switch or an outlet the circuit divides into two parts, what is the loss in the two branches?

Suppose we have a circuit as shown in Fig. 6. It is evident that you proceed in this case in a manner similar to the last one. Here we take the first section to the point where the circuit divides, in this case in section A, we get:

$$E = \frac{6 \times 30 \times 10.14}{41.06} = .45.$$

In section B we get .2, and in section C we get .15. Now, to get the loss from the cut-out to outlet, X, we add the loss in section A to the loss in section B, which amounts to .65; in similar manner, to get the loss from the cut-out to outlet, Y, we add the loss in section A to the loss in section C, which amounts to .6 of a volt.

LESSONS IN PRACTICAL ELECTRICITY

PRACTICAL APPLICATIONS OF CONDENSERS.

An interesting application of a condenser in connection with an inductance is in obtaining a constant current from a constant-potential circuit, and a constant potential from a constant-current circuit.

This method has been suggested for use in series incandescent lamp distribution from alternating current circuits. It has the advantage that any number of incandescent lamps can be installed in series, instead of the number being limited to a multiple of the circuit voltage. That is to say, a single 100-volt lamp may be used on a 1000-volt circuit or 20 such lamps in series, the same current flowing in each instance. It will be seen that this system differs from the usual alternating current in two respects. First, the combined voltage may exceed the voltage between the mains; and second, a lamp may be turned off or short circuited, and the current will retain the same value, thus doing away with shunt boxes.

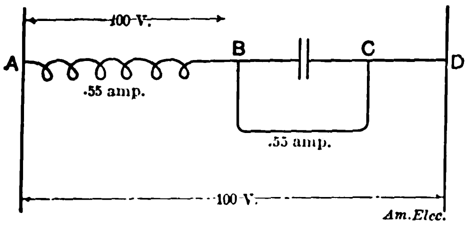

FIG. 1.—CONSTANT-POTENTIAL, CONSTANT-CURRENT CIRCUIT.

This system is illustrated in Fig. 2, where for the sake of the illustration, the voltage between the mains is 100. We will suppose that 110 lamps, each taking .55 amperes, are used in the series circuit. When there is a certain relation between the inductance and the capacity, the latter being in parallel with the series circuit, .55 amperes will flow through the latter circuit whether no lamp is in it, or whether a large number is present, the number only being fixed by the saturation of the iron of the inductance and the strain on the condenser insulation. In practice the arrangement would most probably be used on a high-voltage system, with not necessarily a number of lamps of an aggregate voltage exceeding that of the line.

The relation between the capacity and inductance must be such that when a current of the same value is passed through each, the inductive e.m.f. will be equal to the capacity e.m.f. In other words, the relation is similar to that in the cases previously considered, of an inductance in a circuit nullified by a capacity in parallel or in series. A direct proof could be given that this relation should exist between the two, but for the present it will be assumed, and the method of calculating the value of the inductance and condenser illustrated by an example.

In Fig. 1, suppose that we have a capacity and inductance in series between which the above relation exists; further, suppose that in parallel with the condenser there is a circuit of no resistance, as shown. We will now assume that .55 of an ampere is to flow through the latter circuit, notwithstanding what resistance it may contain, the voltage of the mains being 100 and the frequency 133, or 16,000 alternations per minute.

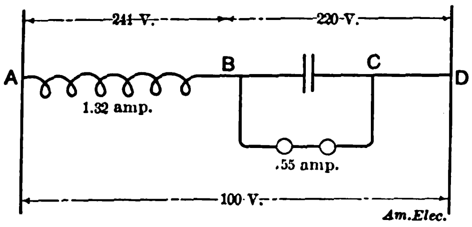

FIG. 2.—CONSTANT-POTENTIAL, CONSTANT-CURRENT CIRCUIT.

Since the circuit in parallel with the condenser has no resistance, there will be no e.m.f. between its terminals B C, and consequently none between the two plates of the condenser, so that the circuit is equivalent to one having in it merely the inductance A B. Substituting in the inductance formula $E = \frac{2 \pi n L C}{1,000}$ (1), the values of E, n and C, we have

$$100 = \frac{6.2832 \times 133 \times L . 55}{1,000}, \text{ or } L = 217.6$$

millihenrys. That is to say, in order that .55 of an ampere shall flow in the circuit, the inductance A B must have a value of 217.6 millihenrys.

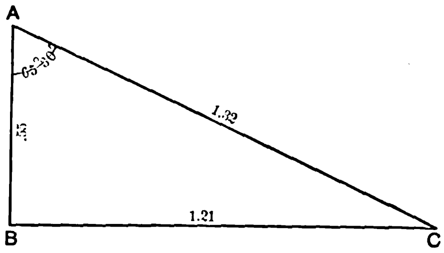

FIG. 3.—CURRENT TRIANGLE.

By definition, the capacity of the condenser should be such that its e.m.f. shall equal the e.m.f. of the inductance with a current of the same value. Our formula for inductive e.m.f. being

$$E = \frac{1,000,000 \, C}{2 \pi n k} \quad (2)$$

this value must be placed equal to (1), since the values of E are assumed equal, which gives us $\frac{6.2832 \times 133 \times 217.6 \times .55}{1,000} = \frac{1,000,000 \times .55}{6.2832 \times 133 \times k}$, or k = 6.58 microfarads.

Referring now to Fig. 2, suppose that in the circuit in parallel with the condenser two 110-volt lamps are placed in series, a lamp taking .55 amperes normally. Since the two lamps are in series, the voltage necessary to send the normal current through them is 220 volts.

To find the value of the condenser current in this case, we substitute in (2) the value of E, or 220, n = 133 and k = 6.58, which gives C = 1.21.

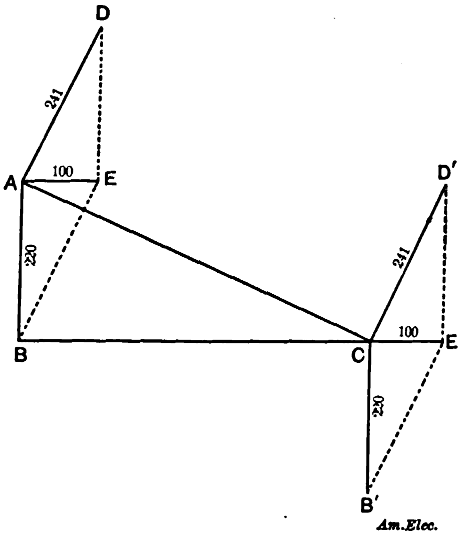

FIG. 4.—E.M.F. TRIANGLE.

It has been shown in previous articles that a current passing through a capacity leads the e.m.f. 90 degrees; on the other hand, a current passing through a plain resistance is in phase with the e.m.f. Consequently, referring to Fig. 3, if A B represents the current passing through the lamps, then B C will represent the current passing through the condenser, and the resultant of these two currents, or the main current passing the inductance, will be A C. Solving the triangle, we find the value of the current passing through the inductance is 1.32 amperes. Substituting this value of current in (1) and also the value of L and n, we have $E = \frac{6.2832 \times 133 \times 217.6 \times 1.32}{1,000} = 241.$ That is, though the e.m.f. between mains is but 100 volts, the e.m.f. between A and B is 241 volts, and the e.m.f. between B and C is 220 volts.

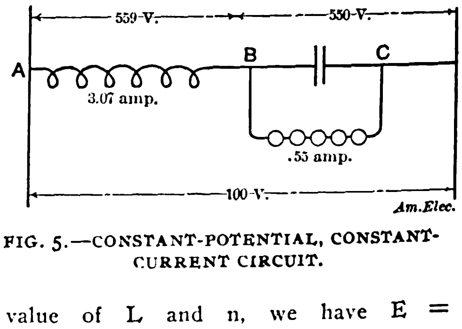

FIG. 5.—CONSTANT-POTENTIAL, CONSTANT-CURRENT CIRCUIT.

To prove now that our supposition concerning the relation between the inductance and capacity is justified, we have to show that the resultant in the above case between 241 and 220 volts is 100 volts.

Referring to Fig. 4, the triangle A B C is, to a different scale, the current triangle of Fig. 3. Since the main circuit A B contains an inductance, the current differs in phase from the e.m.f. by 90 degrees. If, therefore, we draw the line A D perpendicular to the line A C, it will represent the direction of the inductive e.m.f. Since the current in the lamp circuit is in phase with the e.m.f., A B will represent the relative direction of the e.m.f. in that circuit. If now the length by scale of A B is 220, and the length of A D is 241, the resultant of these two e.m.fs., or A E, will be found by measurement to be 100 volts, which proves the supposition made concerning the relating between the inductance and capacity. An analytical proof could also be given. To the right of the figure is another proof, in which the capacity enters, which is left to the reader without explanation.

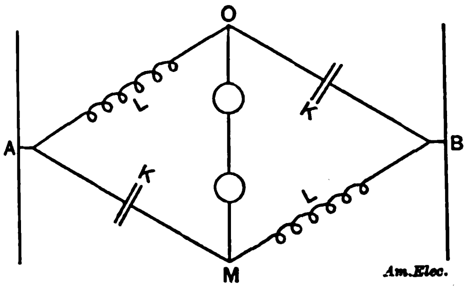

FIG. 6.—CONSTANT-POTENTIAL CONSTANT-CURRENT CIRCUIT.

The data of Fig. 5 illustrates the case where there are five lamps in the circuit in parallel with the condenser, the main current and inductive voltage being found as in the case of Fig. 2.

Boucherot, who proposed the above arrangement* in 1890, has recently modified it as shown in Fig. 6. Here, instead of only one condenser and one inductance, there are two of each, the object being to nullify the idle current. In the case of Fig. 3, the current flowing in the line is 1.32 amperes, and as the voltage across the mains is 100 volts, the apparent watts, or volt-amperes, are 132. On the other hand, there are utilized at the lamps, .55 times 220 =121 watts; in other words, the line current is larger than the useful current in the proportion of 1.32:1.21, or part of the line is so-called idle current. It can be shown, however, that the more lamps there are placed in parallel with the condenser, the less becomes the value of the "idle" current, so that the modified arrangement of Boucherot only has value in special cases.

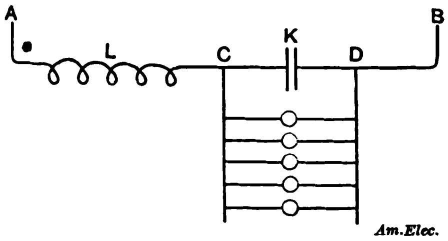

FIG. 7.—CONSTANT-CURRENT, CONSTANT-POTENTIAL CIRCUIT.

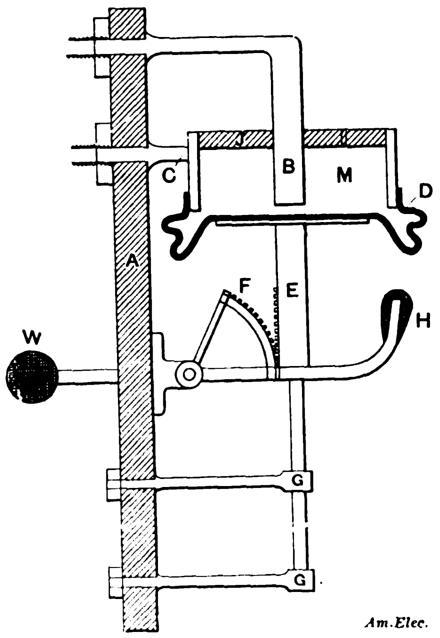
A very singular conclusion from the case illustrated in Figs. 1-5 is that when the circuit in parallel is a short circuit, the flow of current is a minimum; and that when this circuit is broken, the flow is a maximum, the inductance-capacity series circuit then acting, in fact, as a short circuit across the mains.

In the cases above considered, when a constant potential exists between the mains, there is a constant current in the circuit in parallel with the condenser. Referring to Fig. 7, if the inductance and condenser were placed in a constant current line, A B, then a constant potential would always exist between C and D, notwithstanding the number of lamps, or other resistance in that circuit. As the value of the inductance and capacity would be calculated by the same method as given above, this most interesting application of the principle just considered need not be further dwelt upon.

Letters on Practical Subjects

To the Editor of American Electrician:

The accompanying sketch shows a switch for very high voltages and heavy currents, which may be operated without any danger. The special feature of this switch is that there are no moving parts in the circuit, and that there will be very little arcing.



SWITCH FOR HIGH VOLTAGES.

The following references to the illustration will enable the construction of the switch to be very clearly understood: A is a switchboard panel; B and C are contact; D is a rubber bottom and E a supporting rod. F is a gear on the arm H; G, G are binding posts; W a counterweight; M mercury, and J a hard rubber cover.

HENRY P. J. VAN DETH.

Montclair, N. J.

Dry Cells.

To the Editor of American Electrician:

In his letter in the February issue Mr. N. T. Jarvis stated that one of his dry cells gave a current of a little more than ½ amp., while 8 cells gave a little less. I assumed that this was the current indicated on short circuit through an ammeter and based my remarks on this assumption.

The voltmeter Mr. Jarvis employed may be fairly accurate, but on account of its low internal resistance it is not suitable for measuring the voltage of cells having such a large internal resistance as these. The voltmeter indicated the correct voltage of storage cells, but the internal resistance of these cells is probably at least thirty to forty times less than that of the dry cells, so its effect becomes insignificant. The cause of the supposed discrepancy in the voltmeter reading was fully demonstrated by Mr. V. C. Wynne in your April number, who reaches the same conclusions as I did, and it will therefore be unnecessary to go into this any deeper.

It is easily shown that twenty-four cells connected in two rows would give the desired current. Doubling the e.m.f. and keeping the total resistance in circuit constant would double the current. Doubling the number of cells would double the e.m.f., but it also increases the total resistance in circuit by the internal resistance of six cells. But by placing another row of twelve cells in parallel with the first twelve we halve the resistance of our battery, which is now equal to the resistance of the original battery of six cells. The cells are now working under exactly the same conditions as the six cells were, which may be proved as follows:

Denoting the resistance of the external circuit by R, and the current sent through it by six cells by C, we have for the watts delivered to the external circuit, C^2R. Now doubling the current it becomes 2C, and the watts $(2C)^2R = 4C^2R$. The energy delivered is therefore four times as large as in the first case, and it will take four times the number of cells to supply it if they are to work at the same rate of discharge as the six cells did.

P. M. HELDT.

Chicago, Ill.

To the Editor of American Electrician:

There is evidently something uncanny and mysterious and altogether unsatisfactory about those dry cells of your correspondent, Mr. Jarvis, or else he has forgotten his previous statement about them in the February issue, or the printer is sadly to blame.

In the February number we are told that "the current from eight cells is a little less than ½ amp., and the current from a single cell is a trifle more than ½ amp."; whereas, in the April issue he states that "the current derived from each cell was, by ammeter, about 1-6 amp."

If both these statements are true the cells have gone from bad to worse and the sooner Mr. Jarvis discards them entirely the better for his peace of mind. As stated in my former letter, a dry cell with an internal resistance of even 2 ohms is well-nigh worn out, but 6 ohms resistance is so much worse.

---

*The mathematical theory is given in Steinmetz's "Alternating Current Phenomena," pp. 76-82.

There is no reason to assume anything the matter with the voltmeter used, as the resistance of the cells accounts for the fall in the voltage reading. Even in the case of the small storage cells used, the reading of the voltmeter would not be exactly proportional to the number of cells in series on open circuit (so-called), but as the resistance of each cell cannot well exceed 2 ohms, the difference with five cells would be only about .3 volt and not readily noticeable except on a more delicate instrument. With a higher-resistance voltmeter the error would be less.

The mathematical explanation of Mr. Heldt's statement is as follows, and of course this assumes a constant voltage and resistance for each cell: Let E = voltage and R = resistance of 1 cell; r = resistance of all the circuit except the battery; n = number of cells in use at first. Then $\frac{nE}{nR+r} = C$, the current flowing at first. Now, if we double the number of cells in series, we have $\frac{2nE}{2nR+r}$ = the current then flowing, which has a value uncertain and depending on the relative values of R and r. If we put two similar cells in multiple, we virtually double the size of our cell, and therefore halve the resistance; and, if we put two sets of 2n cells in multiple (or parallel), we have $\frac{2nE}{nR+r} = 2\frac{nE}{nR+r} = 2C$, or double the original current. Mr. Jarvis will notice, however, that if R, the resistance of the cells, is very small in comparison with the outside resistance r, then n R in the equation may be almost neglected and the current becomes nearly proportional to the number of cells in series. V. C. Wynne.

◆

ELECTRICA CATECHIS

202. What sort of field exists between the poles of a magnet?

The lines of force go from one pole to the other in nearly straight lines. Between parallel surfaces the lines are straight. The lines of force beyond the parallel surfaces are curves, somewhat as shown in Fig. 1. The magnetic force becomes less and less intense as the distance from the magnet increases, as shown by the lines of iron particles being less and less distinct.

203. What reason is there for believing that the lines of force tend to follow the easiest path possible?

This is a conclusion from the facts that particles of iron are drawn into the magnetic field; that the magnetism is much stronger when its path is largely or entirely through iron; and that the lines tend to become as short as possible.

204. How can it be shown that the lines of force tend to become as short as possible?

This is illustrated by the well-known phenomena of attraction, as when a magnet attracts its keeper. Familiar examples are the telegraph sounder and the electric bell.

205. What is meant by a magnetic line of force?

The term is used either to indicate the direction of the force, or more commonly as a measure of the strength of the field. Perhaps the simplest way to get an idea of the strength of a magnetic field of one line of force is to consider that a wire moving through a magnetic field so as to cut or cross 100,000,000 lines of force per second generates an electromotive force of one volt.

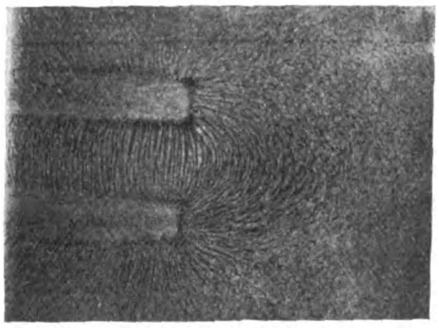

FIG. 1.—MAGNETIC PHANTOM.

206. How is the attraction of unlike poles and the repulsion of like poles explained?

There is no complete explanation agreed upon, although all the actions can be referred to simple laws. There is a tension along the lines of force and a pressure at right angles to them; in other words, the lines tend to shorten and to spread apart with a definite and known force.

207. With how much force do the magnetic lines tend to spread apart?

The force measured in dynes equals 0.08 times the square of the number of lines per square centimeter.

208. With how much force do the lines tend to contract or shorten?

With a force one-half the pressure, or 0.04 times the square of the number of lines per square centimeter.

209. What is an example of a simple motor based upon the attraction of two magnets or between a magnet and a piece of iron?

The electric bell, the telegraph sounder or relay and the telephone receiver are simple electric motors.

210. Explain the principle of the electric bell.

An electric bell outfit consists of four essential parts, the bell, the battery, the push button or switch, and the connecting wire. When the button is pushed the circuit is closed, and current from the battery passes through the circuit. In the bell it passes through the coils of an electro-magnet, thereby magnetizing its soft iron core. This attracts the soft iron armature and draws it closer to the coils, and thus the hammer at the end of the armature strikes the bell. But when the armature is drawn up the spring behind it is drawn away from the contact screw, and thus opens the circuit and stops the current. This causes the iron core to lose its magnetism, so that it can no longer hold the armature against the pull of the tension spring. The armature, therefore, falls back until its spring touches the contact screw, when the circuit is closed again, and the same action is repeated. Thus the armature oscillates back and forth, opening and closing the circuit automatically, and we have an elementary motor, which operates so long as the circuit is closed at the push button or switch. The principal parts of the bell are shown in Fig. 2.

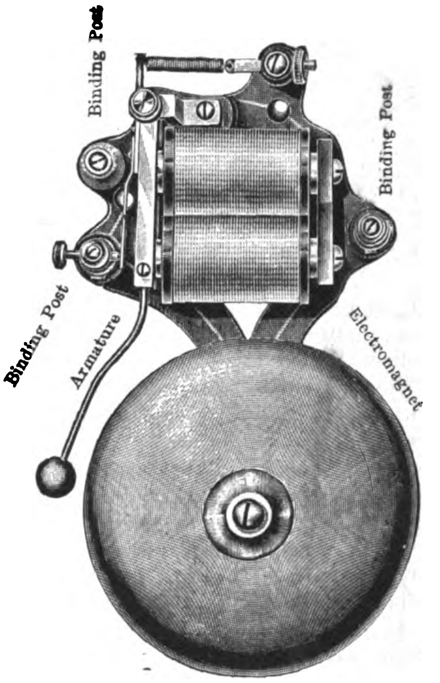

FIG. 2.—ELECTRIC BELL.

211. What is a "single stroke" electric bell?

The vibrating contact is removed so that there is no automatic make-and-break in the bell itself. The armature is therefore attracted only once, and strikes the gong one blow each time the circuit is closed at the switch. It is thus suitable for giving signals.

212. What is an electro-mechanical bell?

Electro-mechanical bells are usually single stroke. When the magnet attracts its armature this releases some sort of a catch or trigger that sets free a train of clockwork which strikes the gong a harder blow than would be practicable with the magnet alone. The electro-magnet thus acts as a sort of relay or starter, while the blow on the gong is struck by a mechanism driven by a spring or weight.

213. What is a buzzer?

A buzzer is electrically the same as an ordinary electric bell, except that there is no gong. The armature vibrates rapidly and makes a buzzing noise that is sufficient to attract the attention of a person near by.

QUERIES AND ANSWERS

What margin of h.p. is usually allowed between the indicated h.p. of an engine and the total out-put of a dynamo? L. E. S.

The horse power should be about twice the kilowatt capacity of the machine.

What is a good varnish for copper? J. K. B.

One part of carbon di-sulphide, 1 part of benzine, 1 part of turpentine, 2 parts of methylic alcohol and 1 part of gum copal.

What is the rate of deposition of electrolytic copper? S. N.

About one pound per 450 ampere-hours. The current density is about 10 amperes per square foot, counting both sides of the anode.

How can the three-wire system be operated from transformers? C. M. A.

By placing two transformers in series and running the neutral from a point between the two. Three-wire transformers are manufactured with a neutral connection to the middle point of the secondary.

Is there any rule for the allowable current density in interior electrical conductors? J. B. S.

One thousand amperes per square inch is the rule used in the navy, but in work ashore the current density or carrying capacity is fixed by the Underwriters' electrical code.

How can the polarity of an electrical source be determined? L. E.

Connect the two poles or two sides of the circuit to be tested with two small pieces of lead dipping in a glass of water, acidulated with sulphuric acid. The piece of lead connected with the positive side will turn brown.

Why is concentric wiring not permitted in this country by fire underwriters? N. M.

We do not know the reason. Concentric wiring has given much satisfaction abroad, being very largely used in Great Britain. It would appear to involve less fire risk than the ordinary system of wiring, besides being cheaper to install.

Why does joining in parallel of two circuits of a transformer secondary reduce the voltage? L. E.

If two cells of primary battery in series are connected in parallel, the voltage will be halved; since the two parts of the secondary circuit are also seats of e.m.f., the same result will follow if they are placed in parallel.

Would it not be advisable to wind a 20-k.w. smooth core bipolar 110-volt direct current machine, with strip copper, in place of the six wires in parallel with which it is at present wound? J. S. J.

It would not be advisable on account of the loss of eddy currents that would ensue. Strip conductors may be used in slots, but not on a smooth core.

What are the core dimensions and windings of a telephone transmitter induction coil? N. L. D.

For granular carbon transmitters, on a core of soft iron wires, 4¾ ins. long by 1" in. in diameter, wind about 150 turns of No. 36 wire for the primary. For the secondary, about 4000 turns of wire of the same size may be used.

I have made a static machine, but it will not excite. The glass plates are 3¼ ins. apart, and there are two Leyden jars, both connected from the inside. J. W.

The plates are too far apart. The outside coatings of all the jars should be connected, and the inside coatings of the jars carrying one comb should be carefully insulated from the inside coatings of the set carrying the other comb.

What is the voltage of a sulphate of mercury cell, and is such a cell subject to local action on open circuit? C. S. H.

The Marie-Davy type of cell referred to is merely a Bunsen cell, in which the nitric acid is replaced by sulphate of mercury, and, as in the case of the Bunsen cell, there is no local action on open circuit. The voltage varies from 1.3 to 1.5, depending upon the degree of acidulation.

If a spectrum of light from an arc lamp were obtained through a prism, what would be the effect if a thermometer were slowly passed from one side of the spectrum to the other? G. H.

The mercury would rise in the thermometer as it was moved from the violet toward the red ray, and would continue to rise for some distance beyond the latter. The heat spectrum has its maximum beyond the red, and overlaps the light spectrum.

I have been unable to make T. H., Brush and W. E. lamps work on the same circuit. Is there any reason for this? D. B.

Brush and T. H. lamps will not work well on a closed coil arc machine, these and some other types requiring the pulsating current of the open coil, or T. H. or Brush machines, in order to create a slight vibration in their mechanisms to keep them from sticking. A differentially wound lamp will also not work well with shunt wound lamps.

What is a good insulating material for wood bobbins and cores? J. L.

A French recipe is for a mixture of 10 parts of yellow rosin and 1 part of white wax. First dry the bobbins during five hours at a temperature above the boiling point, and then quickly plunge them into the mixture, the temperature of which should be about 350 deg. F. After the bobbin is inserted let the mixture cool and take out the bobbin when it becomes slushy. The covering on the surface is removed by warming the bobbins.

Why is the cross section of one of the wires of a three-phase line taken at half the cross section of one of the wires of a direct current line transmitting the same energy? H. H. B.

Calling the cross sectional area of one conductor of the last mentioned line A, the total cross section will be 2 A. In the three-phase system there is a saving in copper of 25 per cent, which reduces this cross sectional area to 6A : 4. Since there are three wires the cross section of one wire will consequently be one third this, or ½ A.

We have a T. H. 30 h.p. railway motor which we wish to change to a shunt motor. How may this be done? H. A. T.

Knowing the current used normally by the machine running as a series motor, multiply this quantity by the number of series turns, which will give the ampere turns of the shunt motor. Assuming that two amperes will be used in the shunt, the number of shunt turns will be found by dividing the above quantity by two, and the resistance of these turns will, for a 500-volt circuit, be 250 ohms. If three or four amperes are used, the resistance will be correspondingly reduced.

Why does a machine have a different rating as a motor and as a dynamo? J. P. L.

Assuming the same current in each case, and the same E.M.F. at binding posts, the motor will have less power: First, because the E.M.F. absorbed in the armature does not appear at the binding posts in the case of the dynamo, but does in the case of the motor; if this is 10 volts, the electrical energy in a 110-volt dynamo is $C \times 120$, and that in the motor, $C \times 100$. Second, in the case of a dynamo the mechanical losses of friction are supplied mechanically at the pulley, but in the case of a motor, must be subtracted from the electrical energy supplied. A good rule is that a motor will develop at the pulley 75 per cent of the pulley power required to run the same machine as a dynamo, the voltage and current being the same in each case.

Will you please explain the following occurrence which recently came under my observation: A telegraphic wire was grounded 30 miles from a city, the wire being connected with other offices on both sides. Soon after grounding the sounder clicked, showing that the current was on, and almost immediately a musical note was emitted, the sound filling the entire room and being of about the note E in pitch. This was continued for nearly two minutes, and then ceased. All the line current was supplied from the city, from which the line wire runs on the same poles as the telegraph wires of a railroad line. S. L.

A number of causes may be given, such as an alternating current at some point getting on to the wire, a cross between the coil and core of the relay, a buzzer inserted in the circuit somewhere for fun or otherwise; an imperfect vibrating contact would perhaps set up a tone; the box of the relay probably acted as a resonator, making the effect more pronounced.

What means of protection have been adopted to prevent primary currents from entering buildings, due to the breaking down of transformers from lightning and other causes? S. S.

The Cardew earthing device, much used in England, consists of a piece of aluminum foil, one end of which is fastened to a plate connected to the primary, the other end being attracted to an opposite ground plate when the primary is connected with a grounded secondary, the primary thus being grounded. The Thomson film cut-out is a thin film of paper placed between two plates, connected as above, which is pierced by a potential of 300 volts. The Thomson ground shield and grounded secondary consists of a sheet of metal placed in the transformer between the primary and secondary windings in such a way that it is impossible for any current to pass from the primary toward the secondary without encountering the metal shield, which is grounded.

New Apparatus and Appliances.

HIGH VOLTAGE INSULATORS.

In the descriptive account of a new type of high-voltage insulator, on page 178 of April issue, the following paragraph was omitted by the printer.

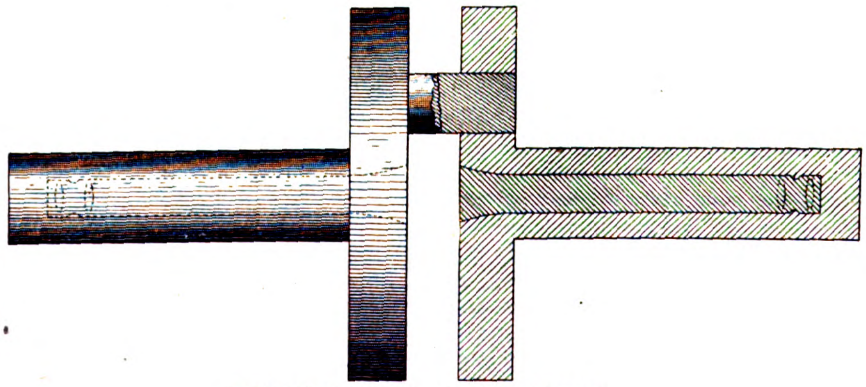
The insulators being made of a high-grade porcelain body, thoroughly vitrified, and with the glazing as described above, reduce the danger of a breakdown through puncturing between the conductor and iron pin to a minimum. This type of insulators is manufactured by the R. Thomas & Sons Company, East Liverpool, Ohio, under the "Boch" Patent No. 600,475, issued March 8, 1898.

COMBINED CRANK SHAFT AND DISK.

The crank shaft construction shown in the accompanying illustration consists of a shaft and disk of one piece of gun metal or one integral casting, with a steel core or strengthening rod cast in the center of the shaft and made a part thereof.

In casting, the strengthening core is supported in a mold and the metal poured or cast so as to form the disk and the shaft covering the core, the latter being flared at the disk end and scored at the opposite end. The core is heated to a degree which will enable it to become fused with the molten cast metal surrounding it, thus establishing a firm physical union between the core and the cast portion.

This construction has been used by A. L. Ide & Sons, Springfield, Ill., for several years past, and on April 5 a patent was issued in the name of the late A. L. Ide. We are informed that out of several thousand engines equipped with these shafts, not one has failed to withstand the greatest strain of the most exacting service. It has also been found that the gun metal makes a more serviceable, better wearing and more perfect journal than a shaft where the steel comes in contact with the babbitt of the bearing.



COMBINED CRANK SHAFT AND DISK.

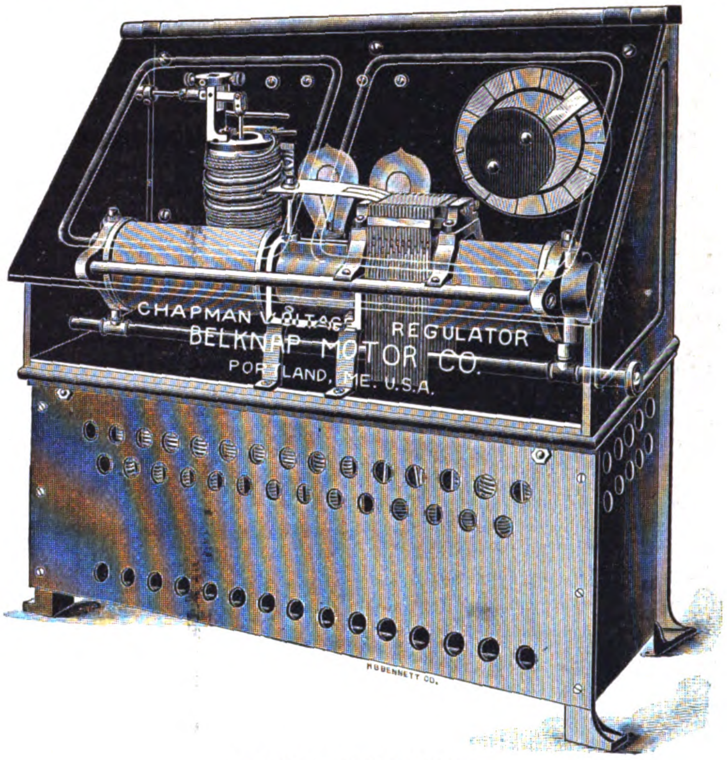
VOLTAGE REGULATOR.

The new type of voltage regulator shown herewith consists of three essential parts—a set of resistance coils to be inserted or removed from the field magnet circuit of the generator to be regulated; a working solenoid to do the work of inserting and removing the coil from the circuit, and an auxiliary solenoid to determine the movement of the working solenoid.

The resistance coils are made of German silver and the size of the wire used is such as will afford ample capacity to control the field current of the generator for which it is constructed. These coils are connected to a series of copper segments placed in a horizontal row, and having a contact slider arranged to move over their surface. This contact slider is operated by being mechanically connected to the moving core of the working solenoid.

The working solenoid consists of two differentially wound coils of wire placed on a brass tube, one at each end of the tube, and the whole placed in a horizontal position. The middle portion of the tube is left vacant. Inside of the tube is fitted a soft iron plunger somewhat shorter than the distance through the two coils; at the center portion of the plunger a rod is attached which passes out through a longitudinal slot cut in the vacant portion of the tube. The contact slider above described is attached to this rod and so moves with it and with the iron plunger.

In order to prevent too quick a movement of the plunger, a very simple and ingenious retarding device is used, in which the moving iron plunger is made to serve the purpose also of an oil pump. From one end of the brass tube to the other a small pipe is connected, having a hand valve in it, to regulate the flow of oil. The two ends of the brass tube, together with its connecting pipe, are completely filled with oil and closed up tight. The movement of the iron plunger toward either end can then take place only as it displaces this oil and causes it to move through the pipe and to the other end, the rapidity of which movement can be very finely adjusted by means of the valve above described.

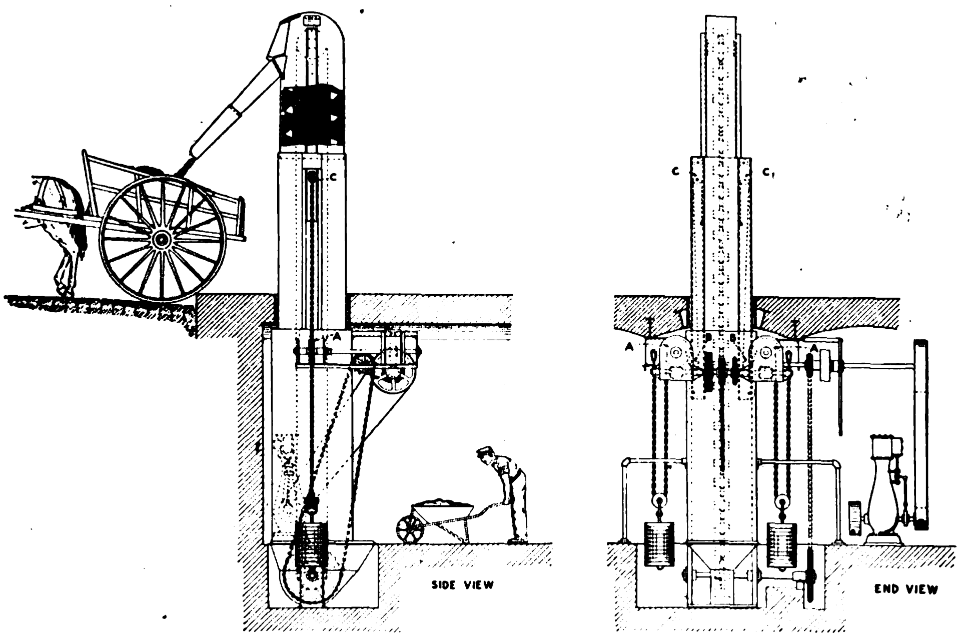


VOLTAGE REGULATOR.

The force tending to move the iron plunger depends on the balancing against each other of oppositely wound coils, and this balancing is determined by the action of a small auxiliary solenoid whose only work is to cause one or another of two platinum pointed screws to make contact with the brass lever supporting its core. Contact with one screw causes perfect neutralization of the differential coil at one end of the working solenoid, and so disturbs the balance and causes the plunger to move forward the other coil; contact with the other screw causes neutralization of the coil at the other end and a movement in the other direction. The small solenoid may be wound to suit a variety of purposes, any one of which may be required in fulfilling the demands of station regulation.

First, it may be wound with a simple fine winding to be connected as a shunt across the lines to be regulated, and in this case it will secure constant-potential regulation at the point of attachment to the line.

Second, it may be wound with a fine winding as before, and also with a coarse winding, the fine winding connected as a shunt to the line, and the coarse winding in series with the line. In this case it will regulate for constant potential at some distant point on the line which may be predetermined by the setting of an adjustable compounding switch provided as a part of the regulator.



TELESCOPIC ASHES ELEVATOR.

Finally, the small solenoid may be wound with a single coarse wire placed in series with the line; in this case it will secure regulation for constant current in the lines.

But whatever be the nature of the regulation, the small solenoid will perform its duties with an accuracy as close as 1 per cent above or below the normal, and is adapted to either direct or alternating currents. Alternating currents are especially capable of close regulation by this instrument, as the slight jar incident to its flow through the small solenoid almost entirely eliminates the element of friction at the pivots of the lever supporting the core, and it will easily recognize a change of ½ of a volt on a 110-volt circuit.

The Belknap Motor Company, of Portland, Maine, manufactures the regulator described, known as the Chapman voltage regulator.

TELESCOPIC ASHES ELEVATOR.

The ash-handling apparatus illustrated herewith is being installed by the U. S. Appraisers' Warehousing Company, in New York City, and will handle ashes at the rate of 18 tons per hour. The outline sketch shows it in operating position. The ashes are thrown into the hopper-shaped boot, and buckets attached to a single strand of chain scoop them from the bottom of the boot, carry them over the head wheel of the elevator and drop them into the inclined discharging chute. The boot, about 3 ft. deep, is placed below the floor line of the basement, making it an easy matter to dump the ashes into it.

To comply with the legal requirement that the elevator shall not permanently obstruct the sidewalk, the machine is so made that when not in use the part above the pavement may be telescoped into that in the basement; hence the name of the device. From the floor level to the sidewalk is a distance of 11 ft., and as the upper portion of the elevator is about 13 ft. long, it is necessary that this part shall be in two sections. The upper of these is designed to telescope into the lower, thus making it possible to slide the 13 ft. above ground into the 11 ft. erected below the surface.

The second and third sections, constituting the upper portion, when being hoisted are slid on wheels and rollers set in the channel iron sides of the structure, which minimizes frictional resistance. This, together with the counter weights employed, makes raising a matter in which the motive power is found to be an inappreciable quantity.

The raising is done by two sets of worm gearing, chains and counterweights. The chain passes from its counterweight and over the wheel "A," which is actuated by the driving worm shown. The wheel "B" is on the lower end of section two. The chain running under it completes the first portion of the leverage, and thus the second section may be placed in working position. In like manner the third section is hoisted, the chain continuing to and over the fulcrum wheel "C," at the top of section two, and being fastened at the lower end of No. 3 section. In lowering, the worm gearing is run in a reverse direction, and as the sections descend, the counterweights rise to the ceiling of the basement. The projecting discharge chute and the hood above it are folded over the top of the elevator previous to the operation of telescoping and disappear with it.

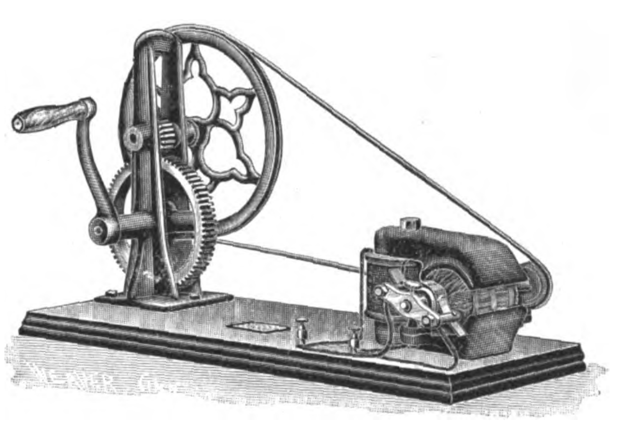
That the elevator shall not drop the ashes except into the carts, it is completely inclosed in a steel casing. The hoisting and lowering mechanism is outside of this casing, and the worm gearing, which runs in an oil bath, is covered by a housing so that ashes cannot come in contact with these parts.

Some time since, to meet the demand for a chain that would stand the hard service of conveying and elevating the gritty material of the South Africa diamond fields, there was devised a chain known as the "Ley Bushed," which consists of strong malleable-iron links fitted with steel bushings and pins. These bushings and pins take all the wear that comes on the chain, and after being worn out may be replaced at a comparatively small cost. A chain like this is particularly desirable for handling such an abrasive material as ashes, and it is employed in the elevator described.

The machine described above was designed and is being built by The Link-Belt Engineering Company, of Philadelphia and New York. During the earlier stages of the evolution of this machine, they installed somewhat similar outfits at the Waldorf Hotel, New York City, and at the Philadelphia City Hall.

MODEL EXPERIMENTAL DYNAMOS.

In the accompanying cut is shown an experimental machine designed for the instruction of students and the use of amateur investigators. It has an output of 75 volts, and is made for either direct or alternating currents, or for both combined. This machine, which is wound for any voltage from 5 to 25, is made by the T. & H. Electric Company, Eldridge, N. Y.



MODEL DYNAMO.

ELECTRIC ELEVATOR WITH NON-REVERSIBLE MOTOR.

The electric elevator shown in Fig. 1 possesses the rather novel feature of being a strictly high-duty machine in which the motor runs in but one direction. The reversal of the movement of the car is accomplished, not by means of some complicated electrical device, but by a mechanical expedient which has stood the test of half a century, that is, friction gearing. In taking up the problem of electric elevators, the manufacturers considered that with the rapid manipulation made necessary by modern practice no system in which the motor is started, stopped and reversed with the car would meet the requirements.

In carrying out this idea in practice, upon the worm shaft are mounted two bevel iron friction gears, either of which may be engaged with a specially prepared paper friction gear upon the motor shaft, the engagement with one iron friction gear producing the upward movement of the car and the engagement with the remaining one the reverse movement, the motor, as before stated, being non-reversible.

Believing that the whole apparatus should be built in one shop, the next step was to bring out a suitable motor and controller, the result being the inclosed multipolar motor and auto-starter shown. The latter is entirely mechanical in action and free from magnets and dash-pots, the rheostat being manipulated by a centrifugal device mounted upon the motor shaft, thus giving a positive control of the resistance.

The motor field is in one piece of cast steel, with diagonal pole pieces. The armature is slotted to receive machine-wound coils of uniform length, giving an armature symmetrical both electrically and mechanically. The method of winding is shown in Fig. 2, which is a half-finished armature in process of winding.

A system of rating has been adopted for this apparatus based upon speed as well as output. The normal rating is for the output at a uniform speed of 1000 r.p.m., a table showing, however, the output at other speeds.

The manufacturers of the elevator described are the Armitage-Herschell Company, North Tonawanda, N. Y.

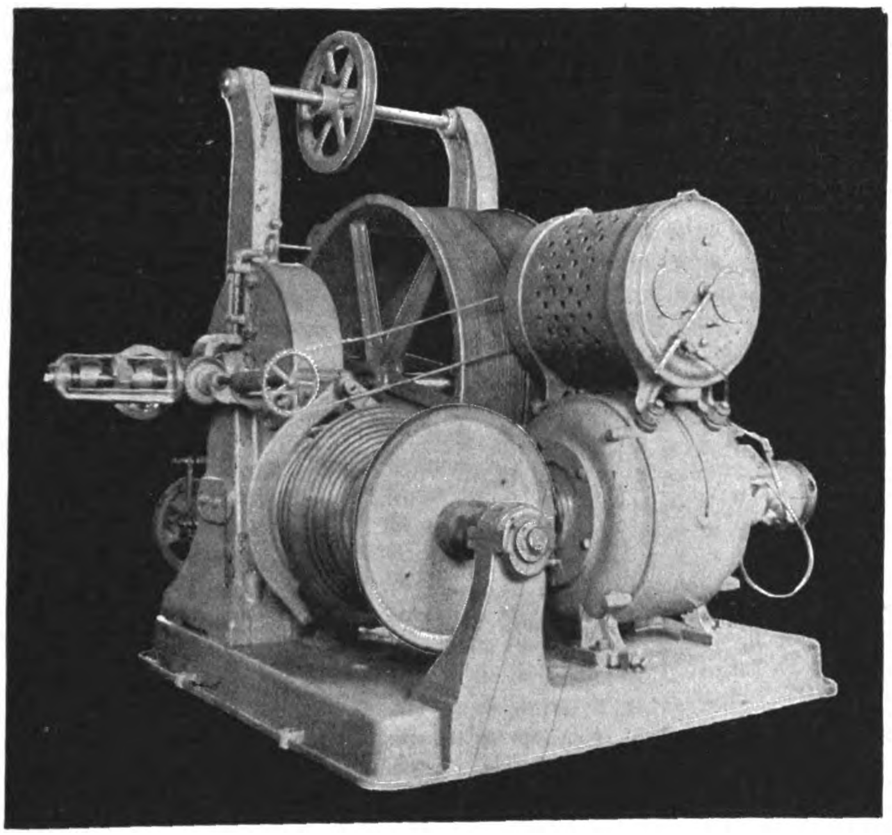


FIG. 1—ELECTRIC ELEVATOR WITH FRICTION GEARING.

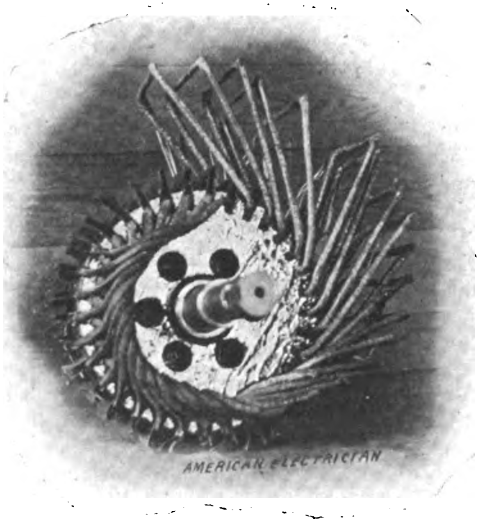

FIG. 2—MOTOR ARMATURE.

STREET CAR ELECTRIC HEATER.

A new type of street car electric heater is shown herewith in one of its forms, which, as will be seen, is highly ornamental in appearance and in keeping with the finish of modern cars. The heater shown is constructed for placing under seats without panels, and may be fastened either to the floor of the car, to the side, or to the under part of a seat. It will be noticed that the shape of the shell containing the heater is such as to allow all heated air to escape freely and quickly from the inner case, the hottest air thus not being retained in the shell to cause discomfort to those sitting above it.

The heater proper consists of a resistance coil of non-oxidizable wire, which is wrapped back and forth around the core. This latter is built up of sections of porcelain placed upon a square iron bar, the wire being looped back and forth over the projection shown. It will be noted that

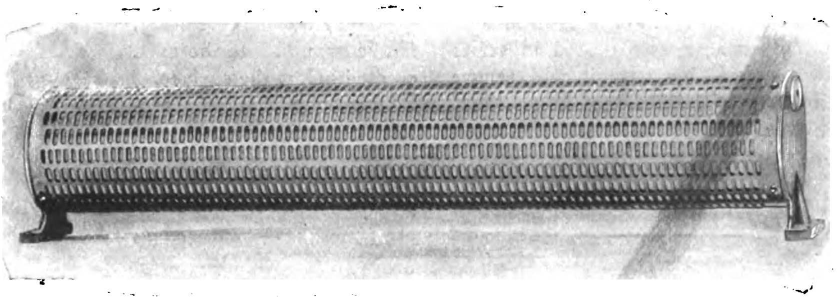

FIG. 1—ELECTRIC HEATER.

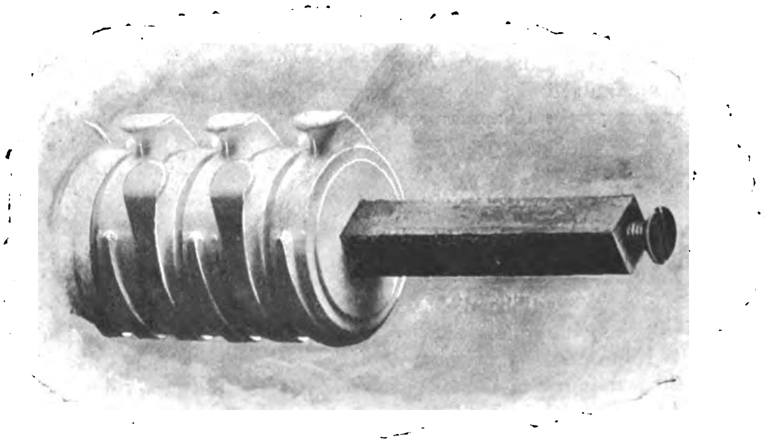

FIG. 2—CORE OF ELECTRIC HEATER.

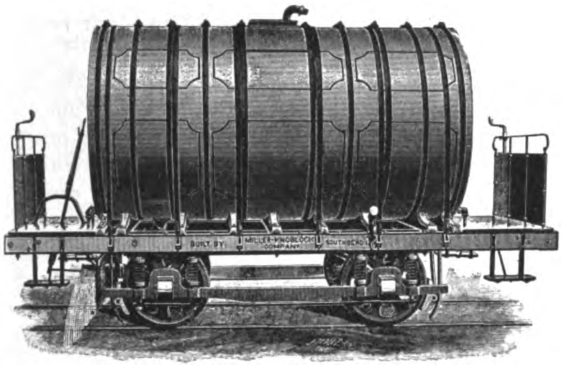
there is a groove formed by the porcelain sections of the core, which allows a circulation of air between the resistance coil and the core, thus materially increasing the radiating surface of the coil and the effectiveness of the heater. The construction of the heater is also such that the resistance coils may be easily cleaned of any accumulations of dust. The manufacturers of this type of heater are the Safety Car Heating & Lighting Company, 160 Broadway, New York City.

ELECTRIC CAR SPRINKLER.

The sprinkling of streets by means of electrically propelled cars seems to be in line with the modern idea of progress, and we illustrate herewith such a car which has come in quite general use. The cars are of two styles, one which operates by gravity only, the width of the spray consequently being limited. These cars are used for sprinkling the tracks and a few feet outside of the outer rail, and are for such sprinkling as is done by street railway companies for their own and their patrons' benefit. It has been found that wetting the rails and the space between them is of considerable advantage, on account of keeping the dust out of the journals and motors, and out of the cars, besides increasing the conductivity of the rails.



STREET-CAR SPRINKLER.

The wide-throwing electrically operated cars are intended for sprinkling the street to the curb, and from them the water is thrown from 30 to 40 feet outward. They are fitted with electric ejectors which throw the water outward and cover the street between the track and the curb, the operation being instantly regulatable. A technical description of these cars is contained in a circular issued by the manufacturers, the Miller-Knoblock Company, South Bend, Ind., from whom a copy can be obtained on application.

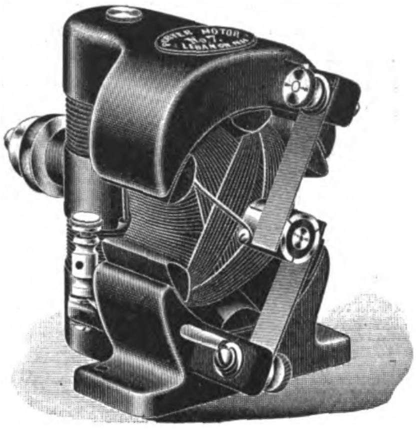
BATTERY MOTOR.

The motor illustrated herewith has been designed for the highest efficiency, and though intended more particularly for use with batteries, it is also wound for 110-volt direct current circuits. The armature has six poles and revolves in a single recessed brass-bushed bearing, thus insuring the least possible friction. The field connections are made inconspicuous by leading the terminals through the field poles to the binding posts, which also safeguards them. The commutator is made of brass tubing in three or six segments mounted on hard rubber. The brushes, which are of hard spring copper, are easily adjusted or removed by means of thumb screws. The machine is supplied with a lubricating device. The motor weighs only 5 lbs., but is capable of carrying an 8 or even a 10-in. fan, if mounted on a bracket. It is finished in black or colored enamel, with full nickel-plated trimmings, and is run from two cells in primary battery.

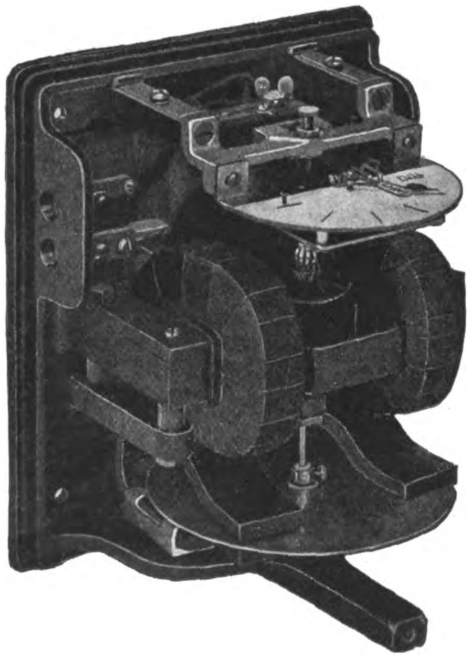
The motor described is made by the Porter Standard Motor Company, Lebanon, N. H.

STORAGE BATTERY METER.

The General Electric Company has developed a special type of meter which will show at a glance the amount of energy available in a storage battery. The meter resembles in general appearance the standard Thomson recording wattmeter, and is, in fact, a development from it, the mechanism being almost exactly similar. The meter is provided with a single indicating needle moving over a horizontal semi-circular dial.



BATTERY MOTOR.



STORAGE BATTERY METER.

The essential requirement for a storage battery meter is that the armature shall rotate in either direction and give equally accurate readings in both. In this meter this requisite is fully preserved. The energy put into the cells is, therefore, added to the reading of the meter, while the energy withdrawn is subtracted, but to compensate for the loss in the cells the meter runs more slowly when charging. The reading of the meter represents, not the amount of energy put into the battery, but the amount available, and when the needle points to zero on the dial, it shows that the battery is completely discharged.

These meters are manufactured with any desired percentage difference between charging and discharging rates, and in all standard sizes. Since, however, this percentage varies in almost every case, the General Electric Company manufactures them only to order.

Electric Motors.

That electricity as a motive power for every class of machinery is bound to entirely supersede steam, is probably quite generally appreciated by power users. Nevertheless, it is also probably true that **the ideas of a great majority of those interested are rather vague on the subject, and** therefore a statement of a few facts will not be without benefit.

Wherever shafting and belting are employed, the waste of power ranges from 25 per cent to sometimes an excess of 80 per cent. Incredible as the latter statement may seem, it can be supported by the result of actual tests. As an illustration, tests recently made by Prof. J. J. Flather at the Baldwin Locomotive Works, Philadelphia, showed that 80 per cent of the power regularly employed was consumed in operating shafts and belts. This, of course, is due to the fact that enough power has always to be transmitted to operate all the shafting and belting, while the machines in this plant, which are of large power, are far from being in continuous operation. Prof. Flather also measured the loss of power in a number of large machine tool works and his report stated that in no one instance did the net loss of power fall below 25 per cent, while the average was 41 per cent. Prof. C. H. Benjamin, in tests of sixteen different factories, each engaged in different kinds of work, found that in no instance did the total waste of power fall below 47.3 per cent, and it ranged as high as 80 per cent.

The printing trade has perhaps been in the lead in taking advantage of the saving incident to the use of electric motors. Among recent installations of this kind are those of the American Book Company and the American Lithographic Company, both of New York. The first mentioned uses motors of the geared type, while the Lithographic Company uses the same type of motor—the Lundell—but direct connected. The engineer of the American Book Company is authority for the statement that not less than $35 per day is saved to his company in the cost of fuel alone, while the American Lithographic Company reports a saving of 44.2 per cent in light, heat and power since the installation of the electrical plant.

A recent notable instance of the recognition by a large house of the economy of electric motors is that of the John Stephenson Company, of Elizabethport, N. J. Each of the machines used in these works will have an independent motor of the Lundell type. The sizes will range up to a 40-h.p., some of them geared and some of them direct connected. This plant will be one of the largest of its kind in the world, and will be a standard illustration of the economy and durability of electric motors.

PERSONAL.

Mr. Chas. Chamberlain has been placed in charge of the press bureau of the Electrical Exhibition. Mr. Chamberlain is one of the best known newspaper men in New York, and on account of his close relations with the metropolitan press and acquaintance with the New York representatives of out of town newspapers his appointment is an ideal one.

Mr. W. F. Osborne, for the past eight years the Eastern manager of the "Western Electrician," has severed his connection with that journal, and will hereafter be identified with the "National Provisioner" as business manager. This journal, which is the leading paper in its field, is fortunate in having secured the services of Mr. Osborne, who had built up an enviable reputation in electrical journalism, and has been one of the most popular of its members in his relations with all identified with the electrical industry.

Mr. W. L. Patterson, for some time past chief engineer of the Union Depot Railway lines in St. Louis, has resigned his position with that road to open an office in connection with Mr. C. L. Wait, formerly of Chicago, and engage in the business of mechanical and consulting engineers. Mr. Patterson's high reputation as a first-class mechanical engineer was well demonstrated by the skillful manner in which he restored order out of chaos when he took entire charge of the wrecked power plant of the Union Depot Railway Company subsequent to the terrible cyclone in 1896. Mr. Patterson's many friends wish him the full mead of success, which his ability deserves.

NEW BOOK.

Modern Switchboards. By Albert B. Herrick, Philadelphia: The Cutter Electrical and Manufacturing Company. 153 pages, illustrated. Price, $3.

Few technical treatises have been produced in this country in a style so elaborate as the present one which, in illustration, typography, paper, printing and binding easily takes rank as an edition de luxe. The titles of the chapters are as follows: Circuit-Breaking Devices; Switchboard Construction; Switchboard Appliances; Protective Devices; Low-Tension Switchboard; Low-Tension Central Station Switchboards; Railway Switchboards; Alternating-Current Switchboards; Arc Light and Special Switchboards; Circuit Breakers and Their Use in Power Transmission; The Development of the Circuit Breakers. As indicated in the sub-title, the work deals largely with switchboard appliances, numerous forms of which are shown in excellent engravings, including several in colors.

BUSINESS NEWS.

J. Jones & Son have removed to 64 Cortlandt street, where they occupy the entire building. The greatly increased space has permitted a large additional stock of goods, bought at very favorable terms, to be laid in, thus enabling close price to be made, and prompt delivery effected.

Incandescent Lamps.—A beautiful specimen of artistic catalogue work has been issued by the Buckeye Electric Company, of Cleveland, Ohio. The various types of lamps manufactured are shown in excellent cuts, and each page contains one or more marginal sketches illustrating an application. The binding, which is of heavy cardboard, is unique, the front cover having a cloth hinge.

Correspondence Instruction.—The Institute for Home Study of Engineering, Cleveland, Ohio, has issued an 1898 edition of its catalogue, which enables a very thorough idea to be formed of the character of the course taught and the methods of instruction. In this issue the name of Prof. E. P. Roberts appears as the head of the department of mechanical and electrical engineering and technical director.

The Ohio Electric Specialty Mfg. Co., Troy, Ohio, is meeting with much success with its lines of rheostats and motor starters, among the features of this apparatus being an improved method of insulating the resistances. The automatic motor starter is fitted with an overload device which affords complete protection to the armature, and speed regulating rheostats are built with a good heating margin. Among the specialties of this company are the "Perfection" brush and the Rogers commutator compound.

Fine Exhibit of the Walker Company, of Cleveland.—The Walker Company, of Cleveland, will exhibit at the Electrical Exposition at Madison Square Garden, New York, two of their No. 20 L motors, mounted on truck; one No. 20 L motor, dismantled to show construction; two No. 4A street car motors, mounted; one 50-k.w. belted alternator; one 50-k.w. street lighting generator, direct connected to Armington & Sims engines, type "S" controllers, assembled and dismantled; railway switchboard complet with feeder and generator panels; ornamental arc lamps; new Walker recording wattmeter, and a large display of photographs of its apparatus. Besides this, there will be a complete section of the new underground conduit with a Broadway car shown in operation. Mr. J. S. Anthony, of the home office, will be in charge, and is now in the city preparing all of the work.

The American School of Correspondence, 156 Tremont Street, Boston, offers to those engaged in electrical pursuits an excellent opportunity to secure a thorough and practical technical education, under the direction of men of acknowledged ability in the engineering field. The school makes a specialty of electrical, mechanical and steam engineering, and has spared no expense to make these courses simple, comprehensive and scientific, and all students have the advantage of being under the personal supervision of some of the best electrical and mechanical experts in the country.

The Electric Light Convention.—The New York Central will provide special accommodations for all those who desire to attend the twenty-first Convention of the National Electric Light Association, to be held in Chicago, Ill., June 7, 8 and 9, 1898. Half the pleasure of attending the convention will be the ride to Chicago over the superb New York Central route. The roadbed is the finest in the world, the dining and sleeping cars are all that can be desired, and the service and all the appointments are perfect. A rate of one fare and a third for the round trip will be granted on the certificate plan

United Correspondence Schools.—The United Correspondence Schools, 154 Fifth Avenue, New York, makes a specialty of its electrical courses, which number seven in all, as follows: Complete electrical engineering, electric station engineering, complete station engineering, electric lighting, electric railway, electro-plating and telegraphy and telephony. As a consequence of the complete manner in which these branches are covered, the number of electrical students enrolled is very large.

Electric Elevators.—Considerable interest is attached to the exhibit of the electric elavator machine for the London Underground Railway, which is to be shown at the Electrical Exposition to be held at Madison Square Garden, commencing May 2. The London machines of this type, which are the largest elevator machines ever built, were made by the Sprague Electric Company. One of the latest electric elevator contracts awarded the Sprague Electric Company is for an outfit of ten machines for the Commerce Realty Building in St. Louis. This is but one of a large number of out-of-town contracts recently awarded the Sprague Company.

Montauk Multiphase Cable.—The Montauk Multiphase Cable Company, 100 Broadway, has received a strong indorsement from the well known Gamewell Fire Alarm Company, which has adopted the multiphase electric cable for use. After a thorough examination of the system, the president of the company informed the owners that the cable is something long known to be desirable, but hitherto considered impracticable, and is a device which the Gamewell Company can safely use for the purpose of combining thermostatic fire alarms with its auxiliary system of connection with public fire alarm telegraph. The weight of this indorsement will be evident when it is considered that the Gamewell Company is the parent of the present fire alarm system, which is used in over 700 of the largest cities in the United States, its apparatus comprising more than 90 per cent of all the fire alarm apparatus used in the United States and Canada.

The Westinghouse Electric and Manufacturing Company has just opened a new branch office at Austin, Texas. Mr. J. E. Johnson will have charge of the office and of the further extension of Westinghouse business in the Southwest. The large contracts which this company has been handling in Mexico and the Texas region have led to the establishment of this new center of electrical trade.

The Burnham-Hall-Chase Company of Boston, report a constant increase of business among surgeons, physicians and dentists for their storage and "Excello" primary battery outfits. These outfits are also highly recommended for running sewing machines and all such work as requires small power. The "Excello" improved gravity battery is well adapted for the work of charging storage cells.

Telephones for the Army.—The Pennsylvania Electric Company of Marietta, Pa., has received a large order for telephones from the War Department to be used for the forts, coast defense and signal stations along the Atlantic coast. The company received instructions to rush the order. This is quite a compliment to the Crescent telephone apparatus, as no doubt all other makes were considered before the order was placed.

Kohler Brothers, Monadnock Block, Chicago, have taken the sales agency for the Northern Electrical Manufacturing Company of Madison, Wis., for the States of Illinois, Iowa, Missouri, Indiana, Nebraska, Kansas, Kentucky, Tennnessee, Michigan, Ohio, Pennsylvania, New Jersey, Maryland, Delaware, and District of Columbia, and are now prepared to figure on all kinds of direct-current electrical apparatus up to 250 kilowatts.

The Ohio Electric Specialty Manufacturing Company, Troy, Ohio, is vigorously pushing the sale of Rogers' lubricant. This lubricant, composed largely of graphite compound, with other first-class lubricating materials, is in stick form, and requires a small amount at each application. This company is also manufacturing a full line of woven wire brushes in all forms and sizes, both lubricating and non-lubricating, and of any desired flexibility.

The Woolverton-Elliott Electric Company has opened an electric repair shop at 442 Niagara Street, Buffalo. Its specialties are armature winding, commutator filling and new armature and commutator building. Special attention is given to overhauling and rebuilding dynamos and motors, and changing from one voltage to another. The members of the firm have had 17 years' practical experience in the above line of work, and can therefore guarantee satisfaction in workmanship, material and price.

Packard Sign Lamp.—Users of miniature incandescent lamps will very readily appreciate the advantage of having a miniature lamp of a standard, reliable make that can be depended upon for efficiency and length of life. The Packard sign lamp, which is a miniature lamp about 2 inches long over all and 1 inch in diameter, fills the demand for a high grade miniature lamp. It is mounted with regular Edison candelabra base, gives about 2 candle power and burns 4 in series on 50 to 60 volts, or 8 in series on 100 to 120 volts. This lamp is carried in stock in Chicago in large quantities by the Electric Appliance Company.

The Q. & C. Company, Western Union Building, Chicago, have acquired the right of sale of the Stanwood step, and it is now known as the Q. & C.-Stanwood steel car step. The Q. & C. Company have recently received a rush order for some 244 complete steps to be used by the United States Naval Department for one of the cruisers being completed at the Norfolk Navy Yard. This company has also furnished this step for the battle ships Iowa, Indiana and Massachusetts, and it is deemed by the United States Naval Department the most efficient step for the service ever manufactured.

Mr. John G. O'Neil, the selling agent for the A. A. Griffing Iron Company, of Jersey City, N. J., located at the Rookery, Chicago, Ill., is meeting with great success in introducing the Bundy steam specialties in that market. A number of his customers express surprise at the excellent results they have experienced, especially in the case of the steam and oil separator. Mr. O'Neil also sells the Bundy feed-water heater, safety water column and exhaust heads. He will be pleased to hear from any one interested in or desiring further information regarding the goods. The A. A. Griffing Iron Company have placed with their selling agent, Mr. George G. Seamans, "U. P." Publication Building, Ninth Street, Pittsburg, Pa., a full line of samples of the Bundy steam specialties. Mr. Seamans has taken up the sale of these goods in the Pittsburg district, and is meeting with good success. He is prepared to answer all communications promptly, and will visit any power plants within reach to make suggestions and estimates looking toward the equipping of the same with Bundy steam and fuel saving devices.

The Filer & Stowell Company, Milwaukee, Wis., has sold to the Worcester & Clinton Street Railway Company, Worcester, Mass., two heavy-duty engines; one of 600 h.p. jet condenser, and one of 600 h.p. heater. It is also building a 500-h.p. tandem compound to be direct-connected to generator for the Bluff City Electric Railway Company, of Chicago, and a 300-h.p. tandem-compound engine, also for street railway work, for the Warren Electric Light Company, Warren, Pa. All of the above engines are of heavy-duty type, with Filer & Stowell Company's latest pattern, or 1900 style, heavy-duty frame. A 500-h.p. cross-compound heavy-duty engine with surface condenser is now being erected for the electric light plant in the city of Jacksonville, Fla.; two single cylinder engines in the electric plant in the city of Donalsonville, La.; a 24 x 48-in. Corliss engine for plant of the Home Electric Company, Baton Rouge, La., and a 14 x 30-in. for electric light and water-works plant at City of West Point, Miss., will soon be shipped. A 24 x 42-in. Corliss has just been started in the elevator of

Modern Switchboards.

BY

Albert B. Herrick.

An elaborate essay, treating of the construction of Switchboards for all purposes, together with a historical sketch of the appliances used thereon, from the inception of the art to the present time. Fully illustrated with several hundred cuts, diagrams, tables, etc., especially prepared for this publication, the whole forming a very handsome book of 220 pages, printed on super-calendered paper, 9x11 inches, and bound in vellum cloth.

Price, $3.00 by express prepaid.

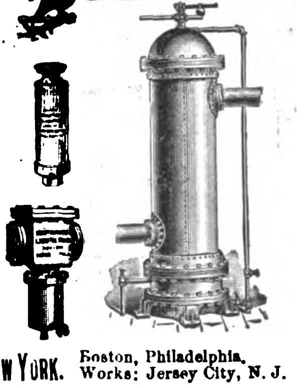
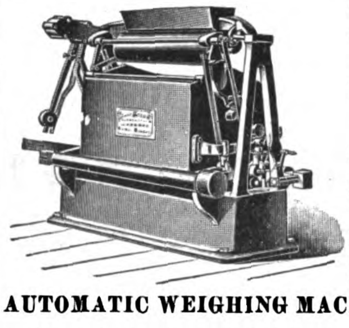
Works: Jersey City, N. J.



the Export Elevator Company, Buffalo, N. Y. This makes the third engine which the Filer & Stowell Company have furnished to these people within two years. They are now building a 500-h.p. cross compound for the Kimberly & Clark Company, who are large paper manufacturers at Neenah, Kimberly and Appleton, Wis. The Filer & Stowell Company take just pride in having received this order from the Kimberly & Clark Company, who have been using two engines of their make for about three years, and at the same time have been using for a number of years past as many as 12 engines of another prominent manufacture.

Electrical Exhibition.—One of the most interesting exhibits in the May Electrical Exhibition at Madison Square Garden will probably be that made by the C. & C. Electric Company of New York. In the basement of the building, where the operative exhibits will be placed, there will be shown a C. & C. multipolar generator directly connected to a 25 h.p. Diesel "Rational Heat Motor," a new type of engine which has created such a stir recently in the engineering field of both Europe and America. On the main floor of the building the C. & C. Company will have an exhibit occupying 500 square feet of floor space, in which will be shown all their latest types of machines, including their well-known types of bipolar dynamos and motors in several sizes; also quite a full line of their now celebrated closed type ironclad motors and dynamos. These machines of the Ironclad type will be shown, some separately and some in combination with other machinery. The 20 h.p. inclosed ironclad motor will be shown mounted in connection with a Lambert hoist and one of the dynamos directly connected to a Case engine. The exhibit will also include one of the ironclads fitted up with back gears for speed reduction. Two of the company's slow speed belt types generators will be exhibited, and numerous other interesting machines, appliances and parts will be also shown. A C. & C. switchboard will form an attractive feature of each exhibit.



HIGH CLASS MACHINE TOOLS
for Machine Shops and General Metal Finishing Use.
Machines, Fixtures, Small Tools and Gauges for the manufacture on the interchangeable plan of Guns, Sewing Machines, Typewriters, Cash Registers, Bicycle Parts, etc.
Brass Finishing Machinery.
Reliable Counting Registers, Standard Measuring and Testing Machines.
Drop Forging Machinery: United States Standard Threading Machines and appliances.
Milling Cutters, Combination Lathe Chucks.
AUTOMATIC WEIGHING MACHINES for accurately weighing coal and all material of a uniform size handled for storage and distribution.
Lathes, Planers, Shapers, Drilling and Milling Machines for Tool Room use.

Bar Iron Limit Gauges, useful to protect the buyer of bolt iron against the delivery of material of sizes unsuitable for use without changing dies for heading or threading and of excessive weight.

Brigg's Standard Pipe Thread Gauges, useful for testing pipe and fittings to insure their delivery in condition for connection without rethreading when ordered to said gauges.

A TECHNICAL EDUCATION 50 CENTS A WEEK

THE new installment plan of The International Correspondence Schools, Scranton, Pa.—the first and most successful institution teaching technical subjects by mail—places an education within the reach of all. A first payment of $2.00 only is required on enrolling, the balance being payable at the rate of $2.00 a month. The charges for tuition are moderate and include all necessary text-books.

The Electrical Power and Lighting Scholarship is a thorough course of instruction in the installation, care and operation of electric light, power and railway plants, designed to meet the wants of busy men who wish to put into practice as soon as possible the information they acquire.

The Mechanical-Electrical Scholarship includes instruction in mechanical and electrical engineering and is intended especially for those who wish to become designers of electrical machinery.

Our 48 courses of study include Steam Engineering, Mechanical Drawing, Machine Design, Civil Engineering, Shorthand, Bookkeeping and English Branches.

Write for free circular, stating subject in which you are interested.

THE "CLARK" WIRE

In a Letter from the Inspector of the Boston Fire Underwriters' Union, he states:

"A Thoroughly Reliable and Desirable Wire in Every Respect."

For Switchboard, Railway and Motor use, we make all sizes of Stranded and Flexible Wire and Cables with Clark's Insulation.

The Clark Wire has been before the public and in use for the past nine years, and has met with universal favor. Thousands of miles of this wire have been sold, and are in use throughout the United States and foreign countries, and the demand for it is constantly increasing, because it always gives perfect satisfaction.

The Rubber used in insulating our Wires and Cables is especially chemically prepared and will not deteriorate, oxidize or crack and will remain flexible in extreme cold weather, and is not affected by heat.

We guarantee our Insulation wherever used, Ærial, Underground or Submarine, and our net prices are as low, if not lower, than any other first-class Insulated Wire.

We shall be pleased to mail catalogues with terms and discounts for quantities.

Sterling : Extra : Insulating Varnish.

The MINNEAPOLIS GENERAL ELECTRIC CO. say:
"Our Superintendent recommends its use."

Why?

BECAUSE:

It is very Tough and Elastic and Will Remain so.
It Will Not Corrode Your Wires and will stand more heat than any other Varnish.
It bakes readily and with very even coat, and is Absolutely Unaffected by Water or Lubricating Oils.
It Does Not Contain Carbon Bisulphide or any other poisonous or objectionable materials
It is a Good Insulator Wet as well as Dry.
It is Low in Price.

What E. B. Newcomb, Manager, says:

OFFICE OF WESTBROOK ELECTRIC LIGHT AND POWER CO.,
S. D. WARREN & CO., Props.
WESTBROOK, ME., February 15, 1897.

Belknap Motor Co., Portland, Me.

Gentlemen:—The Chapman Voltage Regulator put into our station in the Fall of 1895 has proven its ability to control the voltage with a varying speed amounting at times to 25 per cent. above the normal, holding the voltage within 2 per cent. This Regulator, which was connected up with four 80 h. p. Mather 500-volt direct current dynamos, was, we understand, one of the first of these Chapman Regulators ever manufactured. Having made a careful examination of the Regulator as it is at present made, we can see that there has been a vast improvement; especially is this true in regard to the addition of an attachment whereby the Regulator compensates properly for the drop in the line due to all variations of the load.

You may enter our order for a Regulator for our K. W. T. H. Monocyclic Generator, as per our recent conversation. Yours very truly,

WESTBROOK ELECTRIC LIGHT AND POWER CO.
E. B. NEWCOMB, General Manager.

What the Edison Electric Illuminating Co. say:

TOPEKA, KAS., Oct. 27, 1897.

Belknap Motor Co., Portland, Me.

Gentlemen:—In reply to your recent letter regarding Voltage Regulators can say we are very well satisfied with our purchase, and as for wanting additional regulators, will say the two we have regulate the fields of three pair of 45 k. u. Edison Machines. and when we require more than three engines on the buss bars we switch them in with the machines on the regulators and find we get very good results by using the hand rheostats to divide the load as we want it, your regulators keeping the voltage on all the machines constant within three volts.

As I say, we are well pleased with the regulators and could not be without them now we know their worth. Yours very truly,

EDISON ELECTRIC ILLG. CO., C. R. MAUNSELL, Supt.

A GAS ENGINE CENTRAL STATION.

AN INTERESTING POWER PLANT.

BY J. J. FLATHER.

A few years ago the gas engine was known, at least in this country, principally as a motor for small powers, and on account of its irregularity it was deemed unsuitable for operating electrical machinery; but the great economy of the gas engine has led to its introduction in larger sizes, so that to-day engines having a capacity of 750 h.p., are in operation, and larger ones are being contemplated.

With the increase in size, better methods of regulation have been introduced, and their use as a motive power in isolated lighting stations has for some time been an assured success—not only from a mechanical standpoint, but from the commercial side of the problem. Their operation is as smooth and reliable as steam engines under the same conditions, and an economy has been attained showing a consumption of only 10 cubic ft. of gas per h.p. per hour.

The advantages of using gas engines for dynamo driving have been enumerated, as follows: *

"1. Small amount of space required. 2. Small consumption of water—5 to 6 gals. per h.p. hour, or less. 3. No coal to carry; independent of railway station. 4. No smoke. 5. No explosions. 6. Cheaper than steam engines in respect to (1) ground required; (2) relative convenience of gas motors rather than steam engines in a town, whence greater choice of place within a town, and smaller distances to lay cables; (3) gas engines above 100 h.p. being cheaper than steam engines, boilers and chimney. 7. Less loss of electricity, because station more favorably situated. 8. Less attendance and wages. 9. Exact control over fuel."

Where gas engines have been used in isolated electric lighting stations it has been frequently demonstrated that twice as much light can be furnished from a given amount of gas if used in the gas engine than could be obtained from the same

---

* German Imperial Gas Association, Dessau.

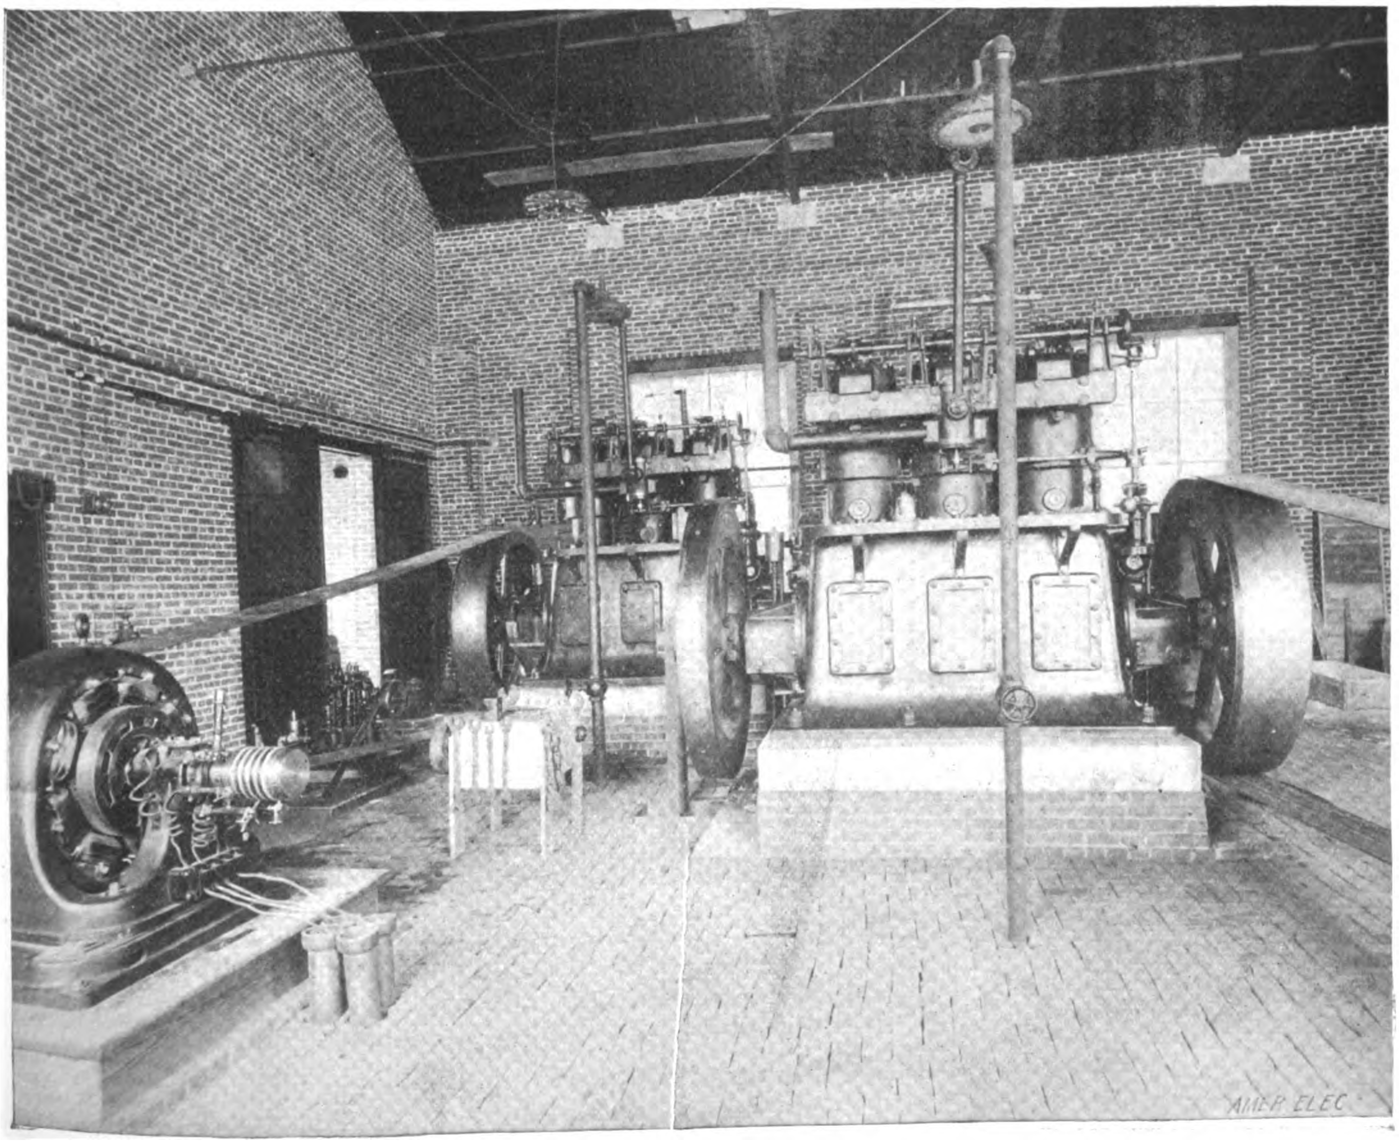

FIG. 1.—INTERIOR VIEW OF STATION.

quantity of gas if burned in the usual way. It has also been repeatedly shown that, even with small engines, the economy of fuel consumption is much greater if the fuel be first converted into gas and used with a certain per cent of air as an explosive mixture in the cylinder of a gas engine. Thus one pound of coal will generate sufficient gas to furnish 1 h.p. hour for a small gas engine.

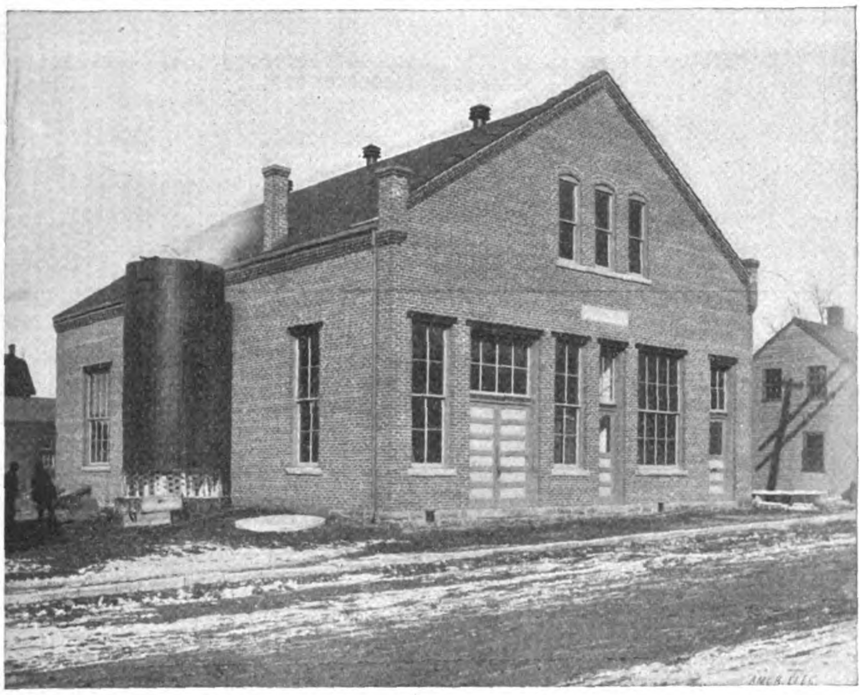

FIG. 2.—EXTERIOR VIEW OF PLANT, SHOWING COOLING TOWER.

The most economical triple expansion steam engines cannot equal this, and, ordinarily, a large steam engine requires about twice as much fuel, while a small steam engine of the same capacity as the gas engine may require from 5 to 10 times as much.

The introduction of the gas engine in larger sizes will undoubtedly be greatly increased, as the means for producing a cheap fuel gas become more extended.

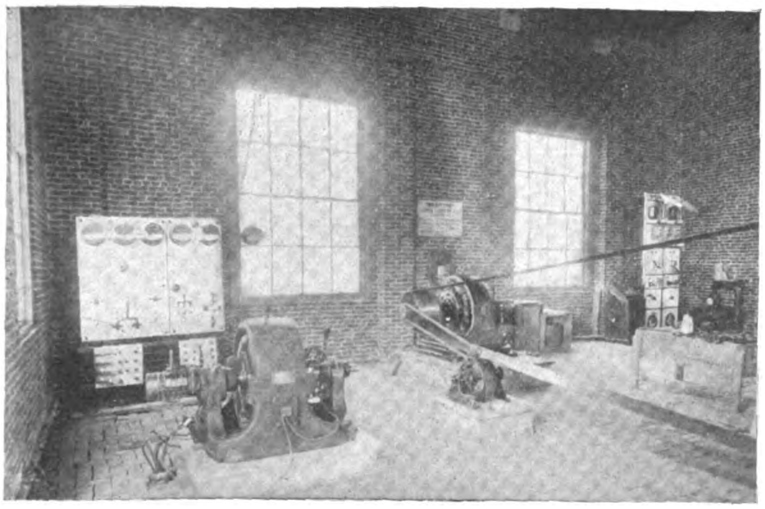

FIG. 3.—INTERIOR VIEW, SHOWING ROTARY TRANSFORMER AND SWITCHBOARD.

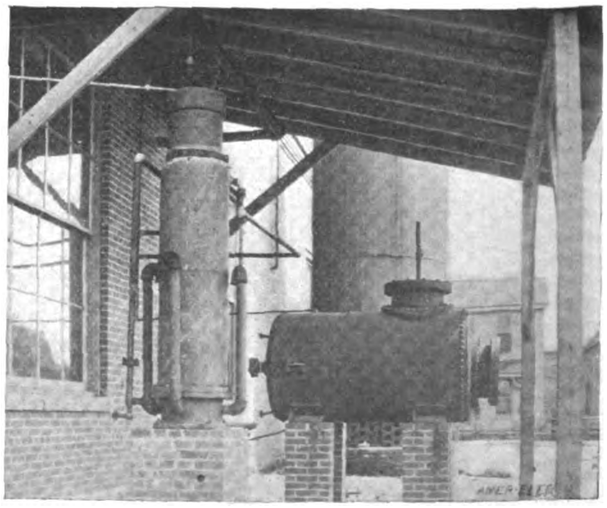

FIG. 4.—GASOLINE TANK, CARBURETOR AND COOLING TOWER.

The possibility of obtaining a higher theoretical efficiency in the conversion of heat energy into mechanical energy through the medium of gas or heat engines is a factor of much importance in the further development of the gas engine.

In the natural gas regions of Ohio and Indiana a gas of high calorific intensity can be obtained for a few cents per 1000 cubic ft., and under these favorable conditions the economy of operation becomes very marked.

An interesting installation, involving the most modern practice in gas engine construction and operation, has recently been erected at Lafayette, Ind., by the Merchants' Electric Association, which illustrates to a remarkable extent the economy obtainable under favorable conditions.

The plant was erected under the direction of Mr. C. C. Chappelle, manager of the company, and the results achieved fully indorse the means employed. Mr. Chappelle states that since the change from steam to gas engines the cost of fuel for operating a given number of lamps is only 22 per cent of that which formerly obtained. The plant is located in a fireproof brick building, 45 ft. x 60 ft., as shown in Figs. 1, 2, 3, 4 and 5, which latter also indicates the position of the various machines. At present a temporary brick floor is used, but it is the intention to place a cement floor in the building as soon as the present filling settles.

The plant was designed for three units, each consisting of a 125 h.p. gas engine, belted to a 60 k.w. dynamo, two of which units are now in operation.

The present electrical equipment consists of two 60 k.w. Westinghouse 2-phase dynamos, 7200 a.p.m., 2000 volts, running at 900 r.p.m., which were installed upon a guaranteed capacity of 25 per cent overload with a heat limit of 50 deg. C.

These dynamos furnish current for about 40 inclosed alternating arc and 1000 incandescent lamps, besides running a 50 h.p. Westinghouse rotary transformer for direct current motors. The current is controlled by a Stillwell regulator, and is transmitted at a potential of about 2100 volts, which is reduced by a service transformer, of 100 and 200 light capacity, to 104 volts in the secondary.

The 4-pole rotary transformer which furnishes direct current at 500 volts for the power circuit, runs at 1800 r.p.m. The motor end of the machine is operated as a 2-phase induction motor, which receives its current from a pair of oil converters at a potential of 400 volts. The power circuit is arranged as a three-wire system for 500 to 250 volts, the neutral wire being connected to the middle of the secondary from each of the two converters, to balance the line.

The method of starting this machine presents some interesting features. At first it was proposed to use a choke coil as a regulator, but this was abandoned and the present method was introduced which involves bringing the motor into synchronism by starting with a greatly reduced voltage and gradually increasing by successively changing the plug connections at the switchboard by means of two 4-pole switches—the secondary on the transformers being suitably divided into sections and connected to the switchboard to permit this. In bringing up the rotary to synchronism by this method of starting, the maximum current is about 40 amps. at 2000 volts, but the power factor is very small, and maximum current only exists during a period of 1½ to 2½ mins., after which time the machine gets in step and the current is immediately reduced.

The motive power equipment is very complete, and may be regarded as a model of its kind. The gas engines were built by the Westinghouse Machine Company, and erected upon a guarantee to deliver 125 brake h.p. with a consumption of from 13½ to 14 cu. ft. of gas per brake h.p. per hour—the gas to contain as many heat units per cubic foot as the Pittsburgh natural gas. These engines are 13 ins. diameter of cylinder by 14 ins. stroke, and run at 265 r.p.m.; they are piped for both natural and artificial gas, since in very cold weather the natural gas supply is liable to be shut off from all manufacturing firms in the city. The two engines installed at Lafayette are shown in Figs. 1, 10 and 11.

In addition to this a gasoline tank and carburetor have recently been erected outside the building, as shown in one of the views, and the engines piped so that either or both may be run on gasoline.

In order to use gasoline vapor, a slight change is necessary, since the high compression carried at full load would probably produce a sufficient amount of heat in the cylinder to cause premature explosion of the charge. This is obviated by placing an extra bonnet upon the top of the cylinder, which thereby enlarges the clearance volume and reduces the compression.

FIG. 5.—PLAN OF STATION.

The cooling water for the jackets is obtained from a 12 ft. cistern, located beneath the floor of the repair shop in the front of the building, although city water may be used independently if desired; the water is heated to about 180 deg. F. in passing through the jackets, and is cooled by evaporation in air currents as it passes down through a series of drain tiles placed in a cooling tower, as shown in Fig. 6.

There is a marked advantage in using the same water continuously, since incrustation in the jackets and pipes is thereby reduced to a minimum. Where water is used containing much carbonate of lime in solution, the temperature of the jackets will have to be reduced unless the lime is precipitated or neutralized with soda or other agent; even then much trouble may be experienced. In the present case only a small amount of scale is formed, and this is largely produced by the use of city water, which is necessary to supply the loss due to evaporation.

A 3-throw water circulating pump is belted either directly from one engine, or from an underground shaft driven from the other engine, as shown at the right in Fig. 1. The quantity of cooling water used by each engine varies from 4 to 5 gals. per h.p. hour.

Each engine is belted to a small air pump, which is used for charging 4 air tanks with a supply of compressed air for starting the engines. These tanks each contain about 7 cubic ft. of air, which is maintained at a pressure of 160 lbs. per sq. in.

The air pump shown in foreground, Fig. 1, can be operated by hand to charge the tanks for the first time, after which they are run by a belt from the engine a short

time each day to restore the pressure after starting the engine.

A pipe leads from these storage tanks to one cylinder of each engine, in which pipe a valve is arranged to be opened and closed at each revolution of the engine by means of a cam on the end of the shaft which operates the exhaust valves, the opening occurring just as the crank is passing its upper centre. By throwing a lever on the crank case to the rear the exhaust valve on this cylinder is set so that it opens on every return stroke of the piston, instead of every other stroke, as when the engine is in normal operation.

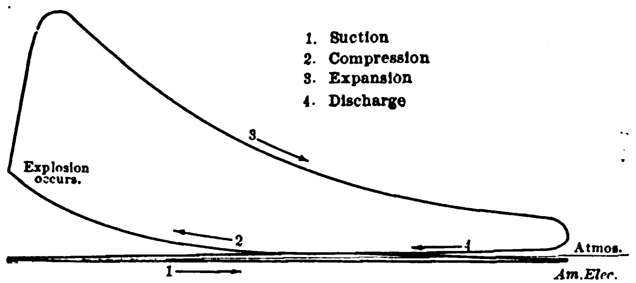

FIG. 7.—STARTING CARD.

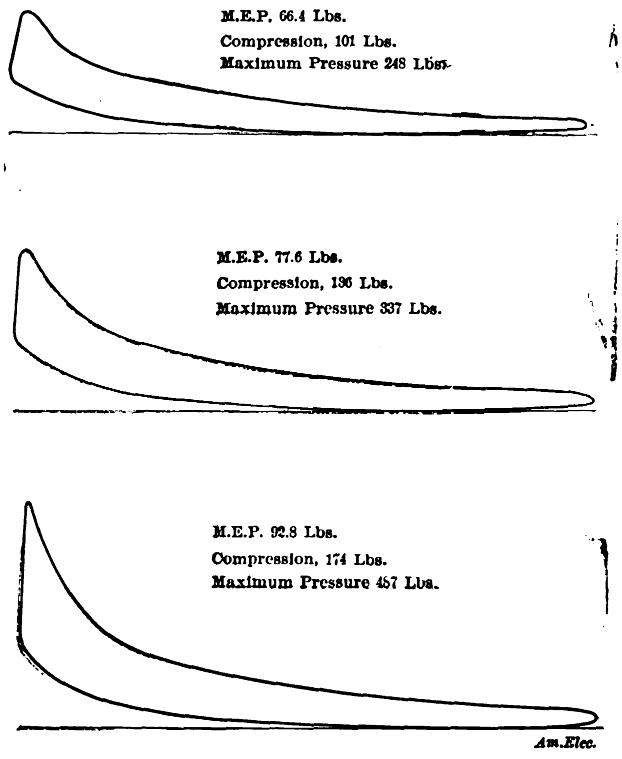

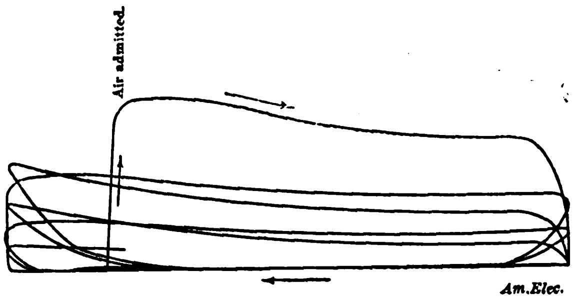

FIG. 8.—TYPICAL GAS ENGINE CARD, OTTO-CYCLE.

FIG. 9.—GAS ENGINE CARDS.

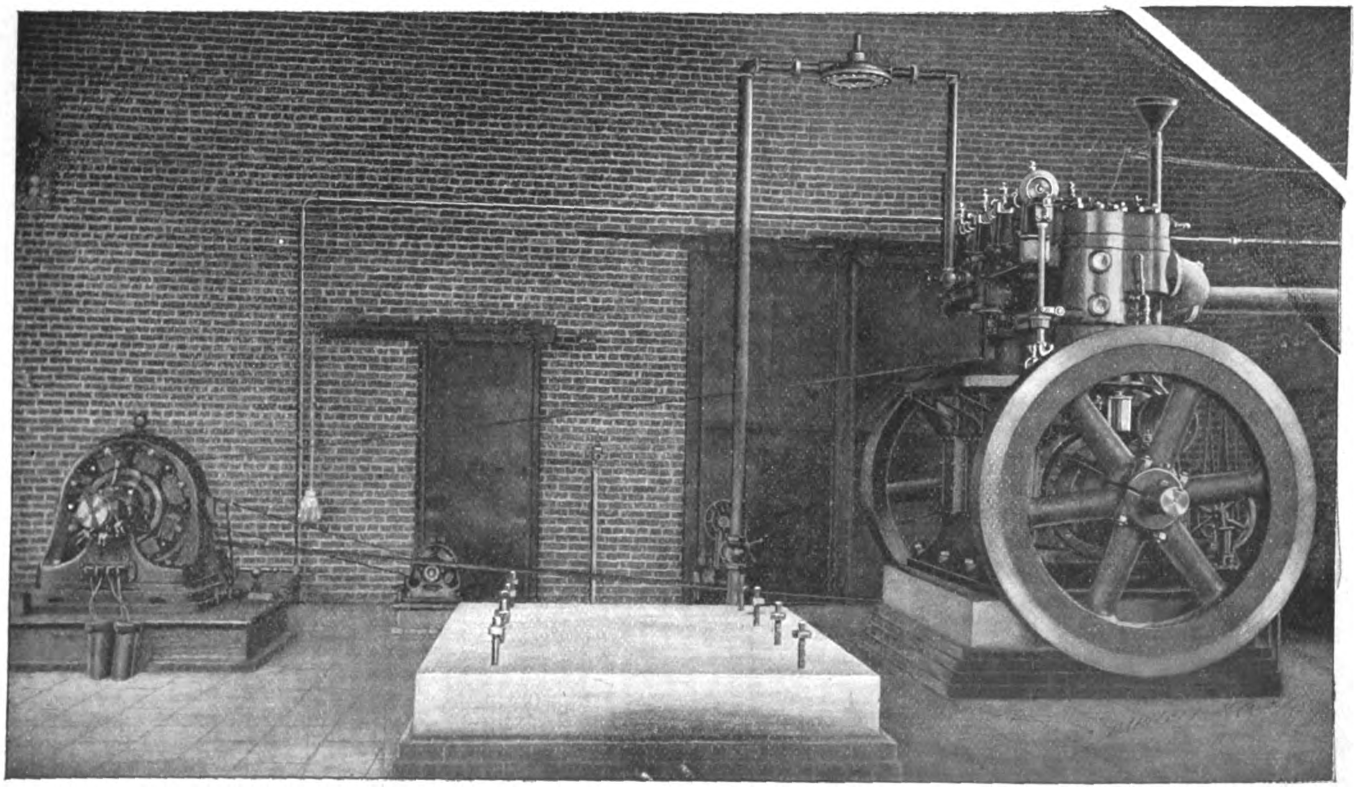

FIG. 10.—INTERIOR OF STATION, SHOWING ONE ENGINE.

A knurled thumb screw on the end of the cam shaft disengages the admission valve cam for this cylinder, and throws the valve out of operation. It will readily be seen that one cylinder of the engine is now converted into a compressed air motor, without in any way disturbing the functions of the other two cylinders. The engine being set with the cranks about 45 deg. beyond the top center, the air and gas inlet valves properly adjusted, and the stop valve on the compressed air tank opened, it starts up and continues to run on the air pressure until explosion takes place in the other cylinders; the stop valve is then closed, the inlet and exhaust valves are brought into normal position again, and explosion follows in this cylinder, as in the others. The operation is entirely automatic, and is extremely simple, as 3 or 4 revolutions with the air pressure are

LIBRARY

generally sufficient to start the engine. Fig. 7 is reproduced from an indicator card, taken while starting the engine, and shows very clearly the pressures inside the cylinder.

The engines operate on the plan proposed by M. Beau de Rochas, popularly known as the "Otto cycle," in which the combustion is assumed to take place at constant volume.

On the first outward stroke, Fig. 10, the piston draws in a charge of the explosive mixture, which it compresses on the return stroke; as the crank passes the center the charge is ignited, and expansion takes place on the next forward or working stroke. During the succeeding return stroke the burnt gases are expelled, leaving the cylinder ready to repeat in regular order the same series of operations or cycle.

The single-acting piston receives in consequence only one impulse for each four strokes, or each two revolutions of the crank. This feature places the single cylinder engine somewhat at a disadvantage in the matter of steady rotative speed, which may be still further aggravated by the hit and miss system of governing in which the regulation is effected by varying the frequency of explosions leaving the intensity the same.

This method is not particularly well adapted to the exacting requirements of electric lighting, especially with the increased use of high efficiency lamps, although it produces very satisfactory results when running under conditions where some variation in speed is permissible.

In any case, the regulations may be improved by the use of suitable flywheels on the engine shaft or on the shaft of the dynamo, or both; but even with the greatest precautions the explosions in the engine can often be counted by the changing brilliancy of the lamps in circuit, and always by fluctuations shown by a sensitive voltmeter.

A better method of regulation is that obtained by the use of two or more cylinders by which more frequent impulse is given to the shaft. In the present case three cylinders are used, and the regulation is obtained by throttling the charge, which is a constant mixture—a lesser or greater amount of the mixture being admitted to the cylinder, depending upon the load.

The cranks are set at 120° and an impulse is received every two-thirds of a revolution, whether the engine be fully loaded or not. As will be noticed from the cards (Fig. 9) the compression at light loads is correspondingly less than at heavy loads, and it has been argued that the efficiency of the engine is thereby impaired. It is undoubtedly true that the efficiency is less at light loads than at full load, but this objection can be urged with equal force against any source of power, be it steam engine, gas engine, electric motor or water wheel.

The absence of reliable data on the subject makes the question as to whether the falling off in efficiency at light loads is more rapid in the engine which keeps the number of explosions constant and adjusts the charge, than in the engine which regulates by the frequency of its explosions, a matter of conjecture. The superior running qualities of the former, and its peculiar adaptability for electric lighting and other purposes where nicety of regulation is essential, will undoubtedly overcome any objection to the principle involved, since the closeness of regulation more than compensates for any loss of theoretical efficiency.

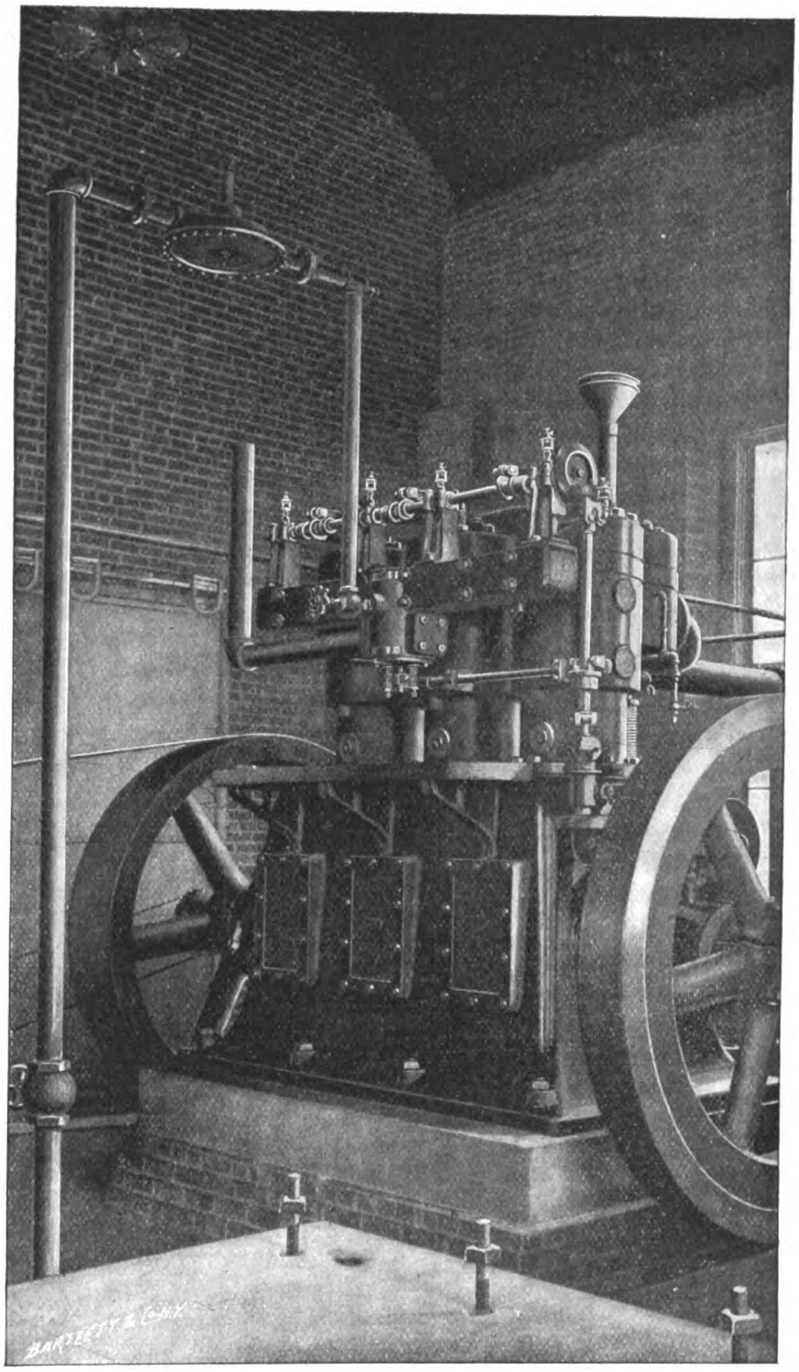

FIG. 11.—ONE OF THE GAS ENGINES.

With natural gas at 7 cents per 1000 cubic ft., the cost of power in gas engines is but a fraction of that obtained by the use of a steam engine, even where the gas is used as fuel for the boilers. In numerous tests made by the writer on various gas engines in Lafayette and vicinity, it was conclusively shown that the fuel cost was less than one-sixth of a cent per h.p. hour.

Chemical analysis and meter tests show that the Indiana natural gas is very rich in hydro-carbons and yields upward of 1050 heat units per cubic ft. This gas may be diluted with from 12 to 14 times its volume of air in order to obtain a suitable explosive mixture.

On the other hand, the artificial or illuminating gas has a much lower heat energy and requires a lesser quantity of air for dilution, the amount being about 10 cu. ft. of air per ft. of gas. Thus illuminating gas not only costs more per 1000 cubic ft., but a greater quantity is required to generate a given quantity of power.

◆

Gas Explosion Temperatures.

From some experiments made in England on gas explosions at constant volume, it was computed that the temperatures ranged from 1483 degs. Fahr. for 1.14 mixture of gas and air, to 3293 degs. for a 1.5 mixture.

A STORAGE BATTERY CENTRAL STATION.

THE CLAREMONT ELECTRIC LIGHT SYSTEM.

BY F. B. SAGE.

The Claremont Electric light plant of Claremont, N. H., is one of the most unique of its kind in this country, and is exceptionally interesting because it conclusively exemplifies the advantage of the application of storage batteries to small lighting installations. The plant is located on the south bank of the Sugar River, from which it obtains power, a head of 15 ft. being available. A general view of the building and dam is shown in Fig. 3. The building is constructed with stone sides and wooden flooring. It was originally a portion of the adjacent rubber factory, and has been adapted to the requirements of the installation it now contains.

The Sugar River has its origin in Lake Surripee, about 18 miles from Claremont, and supplies power for numerous factories and machine shops. At the Claremont plant there is a dam 250 ft. long and 15 ft. high, backing the water up for a mile and a half. During the day the rubber factory and two large shoe factories draw power from this source, and at night the power is utilized by the Electric Light Company. The maximum head is 16½ feet and the minimum 7½ feet.

The wheel pit is bulit of 2-in. chestnut planks nailed to substantial uprights extending between floor beams. It empties into a stone tail race which runs parallel to the north wall for its entire length and opens into the river below. The main floor is divided into three rooms. The dynamo room is the largest, and occupies two-thirds of the length of the building and its entire width. The remainder is divided into two rooms, the larger of which contains the battery plant and the smaller provides office accommodations. In addition to the main floor there are two extensions, one of which contains an auxiliary engine which is used at seasons of low water, and the other is divided into two parts, a repair shop and wagon shed.

The turbine was supplied by the Hunt Turbine Company, of Orange, Mass. It operates under an average head of 15 ft. and drives the horizontal main shaft at a speed of 70 r.p.m., being connected to the latter by the usual bevel gears. Water is supplied to the wheel by two diametrically opposite gates in the casing. These are controlled by hand wheels conveniently located near the dynamos. No automatic governor is used, the speed being entirely regulated by the storage batteries, as will be explained beyond.

The main shaft runs the entire length of the building. It is divided into three sections by two clutches. The first, some 5 ft. from the turbine shaft, is a four-jaw mortise clutch, and cuts off the entire plant. The second clutch is of the friction type and controls the third section of shaft, which supplies power to the rubber works. In case of necessity this section can become a source of power, for the rubber factory also has a 200-h.p. Harris-Corliss engine, which is sometimes used in conjunction with the water wheel and sometimes separately. The middle section of the shaft is 6 ins. in diameter, and carries an 8-ft. pulley which drives a line of counter shafting on the floor above. This pulley has an 18-in. face and transmits its power by means of a two-ply 15-in. belt. To the latter counter-shafts the dynamos are belted, for the most part directly. This shaft may be driven by the auxiliary engine already referred to, which is connected thereto by a clutch pulley. This engine, which was made by the Ball Engine Company of Erie, Pa., is of the single-expansion high-speed type. It receives steam at 90 pounds pressure from the rubber factory boilers, and exhausts into the atmosphere. As it is seldom used, the expense of condenser or heater is not justified.

The electrical equipment of the plant consists of two Edison bipolar dynamos, two boosters and 134 cells of storage bat-

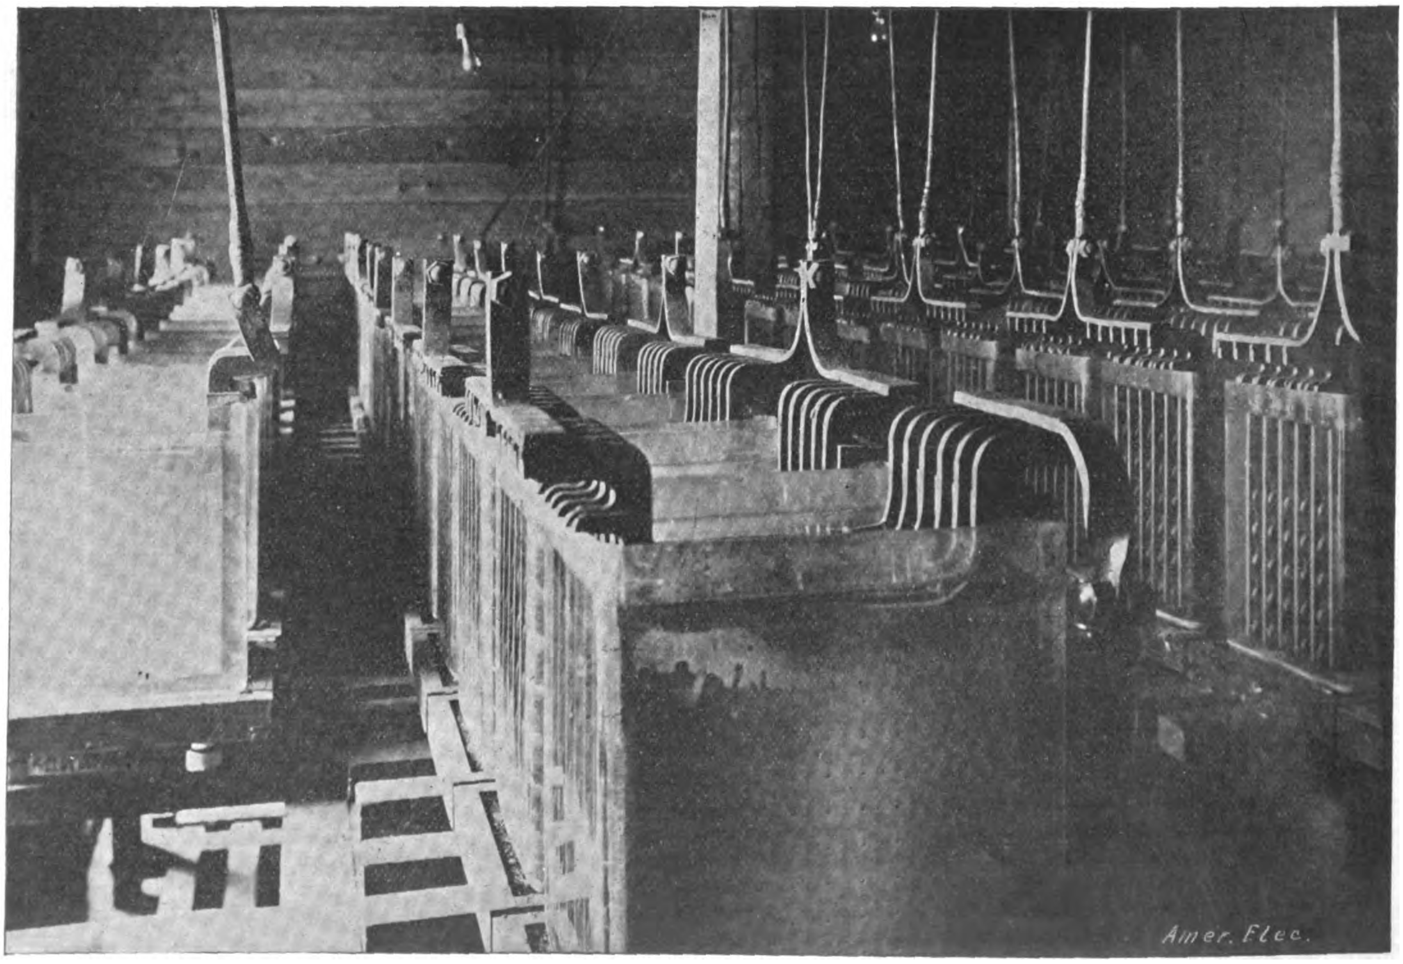

FIG. I.—STORAGE BATTERY ROOM.

tery, all connected on the three-wire system. An arc service is also provided by means of a Thomson-Houston 50-light 2000-c.p. arc dynamo and an appropriate switchboard.
